The Capsule class include additional properties corresponding to the theoretical behavioral model behind the intervention. The interventions that have been developed for the CAPABLE project are all based on the FBM [9]. To take this into account, the Capsule class has a set of properties that reflect factors related to trigger, ability, and motivation. The trigger (prompt) property can represent a signal, spark or facilitator. The two properties called effort_cognitive and effort_physical represent the FBM ability factors related to the mental and physical effort required for the specific behaviour. The two properties cost and in_out_doors are ability factors according to FBM. The FBM motivation factor is modeled through a reward function (has_reward) that assigns a score to the patient at the end of the execution of the practice.

Finally, the Patient class includes properties of the Patient FHIR resource, including name, gender, date of birth, marital status, care takers, and communication language. Similar to the patient model developed in [12], the Patient class also includes the main diagnosis and comorbidities or the patient, and the prescribed Treatment_Requests, which connects the patient to the patient-specific digital interventions and medications (Capsule_Request and Medication_Request). To allow goal-based reasoning [16] that is used in CAPABLE CDSS, we also add the clinical goals of the patient. As in [12], the Patient class also contains the observations related to the patient. Similar to the
Patient preferences used in [12], we represent the patient's ambiance preferences, musical preferences, technological preferences, and physical activity preferences, which allow personalization of recommendations.

Fig 2. The analogy between Medication_Request and (virtual) Capsule_Request for behavioral interventions. Our additions to FHIR resources are highlighted in yellow.

We developed the ontology via the Protégé knowledge modeling tool (protégé.standord.edu) version 3.4.8 using Web Ontology Language (OWL) version 1. Examples for instances of our extensions, for an intervention based on FBM [11], are presented in Section 4.

The presented ontology would fit well into two steps of the IDEAS framework (Fig. 3). The "specify target behavior" step of the "Integrate" phase is focused on making the target behavior highly specific and actionable, and providing the evidence for its potential impact. The goal of our ontology is to make the structure of the intervention explicit. In more detail, some of the properties of the Capsule class (may_treat and fits_wellbeing, for the goal-based view,
reference_effectiveness for the evidence_based view) and the timing property of the Dosage class are specifically devoted to indicate the target of the intervention and to ground its validity on scientific evidence.

The second step of the IDEAS framework that would benefit from the introduction of the presented ontology is the "ideate" step of the Design phase. This step is focused on the implementation strategies. To this end, the Capsule class is provided with a set of properties to explicitly refer to the behavioural model which is used to put the intervention into place (e.g., FBM). The Capsule_Request class is specifically aimed at modeling the implementation of the intervention on the specific user, which in turn modelled using the Patient class. The properties designed in the Patient class make it possible to propose and recommend the user the digital interventions that best fit with his intrinsic characteristics and preferences.

As shown in Fig. 3, the presented ontology extends the IDEAS framework in two specific steps. To get to the final structure of the ontology, though, we also slightly modified two other phases: Empathize and Gather. In IDEAS the users that are involved in collecting insights and requirements are patients, while we have relied on multiple stakeholders, including clinicians, psychologists, nutritionists, clinical and informatics researchers, and software developers. Each of them brought input to the requirement collection, as related to the virtual capsules (behavioral interventions).

Fig.3. The IDEAS framework [8], extended by our method. Changes are in blue.

4. Results in the CAPABLE Case Study

Most cancer patients are managed at home, facing long-term treatments that make the disease comparable to a chronic condition [19]. Patients are expected to assume a more significant role in managing their follow-up care. They must have the ability to control the symptoms and consequences of living with a chronic condition, including treatment, physical, social and lifestyle behavioral changes [20]. To improve patients' well-being [18] and to help them comply with behavioral interventions known to improve mental and physical health, we hypothesize that mobile technology can potentially support. Thus, we had ideated virtual capsules, which serve as the knowledge base of a CDSS patient coaching system.

These digital interventions were developed as part of a European project, part of the Horizon 2020 European program for research and innovation, called CAPABLE (CAncer PAtients Better Life Experience), that aims at building a CDSS to support cancer patients and their care providers during the home management of the disease, using Artificial Intelligence and Big Data potentialities.

In this paper we use CAPABLE as a case study for the design and the implementation of digital interventions using the ontology presented in Section 3. In our case study we profile a patient called, Maria Rossi, a hypothetical Italian female kidney cancer patient aged 66. Maria is modelled as an individual of the Patient class (Fig 4), and she has properties related to personal information (e.g., name, gender, marital_status, care takers, communication language) and life-style preferences (e.g., diet, physical activity, hobbies –following Wikipedia's list of hobbies [21], and technological preferences (i.e., PC/laptop, mobile phone, smart phone, tablet) (Fig 4A), clinical conditions (e.g., main
cancer condition and comorbidities of diarrhea and sleep problems) (Fig 4B), goals that the patient wants to achieve (Fig 4C), and prescribed treatments for these goals, including medications and virtual capsules (Fig 4D).

Fig. 4. Maria Rossi, an individual of the Patient class of the ontology

This profiling helps us to better associate users with personalized digital interventions. In fact, thanks to Maria’s preferences, it is possible to identify some capsules suitable for her, and others that might be inappropriate. As it is possible to see from the regular_physical_activity property value in Figure 4A, Maria does not practice regular physical activity. Tai Chi, which is a short physical and mental practice, could help her increase her level of physicality.
without too much effort. Moreover, since Maria likes to walk (physical_activity_preference property), a digital intervention such as the daily walk in nature can also fit well with Maria’s characteristics. Instead, a static capsule like Deep Breathing, a relaxation technique, is considered unsuitable for Maria, as it does not match her interests.

Fig. 1 shows how the capsules identified as suitable for Maria appear in the actionable part of the Fogg Behavioral Model, as the user has the necessary characteristics to have sufficient ability and motivation to carry out the interventions that are to the right of the curve. Capsules such as Deep Breathing appear below this actionable part, because Maria’s motivation for them is low; to make interventions more appealing to the patient it is necessary to modify them according to the user’s preferences and needs.

As previously mentioned, the Patient class has a property that connects it to individuals of the class Treatment_Request (has_treatment_request – Figure 4D). In the specific case of a behavioural intervention, this property allows us to link the Patient class with the Capsule_Request class, that models the knowledge related to digital intervention prescribed for a single patient.

One of the treatments that is requested for Maria is the Tai Chi (Fig 4D), which is modeled as an individual of the Capsule_Request class, as shown in Figure 2. In particular, Maria’s Capsule Request (Fig 2a) points to the Tai Chi Capsule (Fig 2b). Instances of the Capsule contain all the generic characteristics of the Tai Chi intervention, not strictly related to the user who has to practice it (Fig 2b). The dosage and timing properties of the recommended Treatment_Request (Fig 2a) are represented through an individual of the class Dosage (Fig 2c). The dose, rate, and timing can be used to personalize the intervention to the patient’s ability. For example, for some patients, 30 minutes of Tai Chi could be too much, but they could form a habit of practicing Tai Chi 5 minutes a day (dose) every day (rate) for one month, in the morning (timing).

The Tai-Chi Capsule instance for Maria is shown in Figure 5. It specifies the target behavior (Fig 5A) and the goals that the intervention aims to achieve (Fig 5B), through the properties may_treat and fits_wellbeing. These properties model that this capsule aims to improve sleep problems and fatigue thus improving physical and emotional well-being. Since every digital intervention developed in our work is based on scientific evidence, the Capsule class
contains the reference_effectiveness property (in Figure 5.C), which points at the benefits that the capsule can carry out to solve this issues (in this case the ameliorative effects that Tai Chi can bring in cancer patients).

Part D of Fig. 5 relates the Capsule to the FBM [11]. The trigger chosen for Tai Chi belongs to the Signal type, as notifications are sent to Maria, through the application, that remind her to perform the practice. The effort_cognitive and effort_physical related to the Tai Chi capsule are considered of medium intensity, as Tai Chi requires both mindfulness and body movement. The cost is low, as CAPABLE offers Maria some YouTube videos to perform the practice. Tai Chi may be practiced in- or out-doors. The FBM motivation factor is modeled through a reward function (has_reward) that assigns a score to Maria at the end of the execution of the practice, depending on the duration of the exercise.

Figure 6 presents the taxonomy of classes in our ontology and the properties of the Patient class, exemplified by the Patient individual of Figure 4.
4. Discussion

In this paper we presented the extension of the IDEAS framework with a structured ontology that allows developers of digital behavioral change interventions to address in a systematic and detailed way the specification of the behavioral change intervention (the Capsule), its dosage and timing (Treatment_Request), and the properties of the Patient that could be used to personalize the Capsule_Request to the patient’s characteristics and preferences. By basing our ontology on FHIR resources, we allow modelers and developers of digital interventions a standard way to specify CDSS knowledge in a way that is interoperable with electronic health records. We have used the modified IDEAS framework and the novel ontology that we had developed in our ongoing development of the CAPABLE prototype, which is now in its second iteration and will be used by patients and clinicians in 2023. Its preliminary evaluation has been done by over ten additional members of the CAPABLE project, including software developers, clinicians and patients.

The novel Capsule class structures the potential delivery model of the digital intervention according to Fogg Behavioral Model [1]. As part of the CAPABLE project we aim to use machine learning models that would learn how to dynamically personalize the customizable capsules by modulating the duration of the Capsule_Request or its intensity level in order to meet the patient’s "ability" factor of FBM. We have also started to develop methods for personalizing triggers by learning the user’s daily routine from sensors - when is she usually outside, when is she not moving enough, when is she sleeping, etc. This information could be used to predict the most suitable time for triggering (prompting) the reminder for the Capsule. We also started thinking about reward functions, as part of the motivation factor of FBM. Another part of the motivation is educating the patient about the benefits of adhering to the capsule recommendations (Capsule_Request).

To make the capsules more actionable, future work will target quantifying the effort required to complete the capsule (physical and cognitive) as well as the ability and motivation of the patient. The effort required for the different capsules can be determined in two ways. The first is the available evidence on the effectiveness of the activity in promoting behavioral change (e.g., we know that Tai Chi is effective if performed every day for 5 minutes, which implies a medium physical effort). The second way to determine the effort is to rely on the knowledge of the expert (physician, psychologist, physiotherapist) who is defining the capsule. This work lays the foundation for a CAPABLE’s virtual coaching system which will deliver personalized digital behavioral interventions to improve cancer patients’ wellbeing. Although our study is aimed at supporting the wellbeing of cancer patients, the behavioral change interventions that we offer could help all other chronic disease patients, whose physical health is often accompanied by mental distress. The mindfulness, nature-based, exercise-based, or positive psychology-based interventions that we offer are applicable to many other chronic disease patients. Furthermore, the work represents a step towards making digital interventions actionable as an integrated part of any knowledge-based CDSS. While we demonstrated our ideas using a particular case study, the ontology is generic and could be extended to support other behavioral models in addition to FBM.

Using the ontology would benefit developers and researchers of digital interventions beyond CAPABLE from the following aspects: (a) structuring their non-pharmacological intervention using a systematically-developed ontology leveraging on the available standards (FHIR, NDFRT, SNOMED-CT), (b) using the same ontology structure for different components of a complex CDSS in order to define the behavioural interventions but also to exchange information about its usage among system components, including the patient electronic health record, and (c) allowing a standard way for researchers to analyze data collected about the delivered interventions (both pharmacological and non-pharmacological) and their impact on the patient’s health and wellbeing in a unified way. Beyond the contribution of this research toward representation of digital behavioral health interventions via an ontological standard-based information model, the integration into the IDEAS framework supports the entire lifecycle of eliciting requirements till implementing a mobile health app.

Creating a Home for Genomic Data in the Electronic Health Record

Nephi Walton MD MS¹, Darren Johnson, MS², Bret Heale PhD¹, Thomas Person MS³, Marc Williams MD²; Intermountain Healthcare, Salt Lake City, UT 84107; Geisinger, Danville, PA 17822; Penn State University, State College, PA 16801

Introduction

Genomic data generated from massively-parallel sequencing have the potential to improve health through targeted clinical management. The integration of genetic information into healthcare is considered a major priority with several national and international initiatives focused on this goal[1]. Only recently have EHR vendors allowed for the storage and access of discrete genomic data. However, many challenges remain related to adoption and implementation of such technologies. Aside from storage of discrete genomic data there are new clinical workflows that are introduced by large scale population sequencing that have not been addressed by EHR vendors. Having worked through the integration of genomics for the two largest EHR platforms and for two large scale sequencing programs, the MyCode® Community Health Initiative (MyCode)[2] at Geisinger, and the Heredigene® Population Study (Heredigene)[3] at Intermountain Healthcare, we have performed an analysis of the current state and future needs for true genomic data integration.

Methods

At Geisinger through MyCode and in collaboration with the Electronic Medical Records and Genomics (eMERGE) network[4]we imported discrete pathogenic and likely pathogenic genomic variants for the Centers for Disease Control and Prevention (CDC) Tier one conditions (Hereditary Breast and Ovarian Cancer syndrome, Lynch syndrome, and Familial Hypercholesterolemia), and variants from seven pharmacogenes. The C282Y variant for hereditary hemochromatosis were also included to assess for challenges related to implementation of autosomal recessive conditions. We constructed context sensitive maintenance guidelines in the EHR for each of the disease conditions and built best practice alerts for medications impacted by the pharmacogenomic variants. Patient and provider facing information was developed for all disease variants as these were accessible through both the physician chart and the patient portal[5]. Similarly, at Intermountain Healthcare through Heredigene and the RxMatch pharmacogenomics platform we constructed a passive decision support system for 17 pharmacogenes and patient and provider facing information for CDC Tier one conditions and hereditary hemochromatosis. At both institutions, we designed data infrastructures and interfaces to handle the clinical workflow of the return of results process as neither EHR vendor had the capability to manage this workflow. Weekly calls were held with pertinent institutional stakeholders to address challenges and barriers to implementation as they arose. A list of these challenges was maintained throughout the process. After each implementation, we analyzed the noted challenges and identified barriers. Metrics were also gathered on usage of CDC for pharmacogenomic (PGx) at both institutions, and changes in management where tracking was possible.

Results

We were able to successfully implement genomics in both systems with compromises. We encountered vendor specific informatics challenges on both EHR vendor platforms including the inability to store discrete variants for pharmacogenomics, necessitating use of star allele diplotypes, and having inadequate infrastructure for autosomal recessive conditions when the patient is a compound heterozygote. Although these were vendor specific issues the vendors data implementations were based on legacy standards, which had deficiencies that contributed to these problems. Other global challenges include: 1) Need for a “home” for genomic data 2) Need for standardization of genetic phenotype. 3) Difficulty in sending discrete data from the genetic testing laboratory directly to the EHR. 4) Addressing the role of the Laboratory Information System (LIS) in the genomics process. 5) Inadequate and discordant standards for genomics in the HL7 genomic report format and the Fast Healthcare Interoperability Resource (FHIR) molecular sequence resource. 6) Challenges related to maintenance of patient/provider information and decision support in a rapidly changing field. 7) Lack of standard resources for patient/provider information. 8) Disparate implementation needs for clinical geneticists compared to primary care providers. 9) Different perception of discrete genomic data versus scanned PDF of the genetic report. 10) Difficulty in maintaining variant classification across patients and reports.
A technical infrastructure was designed to manage the return of results process at each institution that enabled 1) tracking of notifications of patients of their results, 2) genetic counseling processes, 3) provider notifications, 4) specialist referrals, 5) result based clinical actions, 6) cascade testing, 6) variant classification and reclassification.

Metrics on CDS usage in pharmacogenomics demonstrated that 73% (40/55) of providers changed prescriptions based on active decision support for new prescriptions but none of the providers changed dosing or medication when the patient had been established on the medication. Metrics for passive decision support demonstrated that usage was primarily restricted to those who ordered a PGx test for a specific purpose and only used after the initial test result came back and rarely used outside of the ordering provider or by the ordering provider for another indication.

**Discussion**

While we were able to achieve some success in integration of genomic data into the EHR, there are many challenges that need to be addressed. One of the biggest challenges moving forward is the long-term maintenance of gene/variant specific information and decision support. Genomic medicine is a rapidly changing field and EHR systems require support from vendor specific technical personnel to implement changes to patient/provider facing information and decision support. Engaging this technical team can be challenging given their responsibility to maintain all aspects of the EHR and they are generally not skilled in genomics requiring an alignment of teams to make any changes. EHR vendors adhering to more open standards for genomics and decision support, including SMART on FHIR, and CDS Hooks would allow for integration of external applications where maintenance can be performed by staff with genetics training and less technical skill. Another important component to this, is the need for maintained resources such as PharmGKB that are Infobutton compliant and can allow to quick access to the most recent recommendations and information on a specific gene or variant. To our knowledge no vendor has implemented Infobutton support for genomics, and outside of pharmacogenomics no such Infobutton compliant resources exist.

Difficulty in passing data from the laboratory to the EHR is a considerable challenge and one of the greatest components of this challenge is the standardization of the genetic phenotype (i.e., disease, metabolizer status, gene specific phenotype, modifier variant phenotype). We were able to capture discrete genomic data from reporting laboratories, however; laboratories used their own proprietary JSON structured format. Developing the ability to pass phenotypes required manually building a process for each phenotype and each lab, which is neither desirable nor sustainable as more laboratories and conditions are added. To effectively enable integration of genetic data in a scalable manner requires adequate standards for storing and transmitting genomic data and standard API’s that allow ancillary systems to interface with the EHR. While we have developed an external data architecture for managing the return of results process it is unclear at this time how or if this should be integrated into the EHR.

Active decision support was more effective in engaging providers and causing change, especially in situations of a new diagnosis or new medication. Passive decision support was less effective. We believe this was due to providers not seeking genomic information prior to prescribing even when it existed. Lack of training of providers about genomics likely contributed to this, as well as the relatively small number of patients that had genomic results making the information not common to seek. We believe as genomic information becomes more available and providers become better trained on its use that it will be sought after and must have an established place in the EHR similar to imaging or laboratory results. More research is needed to understand and optimize workflows for genomic medicine and to test novel methods of delivering genomic information to patients and providers.

Axes of Prognosis: Identifying Subtypes of COVID-19 Outcomes

Abstract

COVID-19 is a disease with vast impact, yet much remains unclear about patient outcomes. Most approaches to risk prediction of COVID-19 focus on binary or tertiary severity outcomes, despite the heterogeneity of the disease. In this work, we identify heterogeneous subtypes of COVID-19 outcomes by considering ‘axes’ of prognosis. We propose two innovative clustering approaches - ‘Layered Axes’ and ‘Prognosis Space’ – to apply on patients’ outcome data. We then show how these clusters can help predict a patient’s deterioration pathway on their hospital admission, using random forest classification. We illustrate this methodology on a cohort from Wuhan in early 2020. We discover interesting subgroups of poor prognosis, particularly within respiratory patients, and predict respiratory subgroup membership with high accuracy. This work could assist clinicians in identifying appropriate treatments at patients’ hospital admission. Moreover, our method could be used to explore subtypes of ‘long COVID’ and other diseases with heterogeneous outcomes.

Introduction

The clinical heterogeneity within COVID-19 patient outcomes has been demonstrated1,2, however, a great deal of this heterogeneity remains to be explored. Work has been done to classify patients and predict patient outcomes, much of which has been analysed by Wynants et al.3. However, this is often limited to predicting a binary or tertiary severity outcome (death/ICU/none). Our work furthers this by exploring more diverse poor prognosis outcomes.

For a variety of diseases, valuable insights can be gained by using unsupervised clustering to explore prognosis4,5. We propose and demonstrate a pipeline for exploring COVID-19 prognosis by using unsupervised clustering methods on patient outcomes to identify subtypes of poor prognosis. The identification of these subtypes facilitates the prediction of patient trajectories to nuanced poor prognoses. Our aim is thus to discover and predict a broader range of subtypes of COVID-19 prognosis, using a combination of supervised and unsupervised learning techniques.

Methods

Our methodology for this task consists of three steps: (1) Feature extraction from multimodal data: exploring, cleaning and manipulating our multimodal dataset in order to extract rich features; (2) Clustering on outcomes: using features collected at endpoints (discharge or death) to cluster patients, comparing results from a variety of clustering approaches using multiple axes of prognosis; (3) Classification at admission: using features at admission, mapping each patient to a cluster found in the previous step to predict their probable deterioration pathways. The pipeline of our work process is shown in Fig. 1. We will discuss each step in more detail below. Further details and code are available at https://github.com/knowlab/covid-subtypes.

Data

We demonstrate our methodology on a dataset consisting of 2815 health records of COVID-19 inpatients of Wuhan Sixth Hospital and Taikang Tongji Hospital, with admission dates between 4th February 2020 and 30th March 2020. It is worth noting that this cohort was treated in hospitals that were not overwhelmed, in a period with a treat-all policy in Wuhan, meaning that admission was routine for all COVID-19 patients. As a consequence, this cohort contains largely non-severe patients and the mortality rate of this cohort is 2.4%.

*These authors contributed equally to this work.
Pre-processing We removed duplicate records, leaving 2797 patients for whom a wide range of features were available, including general patient information, co-morbidities, smoking status (from free-text), symptoms (from free-text), lab test results, ICD-10 admission and discharge codes, and other prognosis features (death, ICU admission, supplementary oxygen, length of stay). Discharge ICD-10 codes were pre-processed and grouped into chapters. We removed codes ‘U07.1 - COVID-19’ and ‘Z22 - Carrier of infectious disease’ as, predictably, these were reported for the majority of patients. Discharge conditions were represented as one-hot vectors.

Data Imputation For the classification step, we wished to utilise much of the data available on patient admission, including laboratory test results and clinical measurements. However, we did not have readings for each measurement for each patient and so we imputed missing values. Our imputation technique was to randomly choose a value within the normal range for each test result, in order to reduce biasing the results. The values for normal ranges were found from various medical reference sources, the full list of which can be found at [https://github.com/knowlab/covid-subtypes](https://github.com/knowlab/covid-subtypes). We chose this, rather than using the average feature value, as we were advised by clinicians working at the hospitals that the absence of values is informative: a test is more likely to be performed if it is suspected the result will be outside the normal range.

Feature Extraction To prevent data leakage, we split features into two disjoint subsets: ‘outcome’ features for clustering and ‘admission’ features for classification. Outcome features took binary values, with the exception of length of stay, which was converted to two binary values: 00 for 0-2 weeks, 01 for 2-4 weeks, and 10 for 4 weeks+ (11 is not used). The admission features were taken from measurements in the first three days of hospital admission. Where available, the minimum and maximum readings for days 1 and 3 were used as separate features, otherwise, the average values from each day (1 and 3) were used.

Discovering COVID-19 Subtypes via Clustering

Axes of prognosis model We wished to cluster on features related to a patient’s outcome in order to explore nuanced subtypes of poor prognosis. To do this, we considered the idea that there are multiple ‘axes’ to prognosis. For example, the two ‘axes’ that make up an individual’s prognosis might be the system of deterioration (defined as clusters of diseases) and the severity of deterioration (quantified/qualified by proxy variables like mortality, types of treatments and length of stay). Here, if a patient had a respiratory discharge code, this would indicate the system of deterioration, whilst the use of oxygen therapy would be an indicator of the severity. To get a true picture of an individual’s prognosis, we must have a measure across all axes of prognosis - for example, ICD-10 chapters to indicate systems, and features such as ICU admission, death, oxygen therapies, and length of stay to measure severity. We will use different clustering approaches to leverage the idea of ‘axes of prognosis’.

The following example illustrates the potential value of this approach. Consider three patients who are admitted...
with COVID-19: patient A has no significant symptoms and is discharged after 5 days; patient B arrives with no significant symptoms, but is noted to be vitamin D deficient during their stay, recorded as ‘E55.9’, they are discharged after 7 days; patient C has already deteriorated significantly upon arrival and dies 1 day later. Clustering algorithms typically use distance measures to compare data points. If we consider these three patients in the space ‘Has Nutritional Code’ \(\times\) Death = \(\{0, 1\}^2\) then, for most distance measures \(d, d\text{(patient A, patient B)} = d\text{(patient A, patient C)}\). Thus, clustering algorithms lack context and can struggle to note the clearly significant distinction between outcomes. On the other hand, were we to consider the axes ‘system of deterioration’ and ‘severity of deterioration’ individually, or to transform the features into some space where distance can be ‘sensibly’ measured, a clustering algorithm could note the difference in severity of deterioration between patient C and patients A and B.

We propose the use of two novel methods using axes of prognosis: Layered Axes and Prognosis Space with the goal of exploring nuanced subtypes of poor prognosis. These are summarised below and in Fig. 2.

**Layered Axes:**

1. Choose axes of prognosis (e.g. system of deterioration, severity of deterioration, duration of illness) and assign each outcome feature to the axis of which it is most indicative (for example, ICD-10 chapters are indicative of the system of deterioration).
2. Choose one axis and, using only the features assigned to it, apply a standard clustering method to produce clusters. This produces clusters that clearly describe that axis.
3. Discard the features already used and choose a new axis. For each cluster already found, use the features assigned to the new axis and a standard clustering method to produce subclusters. These subclusters now clearly describe both axes.
4. The subclusters become the clusters and step 3 is repeated until all axes have been considered.

**Prognosis Space:**

1. Choose axes of prognosis and assign each outcome feature to the axis of which it is most indicative.
2. Define a ‘space transformation’ function to map features onto the axes - creating an interpretable Prognosis Space with fewer dimensions. This allows domain knowledge to be incorporated into the dimension reduction.
3. Use this function to map patients into the Prognosis Space.
4. Apply a clustering algorithm in the Prognosis Space. As we are no longer in a binary feature space, common distance measures, such as the Euclidean distance, have more meaning - this allows us to apply a wider range of clustering algorithms, such as DBSCAN\(^9\).

**Implementation** Our dataset consists of 2797 patients, for whom we have 16 binary features describing their outcome. As a baseline, we applied a standard clustering method to all features. Then, we applied both of our new methods to the Wuhan dataset and compared the clusters produced. Axes were chosen to demonstrate the potential different strengths of each approach. For the Layered Axes method, we chose our axes of prognosis to be system and severity of deterioration. We used ICD-10 chapter codes to indicate system of deterioration and ICU admission, death, use of noninvasive/invasive oxygen therapy and ECMO, and length of stay to indicate severity of deterioration. We clustered first on the system and then found subclusters using severity.

For the Prognosis Space method, we chose our axes of prognosis to be system of deterioration, need for oxygen therapy, severity of deterioration and duration of illness. As above, ICD-10 codes were used to indicate system; length of stay indicated duration of illness, ICU admission and death indicated severity of deterioration, and use of oxygen therapy and ECMO indicated need for oxygen therapy. We created a ‘space transformation’ function, \(f : \{0, 1\}^{16} \rightarrow \mathbb{R}^4\), that placed more weight on the severity and need for oxygen therapy axes. The function has the
basic form $f(x) = (f_1(x_{\text{system}}), f_2(x_{\text{OXY}}), f_3(x_{\text{severity}}), f_4(x_{\text{duration}}))$, where, for example, $x_{\text{system}}$ refers specifically to the features of $x$ that we used to indicate system. More details of the dimension reduction function used are given at https://github.com/knowlab/covid-subtypes.

As all our outcome features were binary and we wished to demonstrate the potential utility of this method in a clinical setting, we used the K-Modes clustering algorithm\(^{10}\) (implemented using the Python package kmodes\(^{11}\)) for our baseline and Layered Axes approach. This forms clusters based around a ‘centre’ - specifically the mode of the cluster - and uses the Hamming distance to compare points. The cluster centres are actual data points, which can then be used as a description for each cluster produced. The algorithm was run with several different numbers of clusters and the best result for each approach was chosen to reflect the heterogeneity in outcomes. Other clustering methods - such as K-Means clustering and DBSCAN - were also tested, however these algorithms are not optimised for the binary features used and so were less interpretable in our context.

Our Prognosis Space approach maps the binary features into $\mathbb{R}^4$ - this means it now makes sense to use the Euclidean distance to compare points, and a wider range of clustering algorithms become suitable. We demonstrated our Prognosis Space result using DBSCAN as it is more capable of capturing clusters of different shapes. Hyperparameters were optimised using the elbow method.

**Cluster Analysis** As this task is unsupervised, we had no knowledge of what ‘good’ clusters look like. Therefore, we sought clusters with a clear clinical interpretation, showing distinctions between different prognoses. Our cohort contained a large number of patients with mild symptoms: discounting length of stay, 1744 patients had 0s for all features. As such, for this cohort we expected at least one cluster with over 1000 patients, with others significantly smaller in size. To determine the clinical interest of a set of clusters, we examined heatmaps of feature prevalence for all the outcome features, alongside demographic feature prevalence.

**Predicting COVID-19 Subtype at Admission via Classification** For prediction, we used the clusters discovered as labels to generate a supervised classification problem to identify patient trajectories. We trained the classifiers using the results from our clustering methods, using cluster memberships as labels. We then input patient admission data to the classifiers, and cluster memberships were predicted by the classifiers, hence identifying likely patient outcomes. This not only provides information about potential patient deterioration pathways, which can be used to assist clinical decision making (e.g. how best to treat a patient), but also
provides a way to validate the clinical meaning of the clusters found.

Poor Prognosis Subtypes Since we were most interested in predicting the subtypes of poor prognosis, we focused only on the ‘interesting’ patients, which were decided using our understanding of the clinical meaning of the clusters: we disregarded individuals with no recorded discharge codes (since they had no prognosis subtypes on discharge), and performed multiclass classification on the remaining patients using their admission data to predict their deterioration pathway.

Classification Models For our system to be clinically useful, it is imperative the models are interpretable to clinicians. This motivated our choice of a set of ‘transparent models’ including decision trees, logistic regression and random forests\(^\text{12}\). We only present results on random forests as it performed the best. We used scikit-learn\(^\text{13}\) implementation. Random forests utilise many decision trees as an ensemble, which reduces potential issues with overfitting found in decision trees; they can provide better results than single decision trees since the variance between predictions is captured in the overall model. The space used and runtime is greater than that of a single decision tree, but this was not an issue for us due to the small dataset. The trees can be plotted, clearly showing decisions made by the classifier, including the importance of each feature used to aid in these decisions.

Classification Details We implemented grid search to choose the optimal hyperparameters for each classifier, and used scikit-learn\(^\text{13}\) stratified K-fold cross-validation to validate our models. The use of cross-validation was important due to the small cohort size: we wanted to make best use of the data by training and testing the model on multiple combinations of our data. The stratified variant of K-fold preserves the underlying distribution of the data, which we used due to the class imbalance observed. The value of \(k\) was set to 3; this was kept small to ensure there were enough samples in the test data for the least numerous classes in each fold, as some of the subtype classes had very few individuals.

Addressing Data Imbalance A limitation for the success of classification is the class imbalance that arises from many patients experiencing only mild symptoms. Since we are using real-world data, the imbalance of classes is representative of a real Chinese hospital cohort. However, to optimise the generalisability of our classifiers and increase performance, we used upsampling: we upsampled individuals in the least numerous classes in the training data in each fold by randomly sampling with replacement. Overall predictions are improved, however upsampling does not capture the variety of patients, potentially causing overfitting and not improving predictions for those deviating from the training set.

Results

Clustering

For the baseline and Layered Axes approaches, we used the K-Modes cluster centre descriptions for each cluster. For the Prognosis Space approach, we derived similar descriptions using the heatmaps produced. The descriptions of all the clusters found are given in Table 1, and heatmaps of the prevalence of binary features in each cluster are shown in Fig. 3.

Baseline Approach Most severe patients were put in cluster 2, meaning it failed to find subtypes of severe cases. There are two non-severe subtypes with no adverse prognoses: cluster 3 with 2-4 weeks of stay and cluster 1 with mixed stays, most within 2 weeks and a few 4+ weeks.

Layered Axes This method discovered several clinically sensible subtypes within groups with similar severity and background conditions. There are two clear subtypes of severe COVID patients: cluster 0b with high proportion of co-morbidities, particularly a combination of respiratory and nutritional; cluster 1a with mostly respiratory that were complicated with circulatory; the former was generally more severe. There are two subtypes of respiratory patients: cluster 1a - the severe group and cluster 1b - largely non-severe (40% discharged within 2 weeks). This is particularly interesting as respiratory conditions are widely recognised as a high risk-factor of severe COVID-19 cases despite the age group. There are also two subtypes of non-severe patients: cluster 3a with 2-4 weeks of hospital stay and cluster 3b with around 80% discharged in 2 weeks with no recorded complications.

Prognosis Space There are three very interesting subtypes of severe patients: cluster 5 - all stayed in ICU but all recovered; cluster 7 - quick deterioration to death within 2 weeks; cluster 8 - others all died after >2 weeks. For
**Table 1:** Clusters found using the three approaches - the standard baseline clustering approach, the Layered Axes approach and the Prognosis Space approach. Interesting subtypes are highlighted in bold text.

non-severe patients: cluster 1 patients have no underlying conditions and are discharged within 2 weeks; cluster 3 have mostly circulatory conditions (also many other conditions) and a speedy recovery (<2 weeks of stay); cluster 0 - others, with longer admission. There is another distinct finding - cluster 2 were those patients mostly on oxygen therapy but who recovered and never stayed in ICU.

**Classification**

We predicted poor prognosis subtypes of ‘interesting’ patients, disregarding patients without discharge codes or poor prognosis events. This contained classification sub-problems, based on the labels generated by Baseline K-Modes, Layered Axes K-Modes and Prognosis Space DBSCAN. For each of these, we classified using random forests and implemented grid search in order to find the optimal hyperparameters. These, along with additional experimental configurations can be found at our online resource: https://github.com/knowlab/covid-subtypes. A selection of our classification results are presented in Table 2, and Table 3 contains the most important feature for each classifier. Full classification results for all experiments and feature importances are also shown on our online resource.

**Layered Axes** The results for the Layered Axes clusters are shown in Fig. 4, with number of individuals classified into each cluster shown. These display an improved overall accuracy compared to baseline K-Modes, with an $F_1$ score of 0.627 on average. We built separate classifiers to predict the second-layer subcluster membership (within each top-layer cluster of nutritional, respiratory, and circulatory clusters). The $F_1$ score for the classification of respiratory patients’ subtypes is highest at $0.844$. In Fig 5, the confusion matrix for the classification of the most severe patients is shown; the subcluster sizes are very limited which impacts the robustness of these results.

**Prognosis Space** We present the results for the classification of severe patients’ subgroups using the Prognosis Space approach in Fig. 5. Subtypes 5 and 7 are classified with higher accuracy than 8, although these are the most severe patients. This is also highlighted in the greater $F_1$ score of 0.720 for distinguishing clusters 5 and 7, compared to that of 5, 7 and 8 (0.579). The cluster sizes are very limited which impacts the robustness of these results.
Figure 3: Heatmaps showing prevalence of binary features within each cluster found by each approach. OXY refers to use of oxygen therapy and LOS refers to the length of stay. Note that the features shown in the third row, Demographic information, were not used for clustering - they are shown only to aid interpretation of the clusters. For the Layered Axes K-Modes clusters, labels are in the form number-letter where the number indicates the clusters found from the first axis, and the letter the subclusters found within that cluster using features from the second axis. Note also that for the Prognosis Space approach, DBSCAN has been used and -1 indicated points described as ‘noise’.

Discussion

Our approach is able to identify many subtypes of severe COVID-19 cases described with rich clinical features. We believe this is the first work that reveals the heterogeneity of COVID-19 with such detail. Many of these subtypes (such as clusters 1a and 1b for respiratory patients) were surfaced for the first time, conveying novel insights that lead to better understanding of the disease and could potentially guide us to treat patients with more personalised approaches. It is clear that the axes of prognosis approach plays a vital role in achieving this.

Figure 5: Example confusion matrices for classification of severe patients. Left: Layered Axes K-Modes; Right: Prognosis Space DBSCAN. x-axis: predicted label; y-axis: true label.

Comparing to baseline K-Modes, using the Layered Axes approach can discover more nuanced clusters by grouping on one axis at a time and thus selecting a feature of significance from each axis. For example, at baseline, respiratory side effects are only considered in the context of very severe deterioration. In contrast, clusters 1a and 1b capture different outcomes for respiratory patients. It is interesting to note that, despite the very different outcomes of 1a and 1b, the proportion of over 65s is similar in both clusters. We might have expected that older patients were more likely to deteriorate significantly. Prognosis Space is also able to reveal more heterogeneity in outcomes. Clusters 5-8 seem particularly noteworthy for their similar yet distinct characteristics. In particular, clusters 7 and 8 both consist of patients who are admitted to ICU and die, but with quite distinct deterioration speed.

For classification, in Layered Axes, the classification results suggest that these nuanced multi-axis clusters not only make more clinical sense, but they also provide improved classification results in comparison to the baseline. In particular, the excellent classification results for the respiratory subclusters, 1a and 1b, provide a strong example use case. Here, we can predict accurately whether a respiratory patient is likely to deteriorate seriously leading to ICU and death (1a membership) or experience no severe prognosis (1b membership). This is especially interesting since...
there is no significant difference in the age of the patients between these two subclusters (Fig. 3). For Prognosis Space, results are promising, but lacking in robustness due to the larger number of clusters and therefore the smaller number of samples in each cluster. Clusters 5 and 7 both contain severe respiratory patients (5: ICU, 7: death) and can be distinguished with high accuracy by our classifier (Fig. 5) - but it struggles with cluster 8. Cluster 8 contains patients who deteriorate fatally, but not rapidly. Our classifier likely struggles with these individuals since they take a longer time to deteriorate, so their readings upon admission - which we use as classification features - may not be seriously irregular. The feature importances for each classifier also differ significantly. This is potentially clinically informative as it highlights certain test results which are informative for our classifiers (in most cases, even more so than clear risk factors such as age).

**Strengths** We have demonstrated that considering axes of prognosis allows for discovery of more nuanced subtypes of poor prognosis. In particular, our Layered Axes approach allows us to interpret every cluster found along each axis of prognosis being considered and is easily interpretable, especially when only a small number of axes are being used. On the other hand, our Prognosis Space approach allows us to incorporate domain knowledge and combine related binary features in a meaningful way. The Prognosis Space approach is comparable to other dimension reduction-clustering approaches such as Principal Component Analysis (PCA). We believe that compared with methods such as PCA, especially in the context of a binary feature space, our approach is both more interpretable and allows for the incorporation of targeted domain knowledge. Both of our approaches provide a more interpretable and clinically meaningful output than many ‘off-the-shelf’ clustering approaches.

**Limitations** We highlight the fact that the large majority of our cohort did not suffer from any significant side-effects from COVID-19. In fact, the clusters contain over 2300 patients who can be deemed to be ‘non-severe’ (clusters 1 and 3 in baseline K-Modes). This leaves only around 500 patients from whom we can derive more ‘interesting’ clusters and build classification models, leading to classifiers built from very small samples. Upsampling the smaller classes when training our models cannot capture diversity in test samples, so does not appear to be a good solution here. Therefore, our approach, especially when using the clusters found across multiple axes, must be tested on larger datasets.

Additionally, although we have extrapolated meaning from the clusters found, we cannot truly know which clustering is ‘best’, or even, ‘good’ since they are found in an unsupervised setting. If clustering is not optimal, our classification will likely also be worse - but this is a hard problem to overcome! A larger and more diverse dataset may also help with our confidence in clustering ability and predictions made. Additionally, there are potentially different endpoints and trajectories of deterioration that clustering approaches may be unable to pick up. Future work could explore other options for detecting these.

**Future Work**

This work provides a demonstration of our methodology for exploring heterogeneous disease prognosis. Therefore, potential future work is vast. Predominantly, these techniques need to be tested on a larger dataset, particularly with more patients with severe outcomes. This will likely improve the accuracy of clustering on severe patients, and the ability of classifiers to predict them. The methodology behind the Prognosis Space technique in particular should be applied to a larger dataset to properly explore its capabilities. Furthermore, a large dataset would allow for deep methods such as neural networks to be tested - these have been shown to perform very well on unsupervised learning problems with large datasets. Whilst we would not want to use these for our main predictions due to lack of interpretability, they could provide a useful comparison.

Secondly, our model may not be generalisable to cohorts from other countries, due to the different policies on hospital admission. However, we believe this approach could remain useful and provide interesting insights. Testing on different cohorts would enable exploration of the generalisability of the work. Further to this, our methodology needs to be tested and explored more rigorously. In different contexts, there are a vast number of clustering algorithms that could be used within our method - especially when continuous features are used. Moreover, the methodology could be refined and optimised for different contexts and diseases.

In some cases, classifiers could confidently predict patients who would die in a short time frame, yet struggled to identify those who would die after a longer period of deterioration, even if the outcomes were similar. Another aim for future work could be to establish whether using later time series points for these patients would allow correct
classification. We could also explore whether this would have potential applications for predicting long COVID. In particular, if a patient took a certain non-fatal prognosis pathway, this could be linked to the development of specific symptoms of long COVID later on.

**Conclusion**

We have proposed a novel *axes of prognosis* model and demonstrated how it could be used to identify diverse COVID-19 prognosis that accounts for the wide heterogeneity of the disease via a combination of clustering and classification. This methodology is not only suitable for predicting prognosis, but has a wide range of potential applications, for example, risk prediction and helping clinicians take preventative measures earlier on. This methodology could also be easily applied to a range of diseases with heterogeneous prognoses, including studying subtypes of long COVID.

Design and development of an informatics-driven implementation research framework for primary care studies

Jiancheng Ye
Feinberg School of Medicine, Northwestern University, Chicago, USA

Abstract
The digitalization of the healthcare systems has resulted in a deluge of big data and has prompted the rapid growth of data science in medicine. Many informatics tools, such as data science, which is the field of study dedicated to the principled extraction of knowledge from complex data, can also introduce benefits into implementation science, quality improvement (QI), and primary care research. The increased amount of primary care QI initiatives, availability of practice facilitation-related data, the need for better evidence-based care, and the complexity of challenges make the use of data science techniques and data-driven research particularly appealing to primary care. Recent advances in the usability, applicability, and interpretability of data science models offer promising applications to implementation science. Despite the increasing number of studies and publications in the field, thus far there have been few examples of combining informatics and implementation framework to facilitate primary care studies. We designed and developed an informatics-driven implementation research framework to provide a coherent rationale and justification of the complex interrelationships among features, strategies, and outcomes. The proposed framework is a principle-guided tool designed to improve the specification, reproducibility, and testable causal pathways involved in implementation research projects in primary care settings.

INTRODUCTION
Implementation science
Implementation research is the scientific study of methods to promote the systematic uptake of research findings and other evidence-based practices into routine practice, and, hence, to improve the quality and effectiveness of health services and care. This relatively new field includes the study of influences on health care professionals and organizational behaviors. Implementation science shares many characteristics, and the rigorous approach, of clinical research. Implementation science in primary care involves investigation at multi-levels, and the targets of investigation include the patients, health care providers, primary care clinics, organization, community, society, and health system.

Informatics in primary care
Health care systems, especially primary care, suffer from major gaps between evidence and practice, unexplained practice variations, and suboptimal quality. Although health information technologies (HIT), such as information processing, and management are key to health care delivery and considerable evidence to improvements in health care quality and patient safety, primary care has a longstanding gap in the implementation of evidence-based practices and informatics packages. Informatics in primary care includes the development, installation, and implementation of electronic systems and relevant applications, including hardware, software, networking, and communication tools. In the past decade, IT development activities within the health care industry have increased as executives and providers recognized the urgent need for strategic information management and inadequacies of traditional information storage, retrieval, and analysis tools. However, most IT investments in primary care lack feasible guidelines for implementation and maintain sustainable improvement.

Implementation of informatics packages or tools in primary care has two main domains: (1) HIT infrastructure implementation. For example, implementing or updating electronic health record (EHR) systems to enable automated mechanisms for capturing data, and facilitate clinical decision making; (2) leveraging the clinical decision support (CDS) systems to improve health care providers’ performance and generate measurable metrics to evaluate the performance, such as efficiency, effectiveness, cost, efficacy, etc.

In general, most health care information systems are composed of automated billing and financial management, patient admission, discharge, transfers and registration, coordination of communications infrastructure, claims processing, customer service, and electronic data sharing. The informatics infrastructure needed for primary care includes feasible data collection methods, data repositories, clinical event monitoring, health care standards including standardized terminologies, digital sources of evidence, data-mining techniques, and communication technologies.
The informatics system in primary care needs to interface with, and assist, patients, health care providers, primary care managers, health care organizations, communities, and the public.

This study aims to design and develop an informatics-driven implementation research framework to provide a coherent rationale and justification of the complex interrelationships among features, strategies, and outcomes. We will adapt the typical evaluation logic model to integrate existing implementation science frameworks and informatics models as their core elements while keeping to the same aim of facilitating the causal modeling.

METHODS

Framework

To develop the informatics-driven implementation research framework, we adopted the Implementation Research Logic Model (IRLM) that was developed by Smith et al. This model enables a pipeline format for primary care systems that support the adoption and delivery of health practices by involving multiple levels factors within or outside the system and having its own unique characteristics. This framework also incorporated the key elements of the FITT (Fit between Individuals, Task and Technology) framework.7

Figure 1. Informatics-driven implementation research framework standard template
RESULTS

Features

Features are variables or factors that may impact the implementation (i.e., barriers and facilitators). All the features can be mapped onto the Consolidated Framework for Implementation Research (CFIR) framework. In some cases, features may act as moderators or mediators, thus indicating that they are links in a chain of causal mechanisms.

Informatics domains

Task

Tasks in primary care include collecting medical history, gathering preventive service information, completing forms, screening disease, diagnosing, tracking diagnostic data, making treatment protocols, proposing interventions, educating patients about self-care activities and medications, refilling prescriptions, receiving and resolving patients’ inquiries, referral tracking, and arranging home health care.

Technology

In primary care, technology and informatics system have several key elements. In general, a primary care clinic should have an available EHR to enable patients and providers to conduct shared decision-making. EHRs store personal health data, reliable patient-specific tools, and resources. EHRs provide every patient and their caregivers with the necessary information required for optimal care. They can help patients to better understand the complexity of medical care and more readily participate in clinical decision-making and preventive health behaviors. Electronic health information exchange (HIE) ensures security, privacy, and system compatibility. The exchange between organizations facilitates sharing of patient information at the point of the care delivery to eliminate unnecessary testing, improve safety, and facilitate efforts to improve health care quality and patient safety. Clinicians in primary care can leverage CDS can help health care providers utilize state-of-the-art medical knowledge in treatment decisions. CDS provides information management tools for the acquisition, manipulation, application, distribution, and display of appropriate patient- and task-specific clinical data to providers and patients that is conducive to correct, timely, and evidence-based clinical decision-making. Computerized provider order entry (CPOE) can help the tracking and analysis of health care processes. CPOE for tests, medicine, and procedures has the potential to decrease medical error, improve quality. It can help providers coordinate and collect patient-specific information. Population-based health care systems support the creation of large, integrated databases of patient-specific information that allow real-time management of populations of similar patients. These databases can facilitate the evaluation of new implementation strategies and provide insights into new associations between management approaches and health states.

All of these tools coordinate information dissemination and sharing from various databases to equip the provider in providing patient-specific, appropriate, timely, and evidence-based care.

Individual

For implementation research in primary care, there are several key stakeholders during the process, including primary care leaders, managers. Quality improvement practice facilitators are implementation scientists are also important because they work closely with primary care leaders and staff as partners and break down the research-practice divide in order to achieve the ultimate goal of increasing the public health impact. Table 1 demonstrates the informatics-driven interventions and strategies for implementation projects in primary care based on the three domains.

Implementation strategies

**Intervention Characteristics**

Intervention Characteristics are key attributes of interventions that influence the success of implementation.\(^\text{22}\) Information technology management encompasses primary care, its infrastructure, strategies for use, and expected outcomes. Implementation research in primary care requires the support and resources of the organization and leadership. Most primary care systems have limited resources for QI. Resource allocation warrants close examination to maximize the benefits of the delivery of safe, effective, efficient, and high-quality care. Factors influencing organizational decisions surrounding implementation need to explore the characteristics of clinical conditions, practices, and settings, outstanding gaps, expected costs and benefits. The implementation research should be tailored to the needs of the organization. A balanced assessment of the effectiveness and costs of the system is needed to make successful implementation efforts.

**Inner Setting**

The inner setting is an active interacting facet and not just as a backdrop in implementation. Most primary care clinics are still at the stages ranging from considering adoption through early implementation. The lack of financial support for widespread informatics applications is considered a primary barrier to its implementation by both managers and clinicians.\(^\text{23}\) The financial burden of implementation, including acquisition and implementation costs, slow and uncertain financial payoffs, and disruption to clinical practices, is directly related to both the size of primary care and its readiness for conversion.

**Outer Setting**

An effective implementation needs stakeholders outside of the organization, such as policymakers, state and federal entities, and various participants (e.g., physicians, other providers, hospitals, payers, etc.).
Characteristics of Individuals

Organizations, including primary care, are made up of individuals. This framework can facilitate the understating of the interplay between individuals and their ripple effects through their teams, units, networks, and organizations on implementation. Clinicians desire a system that allows them to review and act upon test results safely and efficiently. Taking full advantage of informatics may require a team approach, where active involvement of interdisciplinary groups of providers and users is important. HIT use may empower patients in their exchange with providers and promotes the alignment of care between hospitals/clinics and patients' homes. Human factors such as system usability, process complexity, and user-engagement methods routinely influence the implementation.24

Process

A crucial first step for the organization in the implementation process is to assess both current informatics capabilities and estimate future needs.25 Equally important is the assessment of readiness for major organizational change, such as the ability to invest in change management and training, as well as the culture and processes needed to support implementation.26 Informatics systems to be implemented need to align with processes within the primary care to allow evolution and adaptation.27 On an individual level, the organization and its management need to involve end users' input in improving their work practices. They also need to consider other factors, such as the usability, usefulness, and flexibility of informatics tools and individualized training that will influence uptake. On a system level, a supportive culture, visibility of positive results from IT use, and a realistic timeline will enhance implementation.28

Outcomes

Outcomes include target clinical outcomes, health service outcomes, or indicators of implementation processes. Among these, implementation outcomes are the effects of deliberate and purposive actions to implement new treatments, practices, and services in primary care.29 The interrelated nature of implementation outcomes may present as non-linear, complex, or dynamic sequences of adoption by a delivery agent. Outcomes earlier in the sequence can be conceptualized as mediators and mechanisms of strategies on later implementation outcomes. Specifying which strategies are theoretically intended to affect which outcomes, through which mechanisms of action, is crucial for improving the reproducibility and generalizability of implementation research in primary care and validating the results.

DISCUSSION

A number of exciting challenges face the rapidly developing field of health and biomedical informatics in primary care. Integration of implementation science methodologies into primary care will speed the development of evidence-based interventions that have demonstrable public health impacts. Testing and validating the theories that underlie implementation efforts is needed to enhance the development of next-generation analytic methods and interventions. This informatics-driven framework used systems thinking that allows us better understand how each element in the system interacts and impacts each other, thus proposing intervention strategies accordingly.

The proposed informatics-driven implementation research framework provides a compact visual depiction of implementation research studies. Its use in the planning, executing, reporting, and synthesizing of implementation research could increase the rigor and transparency of complex studies that ultimately could improve reproducibility—a challenge in the field—by offering a common structure to increase consistency and a method for more clearly specifying links and pathways to test theories.6 The proposed framework would be a useful and generalizable guideline for future practice facilitation projects, QI initiatives, and health care intervention implementation studies.

CONCLUSION

We designed and developed an informatics-driven implementation research framework to provide a coherent rationale and justification of the complex interrelationships among features, strategies, and outcomes. The promise of implementation science lies in the ability to conduct rigorous and reproducible research, to clearly understand the findings, and to synthesize findings from which generalizable conclusions can be drawn and actionable.
recommendations for practice change emerge. The proposed framework is a principle-guided tool designed to improve the specification, reproducibility, and testable causal pathways involved in implementation research projects in primary care settings.

Abstract  Epilepsy is a kind of neurological disorder characterized by recurrent epileptic seizures. While it is crucial to characterize pre-ictal brain electrical activities, the problem to this day still remains computationally challenging. Using brain signal acquisition and advances in deep learning technology, we aim to classify pre-ictal signals and characterize the brain waveforms of patients with epilepsy during the pre-ictal period. We develop a novel machine learning model called Pre-ictal Signal Classification (PiSC) for pre-ictal signal classification and for identifying brain waveform patterns critical for seizure onset early detection. In PiSC, a unique preprocessing procedure is developed to convert the stereo-electroencephalography (sEEG) signals to data blocks ready for pre-ictal signal classification. Also, a novel deep learning framework is developed to integrate deep neural networks and meta-learning to effectively mitigate patient-to-patient variances as well as fine-tuning a trained classification model for new patients. The unique network architecture ensures model stability and generalization in sEEG data modeling. The experimental results on a real-world patient dataset show that PiSC improved the accuracy and F1 score by 10% compared with the existing models. Two types of sEEG patterns were discovered to be associated with seizure development in nocturnal epileptic patients.

1 Introduction

Epilepsy, as one of the most common neurological diseases, can be characterized by a combination of complexity and intractability. It is a persistent or secondary change in the brain and can cause serious consequences in neurobiology, psychology, sociology, and cognitive dysfunction. Improving the diagnosis of epilepsy and providing better treatment has been a significant and challenging research problem around the world. Electroencephalogram (EEG) is one of the main means to observe the electrophysiological activity of the brain, although, for different purposes, the way of obtaining brain signals could vary. Common forms of brain signals include scalp electroencephalogram (EEG), electrocorticography (ECoG), and Stereo-electroencephalography (sEEG). Among them, sEEG is a minimally invasive surgical procedure used to identify areas of the brain where epileptic seizures originate. During sEEG, doctors place electrodes in targeted brain areas, which are then monitored to precisely locate the source of the seizure. sEEG can find seizure sites deep in the brain that a regular EEG test may not reach.

In recent years, with the rapid development of deep learning technologies, deep neural networks have been extensively used in EEG analysis. However, there is still little work on sEEG. One of the most important reasons is that sEEG data contains strong individual characteristics, which may interfere with the judgment of the model. Furthermore, in the existing studies, the pre-ictal and the inter-ictal periods of epilepsy have not been completely unified. Although a trained neurologist can recognize seizure-specific signals 30-60 minutes before the seizure, the size of the time window depends on the sensitivity of the algorithm and signal significance. Finally, compared to EEG databases with hundreds of patients, sEEG data is scarce. As far as model training is concerned, it is more challenging to train a deep learning model on small data while maintaining its generalizability.

Leveraging recent advances in brain signal analysis, we propose a deep learning algorithm called Pre-ictal Signal Classification (PiSC) that can distinguish seizures from non-seizure using sEEG signals a certain time before seizure onset (see Figure 1(b)). The goal is to identify sEEG patterns closely related to pre-ictal signals. Knowing the seizure patterns in sEEG will help doctors improve the location of epileptic areas in patients and understand the underlying mechanism of seizure initiation and spread. As shown in Fig 2, PiSC has two phases: a deep learning model to classify the pre-ictal signals and a pattern recognition procedure to identify and categorize critical sEEG patterns related to seizure onset.
Figure 1: sEEG data acquisition and segmentation. (a) an example of the raw sEEG data where the x-axis is time, the y-axis is channel name, and the dotted line indicates seizure onset, and (b) sEEG data segmentation where data for both pre-ictal signals (red) and no-seizure (blue) are separated into 2-second segments. All the consecutive 2-second segments in a 95-second sEEG sliding window will be used for voting.

In summary, our main contributions are described below:

- We propose PiSC, a deep learning framework that integrates data harmonization and meta-learning. While the former effectively mitigates patient-to-patient variances, the latter can fine-tune a trained epileptic pre-ictal signal classification model using a few cases from a new patient. The design improves the model training stability and model generalizability.

- A unique preprocessing procedure is developed to convert raw sEEG signals to data blocks ready to apply deep learning and traditional machine learning models for seizure pre-ictal signal classification. PiSC can automatically identify pre-ictal brain signal patterns in the raw sEEG data that could be critical for the development of seizure prediction or seizure detection tools.

- Experimental results show that PiSC has increased the accuracy and F1 on seizure classification by at least 10% compared with baselines.

- Two types of novel sEEG waveforms that correlate well with seizure development have been identified.

2 Related work

sEEG directly captures electrical signals on the brain through electrodes implanted in the deep part of brain tissue. Compared with scalp EEG, sEEG can provide richer information and has a higher signal-to-noise ratio. The procedure usually involves implanting multiple electrodes into the patient’s brain, and there are usually 8-16 contacts along the electrode axis, with a center-to-center distance of 3.5mm.

To automatically characterize seizure patterns from brain signals, brain signal processing tools have been developed. However, most of these works are focused on scalp EEG data, which cannot be directly adapted to analyzing sEEG data. This is mainly because of the technical differences on data acquisition. EEG channel positions are common for almost all patients. Whereas the implantation of sEEG electrodes is based on the anato-electro-clinical analysis and the potential epileptic area of each patient. Needless to say, sEEG has a higher sampling rate than EEG.

Currently, only a few studies have studied seizure patterns based on sEEG data. Among them, EDFbrowser, MNE, and Brainstorm are multi-platform universal browsing applications with rich and intuitive graphical interfaces and convenient toolkits for the analysis of time series sEEG or EEG data. These platforms support neurophysiological data exploration, visualization, and analysis. Sharma et al. is an sEEG data analysis model that predicts seizure timing and identifies epileptic areas. Zhang et al. proposed a model that uses the power spectrum of to classify the sEEG. To our knowledge, the recently developed deep learning models have not been adapted to advance sEEG data characterization.
Finally, we build a set of fixed-length sEEG segments $X$ where $L$ are channels sorted according to the order in brain, $C$ channel in $C$ white matter cortex, which are two major brain functional areas. Mathematically, let $X_{win}(c_i, r)$ be a window function to convert a long sEEG signal into multiple fixed-size data blocks with natural orders on both rows and columns, facilitating the application of deep learning models on sEEG data.

Next, we sort all the sEEG channels in the gray (or white) matter by constructing a minimal spanning tree $T^g$ (or $T^w$) where each node is a channel and the channel-channel distance is measured using physical coordinates in the Talairach coordinate space. By traversing through $T^g$ (or $T^w$) with the depth-first search, we sort all the channels in $T^g$ (or $T^w$), saved in channel list $L^g$ (or $L^w$) so that roughly speaking, channels that are close to each other in the Talairach coordinate space are also close to each other in $L^g$ (or $L^w$). The output is sEEG signal matrix $Z$, where rows are channels sorted according to the order in $L^g$ and $L^w$, and columns are time points.

Finally, we build a set of fixed-length sEEG segments $X$:

$$X = win(fl t(sam pl(Z, r), f_{low}, f_{high}), \omega)$$

where $sam pl(.)$ is a resampling function with sampling rate $r$; $fl t(.)$ is a band passing function where $f_{low}$ and $f_{high}$ are low and high frequency thresholds; $win(.)$ is a window function to convert a long sEEG signal into multiple

### 3 Method

To classify epileptic pre-ictal signals and to identify seizure patterns, PiSC has two phases: to classify pre-ictal events, and to identify and categorize critical patterns in epileptic pre-ictal signals. The model architecture is shown in Fig. 2.

#### sEEG Data Preprocessing

A data preprocessing procedure is developed to rearrange the raw sEEG data based on the functional area of the brain and the channel location in the Talairach coordinate space, such that long and continuous raw sEEG signals can be transferred into multiple fixed-size data blocks with natural orders on both rows and columns, facilitating the application of deep learning models on sEEG data.

First, we separate all the sEEG channels (see example in Fig. 1(a)) based on whether they are in the gray matter or in white matter cortex, which are two major brain functional areas. Mathematically, let $C^g$ be a set of $n$ channels located in the gray matter cortex of the brain, $C^g = \{c_1^g, c_2^g, c_3^g \ldots c_n^g\}$, where $c_i^g$ represents the physical coordinates of the $i^{th}$ channel in $C^g (i = 1\ldots n)$. Similarly, let $C^w$ represents the set of $m$ channels located in the white matter cortex of the brain, $C^w = \{c_1^w, c_2^w, c_3^w \ldots c_m^w\}$, where $c_j^w$ represents the physical coordinates of the $j^{th}$ element in $C^w (j = 1\ldots m)$.

Next, we sort all the sEEG channels in the gray (or white) matter by constructing a minimal spanning tree $T^g$ (or $T^w$) where each node is a channel and the channel-channel distance is measured using physical coordinates in the Talairach coordinate space. By traversing through $T^g$ (or $T^w$) with the depth-first search, we sort all the channels in $T^g$ (or $T^w$), saved in channel list $L^g$ (or $L^w$) so that roughly speaking, channels that are close to each other in the Talairach coordinate space are also close to each other in $L^g$ (or $L^w$). The output is sEEG signal matrix $Z$, where rows are channels sorted according to the order in $L^g$ and $L^w$, and columns are time points.

Finally, we build a set of fixed-length sEEG segments $X$:

$$X = win(fl t(sam pl(Z, r), f_{low}, f_{high}), \omega)$$
PiSC Phase 1. Pre-ictal Signal Classification

PiSC Phase 1 consists of two data harmonization models and a classification model. While the former are encoder-decoder designed to mitigate patient-to-patient variances in the training data, the latter is a CNN enhanced with few-shot learning to improve the learning effectiveness on new patients using only a few samples. The model architecture is shown in Fig. 2(a).

Using a dedicated encoder-decoder structure for the positive training data (i.e. pre-ictal) and the other for the negative training data (i.e. no-seizure), we expect to preserve critical features that describe the differences between positive and negative while minimizing patient-to-patient variances. Let sEEG segment \( x_i \) \((x_i \in X)\) be the input and \( z \) be the hidden representation with parameter \( \theta \), the encoder can be denoted as \( q_\theta(z|x) \). Using the hidden representation \( z \) as the input, the decoder \( p_\phi(\tilde{x}|z) \) reconstructs the probability distribution of sEEG segments, where \( \phi \) is the parameter of the decoder. The models are trained to minimize the loss \( L_{ed} \):

\[
L_{ed} = \frac{1}{N} \sum_{i=1}^{N} L_i(\theta, \phi)
\]  

(2)

where \( N \) is the total number of sEEG segments and

\[
L_i(\theta, \phi) = -E_{z \sim q_\theta(z|x_i)} [\log p_\phi(\tilde{x}_i|z)] + KL(q_\theta(z|x_i) \parallel p(z))
\]  

(3)

where the first part is the reconstruction loss, and the second part is a regularizer. While the patient-to-patient variances in training can be reduced using two encoder-decoders, the testing data need to feed directly to the classifier. To maintain the same data dimension for training and testing, we follow the same strategy in Rusu et al. 21 that the decoder output \( \tilde{x} \), instead of the hidden representation \( z \), is used as the encoder-decoder output. Fig. 4(a,b) shows an example of the sEEG segment \( x \) and its corresponding decoder output \( \tilde{x} \).

The second component of PiSC is meta-learning. To train a classifier (e.g. CNN) using limited training data and then adapting it for new patients, we define a two-way \( K \)-shot problem with the episodic formulation in MAML. 19. Specifically, PiSC is trained iteratively with all the tasks \( T_{mtn} \), where \( T_{mtn} \) in \( T_{mtn} \) represents a task instance that includes \( K \) positive and \( K \) negative cases drawn randomly from the training data (see Algorithm 1). In the model testing stage, we randomly split every new patient’s sEEG signals into small support set \( S \) and a large query set \( Q \).
Testing task instance $T^m_{i\text{ttn}}$ consists of $K$ positive and $K$ negative cases in $S$ and $2K$ testing cases in $Q$. The trained PiSC is then fine-tuned with all the tasks $T^m_{i\text{ttn}}$ (see Algorithm 2).

The loss function of PiSC is defined as:

$$L_{\text{total}} = \lambda_\beta (L^p_{\text{ed}} + L^n_{\text{ed}}) + \lambda_\alpha L_T$$

(4)

where $L^p_{\text{ed}}$ is the loss of the negative encoder-decoder trained with no-seizure (negative) data; $L^n_{\text{ed}}$ is the loss of the positive encoder-decoder trained by pre-ictal (positive) data; $\lambda_\alpha$ and $\lambda_\beta$ are hyperparameters; and $L_T$ is the cross entropy loss of PiSC defined as:

$$L_T = -\frac{1}{N}\sum_{i}^{N} [y_i \ln(F(\tilde{x}_i)) + (1 - y_i) \ln(1 - F(\tilde{x}_i))]$$

(5)

where $\tilde{x}$ represents the input of CNN; $y$ is the label of $\tilde{x}$; and $F(\tilde{x})$ returns the predictive value of $\tilde{x}$ using PiSC.

Finally, majority voting is used to obtain the result of every sEEG sliding window. An sEEG sliding window consists of many non-overlap fixed-size consecutive sEEG segments. For every sEEG segment, its label can be predicted using PiSC. For all the segments in the same sliding window, we compare the number of positives and negatives. If more than a certain percentage of the segments are positive, the whole sliding window is labeled as pre-ictal.

**PiSC Phase 2. sEEG Pattern Identification**

To identify critical seizure pre-ictal patterns in the raw sEEG data, we develop a three-step procedure shown in Fig. 2(b). In the first step, for every positive sEEG segment that is correctly classified, we generate a localization map and identify hot spots using the Gradient-weighted Class Activate Mapping (Grad-CAM) algorithm22. In Grad-CAM, the gradients flow into the final convolutional layer to produce a coarse localization map highlighting important regions in the input data (see Fig. 4(c)). In the localization map, each hot spot indicates the channels and time points critical for pre-ictal signal classification. In the second step, we map each hot spot in a localization map to the raw sEEG data using both the temporal range and the channel information, resulting in raw sEEG fragments critical for pre-ictal signal classification. Fig. 4(d) shows an example of localized raw sEEG signals. Finally, we align all the hot spots using dynamic time warping (DTW) and separate them into multiple clusters using hierarchical clustering. The optimal number of clusters can be determined using Davies-Bouldin Index (DBI)12. The representative sEEG segment of each cluster can be identified using the scoring function in Eq. 6:

$$\text{Cluster Score}(x_i) = 1 - \text{ReLU}(DTW(x_i, DBA(X)))$$

(6)

where $X$ is a set of the sEEG segments in a cluster, $x_i$ represents the $i^{th}$ segment in $X$, $DTW(\cdot)$ aligns and compares any two waveforms using dynamic programming23, $DBA(\cdot)$ identifies the gravity center of all the sEEG segments in $X^{24}$, and $ReLU(\cdot)$ is the linear activation function25. Segment with the highest score is selected as the cluster center.

### 4 Experimental Results

**Data and Model Implementation**

sEEG data were collected from 42 epileptic patients in the Huashan Hospital affiliated to Fudan University, Shanghai, China. The data include 20.4 hours of no-seizure signals and 5.8 hours of pre-ictal signals. Among all the patients,

Figure 4: sEEG segment and its localization map. (a) sEEG segment $x$. (b) encoder-decoder output $\hat{x}$. (c) localization map where hot spots (red) indicate the channels and time points critical for seizure onset classification. All were visualized with Python matplotlib with the default color scheme. (d) raw sEEG signal in the hot spot indicated channel.

six nocturnal epileptic patients contributed 85% of pre-ictal data and 100% no-seizure data (see patient information in Table 1), while the other epileptic patients contributed 15% pre-ictal data. The no-seizure signals were collected when patients were sleeping or resting and did not experience any seizure. The pre-ictal signals were collected at most one hour before seizure onset. The data within 30 seconds before seizure onset were discarded (see Fig 1(b)).

PiSC was built on Pytorch and deployed on a server with Intel i7 CPU and Nvidia GeForce RTX 1080 GPU. It took an average of 1.5 hours to complete the model training. The code and manual of PiSC are available at https://github.com/jinchen74/SEEG_LSTM.
Figure 5: Trend of accuracy of pre-ictal signal classification. sEEG data were aligned to the last time point. The 0 at the x-axis was 30 seconds before seizure onset. It shows that on long sEEG data (P1 and P4) PiSC’s performance was above 90% at one hour before seizure onset, and then dropped sharply to about 70% at 10 minutes before seizure onset, indicating that there may be a turning point before seizure onset where the sEEG patterns may change. The results on short sEEG data (P5 and P6) show the performance of PiSC is high and relatively stable, indicating that the local abnormal discharge patterns, once captured by the model, can be used to infer seizure onset precisely.

Figure 6: sEEG segment clustering. The raw sEEG segments critical for the classification of pre-ictal signals were separated into five clusters. The visualization of the cluster centers reveals that there were two types of brain discharge patterns i.e., spikes in cluster 1 and 3 and high frequency oscillations in cluster 0, 2, and 4.

In data preprocessing, the length of sEEG segments was two seconds, and the length of sEEG sliding windows for voting was 95 seconds. sEEG re-sampling rate was 100 Hz, and band passing thresholds were 0 Hz and 30 Hz respectively. The outputs were 130-by-200 data blocks. In PiSC phase 1, the hyperparameters were $\lambda_\alpha = 0.8$, $\lambda_\beta = 0.2$, $\alpha = 0.001$, $\beta = 0.01$, and $\gamma = 0.001$. To avoid model overfitting, a simple CNN was selected as the classifier. The CNN includes four convolutional layers, four max-pooling layers, four ReLu regularization functions, and a dropout (0.5) layer. In PiSC phase 2, the optimal number of clusters identified using DBI$^{12}$ is five. A representative sEEG segment closest to each cluster center was used for further analysis.

Pre-ictal Signal Classification Results

In practice, a trained model shall be applied to new patients for seizure onset classification. To evaluate the performance of PiSC on new patients, we used the leave-one-out approach. Precisely, all six nocturnal epileptic patients but one were used for training, and the last nocturnal epileptic patient and all the non-nocturnal epileptic patients were used for model testing. In testing, the ratio of positive to negative samples is 1. We fed every 95-second sEEG sliding window of the testing patient, which included multiple short and consecutive sEEG segments, to a trained PiSC. By aggregating PiSC’s outcomes for all the short segments using voting, we predicted the label for that sliding window and compared it with the ground truth. After assessing all the sEEG sliding windows, we computed precision, recall,
the model performance decreased sharply from above i.e. 30 seconds before seizure onset. For P1 (red) and P4 (green), whose sEEG data duration was about one hour, testing data collected before or after the changing point. Here, all the sEEG data were aligned to the last time point, mechanisms that trigger epileptic seizures. As shown in Fig. 5, the performance of PiSC varied dramatically on the average, PiSC increased by 10% on accuracy, indicating that in the PiSC architecture, the data harmonization model precisely identified pre-ictal patterns and classified pre-ictal signals precisely one hour before seizure onset. On short sEEG data respectively. It shows that although there is no standard definition of the duration of pre-ictal period, PiSC precisely identified pre-ictal patterns and classified pre-ictal signals precisely one hour before seizure onset. On average, PiSC increased by 10% on accuracy, indicating that in the PiSC architecture, the data harmonization model (Fig 2(a) left) mitigated patient-wise differences, meta-learning (Fig 2(a) right) fine-tuned the trained PiSC for new patients, and voting on a long sliding window improved model performance. In addition, we found that channel shorting plays an important role on signal convolution. Without channel sorting, the accuracy of the PiSC w/o MAML model dropped to 45% on P1, which is 10% lower than the same data with channels sorted. The results also show that there could be a changing point around 10 minutes before seizure onset. It may be associated with the underlying mechanisms that trigger epileptic seizures. As shown in Fig. 5, the performance of PiSC varied dramatically on the testing data collected before or after the changing point. Here, all the sEEG data were aligned to the last time point, i.e. 30 seconds before seizure onset. For P1 (red) and P4 (green), whose sEEG data duration was about one hour, the model performance decreased sharply from above 85% to about 70% at roughly 10 minutes before seizure onset, suggesting that the sEEG patterns before and after the changing point were distinctively different from each other. For P5 (purple) and P6 (brown) with short sEEG duration (~15 minutes), the performance of PiSC was high and relatively stable, showing that the local abnormal discharge patterns, once captured by the model, might be used to infer seizure precisely.

**Pre-ictal Pattern Identification in Raw sEEG**

In PiSC phase 2, we separated all the positive sEEG segments correctly classified by PiSC into five clusters. The representative segments of each cluster are shown in Fig. 6. Two neurosurgeons specialized in epilepsy independently examined 50 sEEG segments mostly close to the cluster centers (see the pair-wise similarity in Fig. 7(a)). It was found that there were two types of sEEG waveforms in the data. The first type, as shown in clusters 1 and 3, is a type of interictal epileptiform discharges that usually indicates a potential area with seizure activity nearby. The second type was thought to be high-frequency oscillations (HFOs), a potential electrophysiological biomarker to improve focal epileptic brain mapping, as shown in clusters 0, 2, and 4. Surgical removal of regions that generate HFOs is more likely to be seizure-free. These nocturnal seizure patterns in raw sEEG may reveal regions with a high probability

**Figure 7: Distribution of pre-ictal signal clusters in relatively long (~1 hour) and short (~10 minutes) sEEG data.** (a) Heatmap shows the pre-ictal signal sEEG segment clustering result. (b) Cluster 3 was abundant when the patient was away from seizure and then it decreased gradually when seizure was approaching. On the contrary, the proportion of cluster 4 increased with time. (c) Cluster 4 quickly accumulated when seizure is about to occur. The 0 at the x-axis is 30 seconds before seizure onset.

accuracy, F1, and ROC AUC. We repeated the process until all the patients were used as testing. We compared PiSC with four existing few-shot learning algorithms, i.e. Matching Network (using advances in attention and memory to achieve rapid learning), Prototypical Network (learning a metric space to compute distances between prototype representations of each class), Relation Network (adopting few-shot learning for image classification and object detection), and MAML (model-agnostic meta-learning) given that a very small amount of training data were provided due to the nature of sEEG. Refer to the original papers for their detailed network architectures.

Table 2 and 3 summarize the performance of PiSC, two ablation models, and four compared models on long and short sEEG data respectively. It shows that although there is no standard definition of the duration of pre-ictal period, PiSC precisely identified pre-ictal patterns and classified pre-ictal signals precisely one hour before seizure onset. On average, PiSC increased by 10% on accuracy, indicating that in the PiSC architecture, the data harmonization model (Fig 2(a) left) mitigated patient-wise differences, meta-learning (Fig 2(a) right) fine-tuned the trained PiSC for new patients, and voting on a long sliding window improved model performance. In addition, we found that channel shorting plays an important role on signal convolution. Without channel sorting, the accuracy of the PiSC w/o MAML model dropped to 45% on P1, which is 10% lower than the same data with channels sorted. The results also show that there could be a changing point around 10 minutes before seizure onset. It may be associated with the underlying mechanisms that trigger epileptic seizures. As shown in Fig. 5, the performance of PiSC varied dramatically on the testing data collected before or after the changing point. Here, all the sEEG data were aligned to the last time point, i.e. 30 seconds before seizure onset. For P1 (red) and P4 (green), whose sEEG data duration was about one hour, the model performance decreased sharply from above 85% to about 70% at roughly 10 minutes before seizure onset, suggesting that the sEEG patterns before and after the changing point were distinctively different from each other. For P5 (purple) and P6 (brown) with short sEEG duration (~15 minutes), the performance of PiSC was high and relatively stable, showing that the local abnormal discharge patterns, once captured by the model, might be used to infer seizure precisely.

**Pre-ictal Pattern Identification in Raw sEEG**

In PiSC phase 2, we separated all the positive sEEG segments correctly classified by PiSC into five clusters. The representative segments of each cluster are shown in Fig. 6. Two neurosurgeons specialized in epilepsy independently examined 50 sEEG segments mostly close to the cluster centers (see the pair-wise similarity in Fig. 7(a)). It was found that there were two types of sEEG waveforms in the data. The first type, as shown in clusters 1 and 3, is a type of interictal epileptiform discharges that usually indicates a potential area with seizure activity nearby. The second type was thought to be high-frequency oscillations (HFOs), a potential electrophysiological biomarker to improve focal epileptic brain mapping, as shown in clusters 0, 2, and 4. Surgical removal of regions that generate HFOs is more likely to be seizure-free. These nocturnal seizure patterns in raw sEEG may reveal regions with a high probability
of seizure generation and could be further applied in a clinical setting.

Further analysis reveals that one of the spikes and one of the HFOs were strongly correlated with seizure development. Fig. 7 shows the temporal distribution of the five pre-ictal sEEG segment clusters in the short and long sEEG data. In Fig. 7b, cluster 3 (yellow), a spike pattern, was abundant when the patient was about 1 hour to 40 minutes before seizure onset and then it gradually decreased when the seizure onset was approaching. On the contrary, the proportion of cluster 4 (blue), an HFO pattern, increased with time. Both patterns correlated well with the trend of PiSC accuracy shown in Fig. 5. Moreover, when a seizure was going to occur (within 10 minutes, see Fig. 7c), the proportion of cluster 4 increased quickly. The results suggest that cluster 3 could be special spikes indicating the patient is a few hours away from seizure and cluster 4 HFO might be a local abnormal discharge pattern that quickly accumulated only when seizure is about to occur. These computer identified new brain wave patterns may be critical for the development of seizure prediction or seizure detection tools.

5 Conclusion

Epilepsy is a kind of neurological disorder characterized by recurrent epileptic seizures. Studies have attempted to recognize brain signal patterns related to seizure using brain signal data. However, reliably prediction or early detection of seizure onset remains a challenging problem. Leveraging high-quality sEEG data and recent advances in deep learning, we develop a novel deep learning algorithm called PiSC. In PiSC, we convert raw sEEG signals to data blocks ready for seizure onset classification, develop a novel deep learning architecture to classify the event of seizure using sEEG data, and identify critical seizure patterns in the raw sEEG data. The architecture of PiSC consists of two data harmonization models to learn the patient-to-patient variances in training and a meta-learning framework to enhance the effectiveness of model fine-tuning. The experimental results show that PiSC is significantly better than the existing models, and the sEEG waveforms identified by PiSC may potentially advance our understanding of the underlying mechanisms of the occurrence of a wide range of epileptic seizures and for guiding anti-epileptic therapy.

PiSC could be further improved in the following aspects. First, the temporal relationships among sEEG segments (critical for seizure classification) have not been considered. We will model segments with varying lengths and model their temporal relationships in the next version of PiSC. Second, sEEG segment embedding may unnecessarily increase the model complexity. We wonder if the data embedding problem can be addressed using a simpler approach. Also, PiSC could be further evaluated by comparing it with the existing EGG-based pre-ictal classification models.

For that, we will extend PiSC to fit EEG or ECoG data and further test the model using public seizure prediction data, including the Freiburg seizure prediction EEG database and the Kaggle seizure prediction database.

Abstract

Social and behavioral determinants of health (SBDoH) have important roles in shaping people’s health. In clinical research studies, especially comparative effectiveness studies, failure to adjust for SBDoH factors will potentially cause confounding issues and misclassification errors in either statistical analyses and machine learning-based models. However, there are limited studies to examine SBDoH factors in clinical outcomes due to the lack of structured SBDoH information in current electronic health record (EHR) systems, while much of the SBDoH information is documented in clinical narratives. Natural language processing (NLP) is thus the key technology to extract such information from unstructured clinical text. However, there is not a mature clinical NLP system focusing on SBDoH. In this study, we examined two state-of-the-art transformer-based NLP models, including BERT and RoBERTa, to extract SBDoH concepts from clinical narratives, applied the best performing model to extract SBDoH concepts on a lung cancer screening patient cohort, and examined the difference of SBDoH information between NLP extracted results and structured EHRs (SBDoH information captured in standard vocabularies such as the International Classification of Diseases codes). The experimental results show that the BERT-based NLP model achieved the best strict/lenient F1-score of 0.8791 and 0.8999, respectively. The comparison between NLP extracted SBDoH information and structured EHRs in the lung cancer patient cohort of 864 patients with 161,933 various types of clinical notes showed that much more detailed information about smoking, education, and employment were only captured in clinical narratives and that it is necessary to use both clinical narratives and structured EHRs to construct a more complete picture of patients’ SBDoH factors.

Introduction

People’s health outcomes are associated with complex, multi-level factors including clinical, biological, social, and health behaviors. To measure health outcomes, transdisciplinary approaches that can leverage a wide range of potential factors are needed. Major initiatives such as the Patient-Centered Outcomes Research Institute (PCORI)-funded PCORnet1 and the Observational Health Data Sciences and Informatics (OHDSI) have been established to promote research using electronic health records (EHRs) for health outcomes research. Clinical factors (e.g., diagnoses, medications) captured in EHRs have been widely used in various clinical studies. Due to lack of resources, patient’s biological, social and health behaviors are under-studied in health outcomes-related studies, which may cause potentially confounding issues (in statistical analyses) or misclassification errors (in machine-learning based classifiers). The Electronic Medical Records and Genomics (eMERGE) network and the NIH All of Us Research program have been established to develop resources of genetic data linked with EHRs. On the other side, through well-established conceptual frameworks such as the social-ecological model4 and the NIMHD Minority Health and Health Disparities Research Framework5, patient’s social determinants of health (SDoH; e.g., education, employment, income disparities) and their health behaviors (or behavioral determinants of health – BDoH; e.g., smoking, alcohol use) are increasingly recognized as important factors influencing health outcomes.6 There is an increasing interest to examine social and behavioral determinants of health (SBDoH) in shaping people’s health.

SBDoH are important risk factors affecting people’s health and healthcare outcomes. The most consistent predictors for the likelihood of death in any given year is level of education7 and poverty, estimated to account for 6% of US mortality8. In cancer, the second leading cause of death in US, up to 75% of cancers occurrences are associated with SBDoH factors9. Studies have reported that many SBDoH contribute to individual cancer risk, influence the likelihood
of survival, and affect cancer early prevention and health equity. A recent study reported that SDoH factors such as poverty, lack of education, neighborhood disadvantage, and social isolation play important roles in breast cancer stage and survival. Many SDoH factors are also associated with the screening of cervical cancer, breast cancer, and lung cancer. Reports from US institutes (e.g., Institute of Medicine, HealthyPeople 2020, and Health and Human Services) and international organizations (e.g., World Health Organization) reflect the increasing consensus of acknowledging SBDHo as significant contributory factors. The World Health Organization (WHO) defined structured codes to capture some of the SBDHo in EHRs. One potential source of SBDHo in the EHRs is in the International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM) Z codes (Z55–Z65).

In February 2018, ICD-10-CM Official Guidelines for Coding and Reporting approved that all clinicians, not just the physicians, involved in the care of a patient can document SBDHo using these Z codes. In our previous study, we have examined the use of ICD10 Z codes in the OneFlorida Clinical Research Consortium and reported a low rate of utilization for these Z codes (270.61 per 100,000 at the encounter level and 2.03% at the patient level). In order to advance cancer control and prevention, a transdisciplinary approach that integrates biological, clinical, social, and behavioral factors is needed. Nonetheless, SBDHo factors are scarcely and inconsistently documented in structured EHRs despite EHR systems provided opportunities for them to be manually entered as discrete data, but are often available in clinical text. Natural language processing (NLP) systems that systematically extract SBDHo factors from unstructured clinical text are needed to better assess cancer outcomes.

NLP is the key technology to unlock this critical information embedded in clinical narratives to support various downstream clinical studies that depend on structured data. NLP has received great attention in recent years. Various clinical NLP systems, such as MedLEE (Medical Language Extraction and Encoding System), MetaMap, KnowledgeMap, and cTAKES (Clinical Text Analysis and Knowledge Extraction System), have been developed to extract medical concepts from clinical narratives. To ensure the accuracy of information extraction, researchers have invested great effort into the development of clinical NLP methods. Clinical NLP systems approach the extraction of medical concepts from clinical narratives as a Named-Entity Recognition (NER) task. NER first identifies the boundaries (start position and end position in text) of medical concepts and then determines their semantic categories (e.g., diseases, medications). NLP methods based on statistical machine learning (ML) models have been increasingly applied and demonstrated good performance. Recently, NLP methods based on deep learning (DL) models have demonstrated superior performance than traditional ML models. However, most of the NLP systems focused on clinical factors (medical concepts directly generated by clinical practice, e.g., diseases and medications); NLP methods to extract SBDHo factors have been under-studied.

There are limited studies exploring NLP methods to extract SBDHo from clinical narratives. Feller et al. developed machine-learning classifiers to determine whether 11 categories of SBDHo are presented in clinical documents. Steer et al. also compared 5 machine-learning classifiers in classifying whether or not 5 categories of SBDHo presented in clinical text. Recently, Lybarger et al. developed an SBDHo corpus that consisted of 4,480 social history sections and applied deep learning-based NLP methods to extract 12 categories of SBDHo. To the best of our knowledge, no study has been reported investigating the difference between SBDHo extracted from clinical narratives and those captured in structured EHRs. This study aims to explore a state-of-the-art NLP model, clinical transformers, to extract SBDHo from clinical narratives. Using cancer as a study case, we (1) systematically examined two state-of-the-art transformer-based NLP models in extraction SBDHo from clinical narratives, (2) applied a transformer-based NLP model to extract SBDHo concepts for a lung cancer screening patient cohort, and (3) examined the difference between SBDHo extracted by NLP and those captured in structured EHRs. This is one of the earliest studies to apply transformer models to extract SBDHo and examine the difference between clinical narratives and structured EHRs.

Methods

Dataset

This study used EHR data from the University of Florida (UF) Health Integrated Data Repository (IDR) from 1999 to 2020, including both structured data and clinical narratives. Supported by the UF Clinical and Translational Institute (CTSI) and the UF Health, the UF Health IDR is a clinical data warehouse (CDW) that aggregates data from the university’s various clinical and administrative information systems, including the Epic (Epic Systems Corporation) electronic medical record (EMR) system. This study was approved by the UF Institutional Review Board (IRB201902362).

Study design
**Identify cancer patient cohorts**: Using UF IDR, we identified a general cancer (GC) cohort and a lung cancer screening (LCS) cohort. The GC cohort consists of 20,000 cancer patients sampled using a stratified random sampling (by cancer types), which has a total number of 1.5 million clinical notes. The LCS cohort was identified using the following rule-based phenotyping method:

1. The age at the first low-dose computed tomography (LDCT) date is between 50 and 80;
2. Most recent smoking status is Never smoker, but there’s evidence on patient ever smoked within the timeframe OR Most recent smoking status is Current smoker OR most recent smoking status is Former smoker, and at least one most recent quit year in structured data or note <= 15 years OR most recent smoking status is Former smoker but has Current smoker record in structured data within the timeframe; and

The LCS cohort consists of a total of 864 lung cancer patients with a total number of 161,933 various types of clinical notes. There are no patients existed in both cohorts.

**Training and test datasets**: We used the GC cohort to train various NLP methods, optimize model parameters. To develop a training corpus for SBDoH, we developed a filtering pipeline using note types (identified by domain experts) and a total number of 30 keywords to identify clinical notes potentially with rich content of SBDoH concepts. Using the filtering pipeline, we identified a total of 225,441 notes potentially with rich SBDoH concepts from the GC cohort, where 500 notes were randomly sampled for annotation. Two annotators manually identified all SBDoH concepts according to predefined guidelines. After annotation, we divided the 500 notes into a training set of 400 notes – used to develop various NLP models, and a test set of 100 notes – used to evaluate the performance of NLP models and select the best model. We trained various transformer-based NLP models using the training set and evaluated the performance using the test set (in terms of F1-score). Then, we identified the best NLP method according to the performance on test set and applied this model to extract SBDoH concepts from all clinical notes of the LCS cohort. To compare the NLP extracted SBDoH with those captured in structured EHRs, we developed a normalization pipeline to align the NLP results into predefined categories from the structured EHRs. Figure 1 shows an overview of the study design.

**Figure 1.** An overview of study design.

**NLP methods**

We explored two state-of-the-art transformer-based NLP methods, including (BERT)\(^7\) and (RoBERTa)\(^8\), and compared them with a widely used deep learning model based on Long short-term memory (LSTM)\(^9\). Previously, we have developed clinical transformer package\(^10\) based on the transformer architectures implemented in the HuggingFace\(^11\) in PyTorch\(^12\). We used the BERT model and RoBERTa model implemented in our clinical transformer package to develop transformer-based NLP solutions for SBDoH as they achieved the top 2 best performances in our previous study\(^13\). For BERT, we used the ‘base’ setting in this study. Following our previous studies\(^14,15,16\) on clinical transformers, we also examined pre-trained transformers from general English corpus (denoted as ‘_general’, e.g., ‘BERT_general’) and clinical transformers pre-trained using clinical notes from the Medical Information Mart for Intensive Care III (MIMIC-III) database\(^17\) (denoted as ‘_mimic’, e.g., ‘BERT_mimic’). We adopted the default parameters optimized in our clinical transformer package\(^18\).

**SBDoH from structured EHRs**
We collected 5 categories of structured SBDoH from the structured tables in the UF IDR database. At UF health IDR database, gender and ethnicity were captured as patient-level information, whereas the smoking status was captured for each encounter (one patient may have multiple smoking status from different encounters). For education and employment, there is no information captured in structured tables.

**NLP results alignment**

Our NLP system identified SBDoH concepts at the document-level, which is different from the structured SBDoH information that was captured at patient-level or encounter-level. In order to compare NLP results with structured EHRs, we developed a rule-based pipeline to align the document-level NLP results to structured EHRs. More specifically, we adopted a majority voting strategy to aggregate multiple mentions of gender and ethnicity from clinical notes into patient-level categories - the most frequent category will be used. Smoking status is a factor that may change over time, therefore, we compared smoking status at a “per patient / per year” setting. Under the “per patient / per year” setting, a patient is supposed to have a smoking status datapoint for each year in the EHR database – e.g., a patient with 5-year history is supposed to have 5 smoking datapoints, one for each year. We aggregated smoking information from both the structured EHRs (encounter-level) and NLP (document-level) into the “per patient/per year” setting for comparison. Similarly, the majority voting strategy was used. According to the structured smoking categories defined in structured EHRs, there are 7 different smoking categories. To align the NLP extracted smoking information to the 7 structured categories, we first generated a list of unique smoking status captured by NLP and then manually reviewed them (a total of 429) to map them into one of the 7 structured categories. As employment status and education were not captured in structured EHR, we were not able to compare.

**Evaluation**

We used both strict (i.e., the beginning and end boundaries of a concept have to be exactly the same with gold-standard annotation) and lenient precision, recall, and F1-score to evaluate our NLP systems. Precision is defined as (the number of SBDoH concepts correctly identified by the NLP system) / (total number of concepts identified by NLP); recall is defined as (the number of SBDoH concepts correctly identified by the NLP system) / (total number of concepts annotated by experts); F1-score is defined as “(2*precision*recall)/(precision+recall)”. To compare NLP results with structured data, we report the number of patients with structured SBDoH vs the number of patients with NLP extracted SBDoH; the number of patients who only have structured information vs the number of patients who only have NLP extracted information.

**Results**

Two annotators annotated 1,876 SBDoH concepts from 500 clinical notes. The inter-annotator agreement measured by token level kappa score with 40 overlapped clinical notes was 0.97, indicating the two annotators have a good agreement in the annotation. Table 1 shows the distribution of SBDoH concepts in the training and test set.

Table 2 compares two transformer-based NLP methods with a widely used deep learning model – LSTM-CRFs in extracting SBDoH concepts from clinical narratives. Both two transformer-based NLP methods outperformed LSTM-CRFs. Among the two transformer-based NLP methods, the BERT_general model achieved the best strict/lenient F1-score of 0.8791 and 0.8999 on the test set, respectively. Table 3 shows the detailed performance for each of the 5 SBDoH categories for the best NLP model. We applied the best NLP model, BERT_general, to extract SBDoH concepts from all clinical notes of the LCS patient cohort and compared them with structured EHRs. Table 4 shows the comparison results between NLP and structured EHRs. For the 864 patients in LCS cohort, the structured EHRs covered 99.65% patients for gender and ethnicity. However, the structured EHRs only covered 56.55% of smoking datapoints vs 71.57% from NLP. There is no information captured in structured EHRs for education and employment. Information about education and employment was documented in the narrative clinical text (39.35% for education and 47.22% for employment).

When compared using from Table 4 that much of the detailed smoking datapoints were still documented in clinical text than structured EHRs with programs and lung cancer screening program compliance. The increase was likely of patients with smoking information in structured EHRs. From Figure 2 we can see that smoking information is consistently documented in clinical text, whereas, the proportion of patients with smoking information in one year (defined as “[number of patients with smoking information in one year] / [total number of patients in that year]”) and plotted the curve from 2009 to 2020 in Figure 2 (structured smoking information showed up in the LCS cohort starting from 2009; the EHR data for 2020 is not complete as we queried data in mid 2020). From Figure 2 we can see that smoking information is consistently documented in clinical text, whereas, the proportion of patients with smoking information in structured EHRs was low in the beginning but increased a lot over time. This increase was likely a result of institutional requirements for tobacco use documentation as part of quality assurance programs and lung cancer screening program compliance. Note that Figure 2 only shows the proportion of patients with smoking information or not, it can’t be used to assess how complete it is in structured EHRs. In fact, we can see from Table 4 that much of the detailed smoking datapoints were still documented in clinical text than structured EHRs when compared using the “per patient / per year” setting.

| #patients only have structured concepts | 2(0.23%) | 150(17.36%) | 308(3.84%) | 0 | 0 |

*For smoking, the numbers and proportions were calculated using datapoints – the 864 patients are supposed to have 104,201 datapoints using “per patient / per year” setting. The proportions for other SBDoH concepts were calculated according to a total number of 864 patients in LCS cohort.

**Discussion and conclusion**

SBDoH are important factors associated with cancer risk, prevention, screening, and survival. This study applied state-of-the-art transformer-based NLP methods to extract SBDoH concepts from clinical narratives and took lung cancer as a study case to compare the difference between clinical narratives and structured EHRs. Our experimental results show that two transformer-based NLP methods, BERT and RoBERTa, outperformed a widely used deep learning model – LSTM-CRFs – in extracting SBDoH from clinical narratives. Among the 4 transformer models, the BERT_general model pretrained using general English corpora achieved the best strict/lentent F1-score of 0.8791 and 0.8999, respectively, indicating the efficiency of transformer-based NLP methods. The BERT_general model pretrained using general English corpora outperformed another BERT_mimic model pretrained using MIMIC III clinical text, which is consistent with our previous study of using transformer models for de-identification of clinical notes.46 Similar to the protected health information in the de-identification task, the SBDoH concepts are closer to the general English language than the medical language. Therefore, the transformer models pretrained with a large volume of general English text are better in recognizing those SBDoH concepts closer to general English.

We examined 5 categories of SBDoH concepts in a lung cancer patient cohort. The best NLP model, BERT_general, was used to extract SBDoH concepts from all clinical notes of the LCS patient cohort. The comparison between NLP extracted results and structured EHRs shows that the structured EHRs have good coverage (>99% patients) for gender and ethnicity; but for smoking, education, and employment, much detailed information was documented in clinical narratives. For smoking, 71.57% of datapoints were documented in clinical notes, whereas, only 56.44% were captured in structured EHRs. Between the smoking datapoints extracted by NLP and structured EHRs, there are only 37.62% consistent with each other; there are 18.92% of smoking datapoints only from NLP, indicating the necessity of using both NLP and structured EHRs for cancer-related studies. For education and employment, currently there was no information captured in structured EHRs; but we can get 39.35% education information and 47.22% employment information from clinical notes using NLP. Smoking, education, and employment are important factors associated with many cancers. NLP systems could fill the gap of using these SBDoH factors in clinical studies. Smoking is an important BDoH factor for lung cancer. To better understand how smoking was documented in clinical narratives and structured EHRs over time, we calculated the normalized proportion of patients with smoking information for each year (defined as “[number of patients with smoking information in one year] / [total number of patients in that year]”) and plotted the curve from 2009 to 2020 in Figure 2 (structured smoking information showed up in the LCS cohort starting from 2009; the EHR data for 2020 is not complete as we queried data in mid 2020). From Figure 2 we can see that smoking information is consistently documented in clinical text, whereas, the proportion of patients with smoking information in structured EHRs was low in the beginning but increased a lot over time. This increase was likely a result of institutional requirements for tobacco use documentation as part of quality assurance programs and lung cancer screening program compliance. Note that Figure 2 only shows the proportion of patients with smoking information or not, it can’t be used to assess how complete it is in structured EHRs. In fact, we can see from Table 4 that much of the detailed smoking datapoints were still documented in clinical text than structured EHRs when compared using the “per patient / per year” setting.
Figure 2. A comparison of patients’ smoking status between clinic narratives and structured EHRs.

NLP is the key technology to extract SBDoH concepts from clinical narratives. Yet, most of the NLP studies focused on clinical factors such as diseases, medications; the application of NLP to extract SBDoH concepts is under-studied. Clinical NLP systems that can accurately identify SBDoH concepts are needed to fill the gap of using these factors in various health outcomes studies. The ultimate goal of this project is to develop a clinical NLP package that can accurately identify a wide range of SBDoH concepts from clinical narratives and populate them into structured EHR databases such as the NLP tables defined in the OHDSI common data model (CDM) and PCORnet CDM.

Limitations and future plans

This study has limitations. As a preliminary study, we limited SBDoH concepts to 5 categories including gender, ethnicity, smoking, education, and employment. Future studies need to examine more SBDoH categories associated with health outcomes. We took lung cancer as a study case to examine how current NLP models could identify SBDoH concepts and how complete they were captured in NLP vs structured EHRs. The documentation of SBDoH concepts might be different in other disease domains. During the time of this study analysis, the institutional policy changed to require more discrete data collection related to smoking use, which can impact the results. We expect more studies to examine the use of SBDoH in various diseases. Also, this study examined clinical notes from a single site, future work should examine the proposed transformer-based NLP system at cross-institute settings.

Abstract

Acute kidney injury (AKI) is potentially catastrophic and commonly seen among inpatients. In the United States, the quality of administrative coding data for capturing AKI accurately is questionable and needs to be updated. This retrospective study validated the quality of administrative coding for hospital-acquired AKI and explored the opportunities to improve the phenotyping performance by utilizing additional data sources from the electronic health record (EHR). A total of 34570 patients were included, and overall prevalence of AKI based on the KDIGO reference standard was 10.13%. We obtained significantly different quality measures (sensitivity:0.486, specificity:0.947, PPV:0.509, NPV:0.942 in the full cohort) of administrative coding from the previously reported ones in the U.S. Additional use of clinical notes by incorporating automatic NLP data extraction has been found to increase the AUC in phenotyping AKI, and AKI was better recognized in patients with heart failure, indicating disparities in the coding and management of AKI.

Introduction

Acute kidney injury (AKI) is a potentially catastrophic complication characterized by rapid loss of kidney function1. The prevalence of hospital-acquired AKI (HA-AKI) is high, affecting 21.6% of hospitalized adults and 33.7% of hospitalized children worldwide2. In the United States, although the incidence rates are lower, age-standardized rate of HA-AKI has increased by more than 139% over the past decade, accounting for 4.4% Medicare fee-for-service beneficiaries in 20183.

Given the incremental public health burden, AKI has received increasing attention in recent years. Healthcare data, including administrative data and clinical data, contains a wealth of information and can afford investigators the opportunity to study AKI on a large scale4. However, investigators need to be aware of the quality and limitations of these datasets 5,6. On one hand, although claims data has long been used by researchers and policy makers, the coding system was designed for administrative purposes and may not reflect the actual status of a patient7. Recent validation studies have been performed in some western countries and suggested that AKI diagnostic codes had very low sensitivity (< 40%) but relatively high specificity (> 90%)8. On the other hand, as the electronic health record (EHR) is emerging as a rich source of information for secondary use, it still requires substantial efforts to convert EHR data into a research database. To counter the challenges, a variety of EHR data components (i.e. clinical notes, lab values, medications) have been used for disease phenotyping, and many previous works and applications have shown promising results9. More specifically regarding the diagnosis of AKI, Grams et al and Ko et al examined the performance of manual chart review in phenotyping AKI. However, their results were not consistent, and their methods were human labor intensive and could be only conducted in small sample size10,11. Although there have been numerous efforts in studying automatic methods in extracting information associated with target diseases from unstructured EHR data, little been applied in the area of AKI.

Despite a large body of research in this field, there are significant gaps in the literature regarding validation of the current healthcare system in capturing HA-AKI. To the best of our knowledge, most validation studies in the U.S. were conducted in early 2000s but almost none have been reported since the publication of KDIGO diagnostic criteria, which is the first international clinical practice guideline on AKI12. Such quality measures (e.g. sensitivity, specificity) are underreported and needs to be updated. Meanwhile, little is known about the disparities in the coding performance across different spectrum of patients, or if leveraging EHR documentation and clinical data may help improve our ability to phenotype HA-AKI. In the study presented here, we utilized both claims and clinical data and evaluated the phenotyping performance of using one or more combinations of four major data components across pre-defined subgroups. We hypothesized that the additional information from EHR would be significant in improving the performance of AKI recognition, and quality performance of administrative coding in capturing AKI would be differed by subgroups.
Methods

Study setting and dataset

A retrospective study was conducted using data from the University of Minnesota Clinical and Translational Institute (CTSI). We extracted data from CTSI clinical data repository, which contains EHR data of > 2 million patients seen at 8 hospitals and more than 40 clinics in Fairview Health Services in Minnesota, USA beginning in 2005. This data repository incorporates administrative and clinical data and is divided into multiple categories regarding demographics, diagnoses, procedures, lab tests, vitals, medications and more. All structured data were de-identified and other free-text data such as clinical notes that could not be de-identified were stored in Academic Health Center Information Exchange (AHC-IE) servers and only accessible by AHC devices, to protect patient confidentiality. The study was approved by the University of Minnesota Institutional Review Board. The overall study design is shown in Figure 1.

Figure 1. Flowchart for validating AKI incidence in administrative and clinical datasets

Criteria for AKI

In this study, Kidney Disease: Improving Global Outcomes (KDIGO) staging system was used as the reference standard to identify AKI cases. According to the KDIGO guidelines, AKI is defined by changes in either serum creatinine (SCr) or urine output (UO) and staged in severity, as described in Table 1. Considering the availability of biomarkers in our database and limitations of the UO criterion, only the SCr diagnostic criterion was used in this study.

Table 1. KDIGO definition of AKI

<td>&lt;0.3 ml/kg/hour for ≥24 hours &lt;br&gt;or anuria for ≥12 hours</td>
</tr>
</tbody>
</table>

Baseline SCr is a key measure in the SCr criterion, and SCr levels measured between 365- and 7-day prior admission are usually considered as baseline. However, baseline SCr is frequently missing in EHR. Although
there are imputation methods such as back-calculations using MDRD, Cockcroft-Gault equations and etc., most of them are creatinine-based and are only useful when renal function is stable and may not be generalizable14. To avoid biased estimation and inaccurate diagnosis, actual SCr levels measured before admission were required. There is no conclusion regarding the best way to estimate baseline SCr when multiple values are available. We adopted the most exclusive rule in this study: using multiple baselines (median and the most recent value) and comparing them with subsequent SCr values simultaneously, if one reached the SCr threshold according to the KDIGO definition, AKI would be considered as present.

Study cohort
We extracted EHR data, containing both administrative and clinical data, of all adult hospitalized patients (age 18-100) admitted for any reasons between 2008 and 2019. Patients with the following characteristics were included in the study cohort: (1) first-time admission only; (2) having pre-admission SCr available; (3) having admission SCr value available, defined as the first SCr level measured within 36hr after admission; (4) having at least one additional SCr measured during inpatient stay, defined as any subsequent SCr measures to the admission SCr; (5) no AKI on admission; and (6) no prior AKI, no history of dialysis or renal transplant therapy (RRT). A look-back period of 1 year from the date of hospital admission was used to determine baseline renal function and comorbidities. We defined four subgroups of interest based on their comorbid conditions of diabetes, hypertension, heart failure and chronic kidney disease that were presented before the discharge time of each hospitalization. ICD 9 and 10 diagnostic codes were used to identify subgroups (Supplementary Appendix Table S3).

Decision rules for AKI
Decision rules for phenotyping HA-AKI were derived using one or more combinations of the following EHR components (codes listed in Supplementary Appendix A): (1) Laboratory SCr, by applying KDIGO diagnostic criteria and was considered as the reference standard; (2) ICD diagnostic codes, including ICD 9 and 10 codes for AKI; (3) AKI-related procedures, including CPT and ICD9/10 procedure codes for dialysis and RRT as group A (usually be considered as severe forms of AKI), as well as procedure codes or lab orders for renal ultrasound and hydration management as group B; and (4) Mentions of AKI in clinical notes, by using an natural language processing (NLP) enabled search engine called NLP-PIER. Due to the interchangeable use of medical terminology and potentially hierarchical relationships between terms (e.g., acute kidney injury is equivalent to acute kidney disease; hemodialysis is one type of dialysis), we used AKI-related medical terms in various expressions as key words and concept unique identifiers (CUI) for semantic search. NLP-PIER also allows fuzzy match on keywords, by enabling related misspellings (through frequency, spellgen score and edit distance) and semantically related terms (through frequency, cosine similarity) that are word vector-based15. These terms were then manually selected based on domain knowledge. Simple negations were excluded using regular expressions on CUI medical terms. Related administrative codes and CUI terms are listed in Supplementary Appendix Table S1-2.

Statistical analysis
We calculated the cohort and subgroup-specific sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and receiver operating characteristic area under curve (ROC AUC) of each decision rule as compared to changes in SCr using the KDIGO diagnostic criteria as the reference standard. P-values were calculated based on AUC scores between different decision rules within and across subgroups. All analysis were conducted using the R software (R Foundation for Statistical Computing, Vienna, Austria).

Results
Study population and characteristics
We identified a total of 34570 patients and unique hospitalization between 2008 and 2019 that met the inclusion criteria. Patient selection diagram is shown in Figure 1. The missing rate of baseline SCr was 64%, higher than the previously reported rate of 25–50%10. The numbers of patients without AKI on admission using either median or the most recent value of pre-admission SCr value were similar. Baseline characteristics of patients are outlined in Table 2. The overall prevalence of HA-AKI (based on KDIGO) in the full cohort was 10.13%. 73.78% of the cohort were in young adulthood (18-35 years), and these patients had a higher prevalence rate of HA-AKI (11.11%) than other age groups. Hypertension was the most common comorbid condition in our cohort, and the incidence rates of HA-AKI were particularly high (~22%) in patients with heart failure and chronic kidney disease (CKD) as compared with other subgroups.
Figure 2. Patients selection flow. EHRs of all adult inpatients were extracted during 2008-2019. 42,612 patients met the SCr inclusion criteria, and the size of final cohort was 34,570.

Table 2. Baseline characteristics of patients. No HA-AKI: patients did not develop HA-AKI during hospitalization. HA-AKI: patients developed HA-AKI during hospitalization.

### Diagnostic performance by decision rules and subgroups

The decision rules used for performance measure are listed in Table 3. Since our study interest was in identifying additional EHR components for quality improvement in phenotyping while maintaining the use of administrative coding, the traditional combination of billing codes for AKI, dialysis and RRT were included in all decision rules. In general, low sensitivity and PPV (~ 0.441) but high specificity and NPV were observed across all decision rules I-IV. No single decision rule consistently received the best scores in sensitivity, specificity, PPV and NPV. The most comprehensive decision rule IV offered the best sensitivity in cohort average (0.525) but its PPV was the lowest. Similarly, the CKD group using decision rule IV had the best sensitivity across all groups but with the lowest specificity and NPV. Trade-offs between sensitivity vs. specificity and PPV vs. NPV were also observed when validating decision rule I: while the highest specificity and PPV were found in groups using the traditional methods, the corresponding sensitivity and NPV scores were among the lowest ones. ROC AUC scores were calculated and pairwise compared with the traditional rule (decision rule I) within the group and the scores of the same decision rule in other groups. The average AUC score in the full cohort was 0.715. Within the full cohort, the addition of clinical notes (decision rule III) had increased the AUC by 0.002 with p-value = 0.05 and was considered to be marginal. Meanwhile, the addition of procedure codes for ultrasound and hydration management decreased the AUC score by 0.03 (p-value = 0.03). No statistically significant changes were observed between different decision rules within each subgroup.

AUC of all decision rules were significantly high in patients with heart failure, with the highest AUC scores (0.738–0.743) and small p-values (0.004–0.028) as compared with other groups. Although the AUC values were also high in diabetic patients (average 0.727), they were not found statistically different from others. Patients with heart failure had the largest AUC. Similar distribution was found when using other decision rules.

hypoalbuminemia (<4 g/dL) in off-threshold levels of biomarkers protected during cardiac surgery was measurable. Cardiovascular events coding or management guidelines were identified that we knew little was known about these codes even decreased the performance with ~12% increase in false positive, suggesting that specifically designed for this project, performs the best when it was trained and built for a specific task.

An explanation for observed phenomena might influence disease phenotyping has been demonstrated and validated by human chart review in many historical EHR research. This may be caused by different sizes of false positive (FP) and false negatives (FN) when using different cohorts. The FPs and FNs were well balanced in our sample, but data to examine these factors and differences in Grams et al were not available.

Besides the comparison with the literature, we also evaluated the additional use of non-traditional EHR components to improve our ability to HA-AKI phenotyping and potentially bring new knowledge about the disease. We observed that the combination of clinical notes and billing codes for AKI, dialysis and RRT improved the ROC AUC score in capturing AKI, and it achieved the best AUC across all subgroups. However, the p-value was close to the cut-off significance level (α=0.05) and may not hold as a strong evidence. Given that the importance of clinical notes in disease phenotyping has been demonstrated and validated by human chart review in many historical EHR research, an explanation for observed phenomena could be that our methods in automatic extracting AKI-related terms was imperfect, which has been a long-standing problem in the secondary use of EHR. An NLP pipeline usually performs the best when it was trained and built for a specific task. Since the NLP tool used in our study was not specifically designed for this project, the semantic search might not be perfect in capturing AKI, which could also explain the relatively low number of AKI cases defined by clinical notes. In addition to EHR notes, we also measured the performance of adding potentially AKI-related procedures (e.g., renal ultrasound and hydration management) but did not find these codes to be helpful in quality improvement. In some groups, the addition of these codes even decreased the performance with ~12% increase in false positive, suggesting that these procedures were not specific indicators of AKI and tend to overestimate the incidence of AKI.

Little was known about the disparities in the coding performance across different spectrum of patients. In this study, we identified that HA-AKI patients with heart failure were better recognized by all decision rules than other groups. The significantly high AUC score in patients with heart failure may be due to a higher degree of adherence to AKI coding or management guidelines in cardiac department. The reported prevalence of cardiac surgery-associated AKI is particularly high (up to 30%) with substantial increase in morbidity and mortality, so that the development of AKI is likely to be closely monitored by cardiologists. Although there is no uniform guideline in managing cardiovascular events-related AKI, there have been extensive research in renal protective strategies that are measurable. For instance, the European Society of Intensive Care Medicine published recommendations to kidney protection during cardiac surgery from aspects of preoperative, intraoperative and postoperative. Details in specific threshold levels of biomarkers, procedures and more measures (e.g., using exogenous albumin to correct hypoalbuminemia (<4 g/dL) in off-pump CABG surgery) were described in each aspect, and such strategies can

**Discussion**

This study measured the quality performance of multiple decision rules using different EHR components in the task of phenotyping HA-AKI. As stated earlier, AKI is a common complication among hospitalized patients, and we found the prevalence of HA-AKI was 9.35% defined by common billing codes, near 8 times of the national reported one (1.17%) in 2018, but less than half of the rate (24.5%) from a meta-analysis in 2014. The difference may be due to the use of different data sources (Fairview EHR vs. The National Inpatient Sample (limited to billing codes) vs. systematic review) and different patient selection criteria. We also found that the incidence rates of HA-AKI were particularly high among patients with heart failure and CKD as expected. To the best of our knowledge, Grabs et al was the most recent validation work done in the U.S, and their sensitivity of billing code-defined AKI was 17.2%, which was substantially lower than our results (sensitivity: 48.6% - 66.1%). However, as Grabs et al observed, the sensitivity of billing codes was significantly higher in more recent time period. Since our study enrollment window was almost 11 years after Grabs et al, the changes in administrative coding and clinical practice over time might influence the performance of billing codes. Also, our PPV values were much lower than Grabs et al. This may be caused by different sizes of false positive (FP) and false negatives (FN) when using different cohorts. The FPs and FNs were well balanced in our sample, but data to examine these factors and differences in Grabs et al were not available.

Besides the comparison with the literature, we also evaluated the additional use of non-traditional EHR components to improve our ability to HA-AKI phenotyping and potentially bring new knowledge about the disease. We observed that the combination of clinical notes and billing codes for AKI, dialysis and RRT improved the ROC AUC score in capturing AKI, and it achieved the best AUC across all subgroups. However, the p-value was close to the cut-off significance level (α=0.05) and may not hold as a strong evidence. Given that the importance of clinical notes in disease phenotyping has been demonstrated and validated by human chart review in many historical EHR research, an explanation for observed phenomena could be that our methods in automatic extracting AKI-related terms was imperfect, which has been a long-standing problem in the secondary use of EHR. An NLP pipeline usually performs the best when it was trained and built for a specific task. Since the NLP tool used in our study was not specifically designed for this project, the semantic search might not be perfect in capturing AKI, which could also explain the relatively low number of AKI cases defined by clinical notes. In addition to EHR notes, we also measured the performance of adding potentially AKI-related procedures (e.g., renal ultrasound and hydration management) but did not find these codes to be helpful in quality improvement. In some groups, the addition of these codes even decreased the performance with ~12% increase in false positive, suggesting that these procedures were not specific indicators of AKI and tend to overestimate the incidence of AKI.

Little was known about the disparities in the coding performance across different spectrum of patients. In this study, we identified that HA-AKI patients with heart failure were better recognized by all decision rules than other groups. The significantly high AUC score in patients with heart failure may be due to a higher degree of adherence to AKI coding or management guidelines in cardiac department. The reported prevalence of cardiac surgery-associated AKI is particularly high (up to 30%) with substantial increase in morbidity and mortality, so that the development of AKI is likely to be closely monitored by cardiologists. Although there is no uniform guideline in managing cardiovascular events-related AKI, there have been extensive research in renal protective strategies that are measurable. For instance, the European Society of Intensive Care Medicine published recommendations to kidney protection during cardiac surgery from aspects of preoperative, intraoperative and postoperative. Details in specific threshold levels of biomarkers, procedures and more measures (e.g., using exogenous albumin to correct hypoalbuminemia (<4 g/dL) in off-pump CABG surgery) were described in each aspect, and such strategies can

serve as strong references to follow in clinical practices\textsuperscript{20}. However, the complex mechanisms of other chronic conditions such as diabetes and hypertension may pose greater challenges in exploring a reliable and scalable way to manage AKI\textsuperscript{21}. For example, though there have been some guidelines published regarding the diabetes management in CKD patients (e.g., KDIGO 2020 Clinical Practice Guideline), few has been done in AKI\textsuperscript{22}. As mentioned earlier, a large portion (41.22\%) of HA-AKI patients in our study also had CKD, but the coding performance in CKD group did not show statistical differences from the diabetes or hypertension group, which was unexpected. CKD and AKI are known as highly inter-correlated diseases, so that CKD patients were supposed to be followed closely for changes in renal function and with better detection of AKI\textsuperscript{23,24}. This unexpected phenomenon may be caused by the limitations in the current criteria for nephrology referral. Oliva-Damaso et al questioned the weight of ‘age factor’ in the current nephrology referral criteria and found that younger CKD patients were less likely to be referred even their renal functions were poorer than the elderly\textsuperscript{25}. Since 73.78\% of HA-AKI patients in this study were in young adulthood, it is likely that some CKD patients did not received necessary nephrology consultation and had AKI under-recognized.

This study has several limitations. First of all, KDIGO diagnostic criteria is a silver standard and is imperfect\textsuperscript{13}. At present, glomerular filtration rate (GFR) is considered as the gold-standard diagnostic criteria for AKI, but GFR is almost never directly measured in the clinical setting. Instead, clinicians rely upon surrogate markers as markers of kidney dysfunction\textsuperscript{26}. Although KDIGO is widely adopted, using SCr as a biomarker of AKI has a number of drawbacks: (a) SCr level may be affected by factors other than renal function; (b) SCr measures the level of renal damage rather than renal function, and it may tend to underestimate AKI during early stages\textsuperscript{12,16}. However, we do believe that the advantages of using KDIGO outweigh the disadvantages. Second, patients without baseline SCr were excluded in this study, which consisted 63.69\% of the total number of inpatients in our study enrollment window. The exclusion on this population may introduce selection bias in study design. Third, subgroups were defined by billing codes and might not be accurate. It was a dilemma that although our study was focused on the capture of AKI, the attempt to explore the disparities by subgroups would inevitably introduce nested problems regarding the capture of conditions of interest (diabetes, hypertension, heart failure and CKD). Depending on the study questions, such inaccuracy may or may not be an issue, but it is important to acknowledge the level of possible errors/inaccuracy before drawing conclusions. This limitation also illustrated the importance of this work to facilitate other AKI research that will utilize admirative database and EHR components. Although the quality of billing codes capturing the subgroups in this database was unknown, our findings could still provide insights to identify certain groups of patients that need better or optimal management in AKI. Meanwhile, a 1-year lookback period for comorbidities might not be long enough, as relatively healthy patients might not have annual checkups and would not have related diagnostic codes recorded in their EHRs during that period. Fourth, our study cohort just represents the population enrolled in the Fairview Health Services system in Minnesota and almost 90\% of the cohort were White, and the majority of our study cohort were young adults, so that the results may not be generalizable. Last but not least, this study only utilized three EHR components (SCr lab value, billing code and clinical notes), but there may exist other EHR data elements that can leverage valuable information to AKI phenotyping.

In summary, we examined the performance of various EHR components in phenotyping AKI in this study. Our results not only updated our knowledge of the the quality of administrative coding for HA-AKI that is important to know for each end user, but also found that leveraging EHR documentation may help improve our ability to phenotyping HA-AKI. To the extent of our knowledge, our study was the first validation work of AKI that adopted automated data extraction from clinical notes. The results indicated clinical notes as a potential data source to improve the current administrative coding system, reduce incorrect coding and billing, and promote better communications between patients, insurers and providers. The improved performance also suggested the feasibility of this method in phenotyping AKI, which can facilitate researchers to study AKI with better quality and less additional cost as compared with human chart review. What’s more, the additional contents (i.e., results and findings from pathology report) and EHR elements (not limited to notes) could be used to discover a more comprehensive risk panel of AKI. Such risk panels may or may not serve as diagnostic evidence but can help discover additional measures to refine the current KDIGO criteria. Differences found across subgroups may be due to varying degrees of adherence to AKI coding or management guidelines. The results in discovering disparities by subgroups may help researchers to identify a specific population and build evidence-based predictive model that are optimized for that population, to ultimately improve patients’ health outcomes. Our results should be interpreted while taking into account the limitations inherent to our study design. In future studies, the diagnostic criteria for AKI needs to be further clarified and refined by using more unbiased imputation method when baseline is missing. Meanwhile, NLP
pipelines need to be optimized for AKI phenotyping. In addition to clinical notes, a panel of reliable indicators of AKI could also be used for better recognition of AKI.

**Conclusion**

Using common definitions of AKI and additional EHR data elements, we obtained significantly different quality measures from the previously reported ones in the U.S. This study highlighted the major limitations of administrative coding in capturing HA-AKI, as well as the opportunities for data quality improvement by potentially leveraging EHR data sources for end users, and ultimately predicting high risk of AKI to intervene earlier and decrease patient morbidity.

Abstract

Epilepsy is a common serious neurological disorder that affects more than 65 million persons worldwide and it is characterized by repeated seizures that lead to higher mortality and disabilities with corresponding negative impact on the quality of life of patients. Network science methods that represent brain regions as nodes and the interactions between brain regions as edges have been extensively used in characterizing network changes in neurological disorders. However, the limited ability of graph network models to represent high dimensional brain interactions are being increasingly realized in the computational neuroscience community. In particular, recent advances in algebraic topology research have led to the development of a large number of applications in brain network studies using topological structures. In this paper, we build on a fundamental construct of cliques, which are all-to-all connected nodes with a k-clique in a graph \( G(V, E) \), where \( V \) is set of nodes and \( E \) is set of edges, consisting of \( k \)-nodes to characterize the brain network dynamics in epilepsy patients using topological structures. Cliques represent brain regions that are coupled for similar functions or engage in information exchange; therefore, cliques are suitable structures to characterize the dynamics of brain dynamics in neurological disorders. We propose to detect and use clique structures during well-defined clinical events, such as epileptic seizures, to combine non-linear correlation measures in a matrix with identification of geometric structures underlying brain connectivity networks to identify discriminating features that can be used for clinical decision making in epilepsy neurological disorder.

Introduction

The characteristics of brain network connectivity representing both white matter fiber tracts (brain structural network) and interactions patterns between different brain regions (brain functional network) are being increasingly recognized as important biomarkers in a variety of neurological disorders [1-3]. In particular, network science methods based on graph theory, which represent brain regions as nodes and the connections between the brain regions as edges, have been used in a large number of studies to identify differences between brain networks in healthy subjects and patients with neurological disorders [3-5]. These studies have found that common characteristics of healthy brain networks, such as “small world network” structures, which include several local connections and few long-range connections across brain regions, are disrupted in patients with neurological disorders [3]. For example, network analysis of electroencephalography (EEG) recordings in epilepsy patients during seizures (ictal period) and between seizures (interictal period) have shown changes in brain connectivity using network metrics such as clustering coefficient, which measure local connectivity, and characteristic path length, which measure global connectivity [6].

Epilepsy is one of the most common serious neurological disorder that affects more than 65 million persons worldwide with more than 2.8 million persons diagnosed with epilepsy in the United States alone [7]. The application of network science method to EEG recordings has lead to greater understanding of epilepsy as a network-based neurological disorder and this has led to development of treatment methods that address seizure events as network events [8]. Further, the application of graph model-based network analysis techniques have also provided new data about comorbidities in epilepsy such as cognitive decline [9, 10]. However, the application of graph theory-based network analysis techniques in epilepsy has led to disparate results with some studies reporting an increase in connectivity [11, 12], while other studies have reported decreased connectivity [13, 14]. Although, these differences may be due to the study methodology, study population among other factors; however, there is growing recognition in the neuroinformatics community that graph models have inherent limitations due their binary representations.

Graph models can only represent interactions between two brain regions (binary interactions); therefore, they are severely constrained to represent high dimensional interactions that involve two or more brain regions simultaneously, which occur frequently as highlighted in epileptic seizure involving multiple foci of interactions [15, 16]. Further, graph-based models often use arbitrary threshold values to include or exclude interactions between brain regions as an edge between two nodes [15]. Therefore, recent studies in brain network research have characterized existing graph theory models as being oversimplification of brain interactions dynamics with a resulting lack of accuracy in representing interaction dynamics [16-18].
To address this critical limitation of graph-based models, we describe the development of a new Epilepsy Topology Data Analysis (ETDA) framework based on recent advances in the field of algebraic topology [19] to accurately characterize aberrant brain interactions in epilepsy patients. Figure 1 shows an overview of our approach using EEG data recorded from intracranial depth electrodes implanted in an epilepsy patient (as part of presurgical evaluation process). Using a nonlinear correlation coefficient measure $h^2$ to compute the degree of coupling between signals recorded by electrode contacts from two brain regions, we generate a directed graph network that represents binary relations between brain regions during epileptic seizure [20, 21]. The nonlinear correlation coefficient is based on the estimation of amplitude $y$ of signal $Y$ from the amplitude $x$ of signal $X$, such that the predicted value of $y$ for given value of $x$ is a regression curve [22]. It is important to note that the $h^2$ values are asymmetric, that is, it is possible that $h^2(y|x) \neq h^2(x|y)$, which can be used to infer directionality of the association between signal [22]. Figure 1 shows that a variety of graph motifs that are formed during a phase called ictal 1 in epileptic seizure when the epileptic seizure propagates beyond the initial seizure onset zone to additional brain regions (subsequent spread of epileptic seizure are labeled as ictal 2 phase, ictal 3 phase etc. before termination of seizure). Among the different graph motifs formed during the ictal period, we select cliques consisting of the set of all-to-all connected vertices in the directed graph model to compute the topological structure called a clique complex as shown in Figure 1 with electrode contacts labeled (RF1, RF2, and RF3) as well as (LF2, LF3, and LJ3) forming two cliques.

**Clique Topology of Epileptic Seizure Networks.** A clique motif in a graph network represents brain regions that have high degree of interaction, and they are of particular relevance in studying the onset and propagation of epileptic seizures. Epilepsy is characterized by a hypersynchronous state of the brain that results in formation of a regular network topology in epilepsy patients as compared to healthy subjects [3, 6, 8]. Therefore, clique motifs are representative of brain regions that have a high degree of interactions and are likely to play a key role in epileptic seizure networks. In this paper, we use the concept of simplex from algebraic topology, such that if the nodes of a graph are assumed to be in higher-dimensional space, then a clique of the graph represents a simplex given by the convex hull of the corresponding nodes [19, 23]. A simplex in algebraic topology is a generalization of graph model to incorporate multi-dimensional interactions (polyadic or n-ary relations) and the collection of these simplices form a simplicial complex that is analyzed to track the lifecycle of these topological structures during normal and abnormal brain activity [15, 18, 20].

We propose that these topological structures can successfully model high-dimensional interactions, such as epileptic seizure activities, that involve two or more brain regions simultaneously; therefore, they address the critical limitations of graph theory-based network analysis methods. Further, using well-defined algebraic topology methods such as persistent homology enables us to characterize local and global interactions between brain regions based on the occurrence of topological constructs called cycles and boundaries respectively [16]. The objectives of the ETDA framework are: (1) accurate modeling of high-dimensional interaction between brain regions during seizure activities using the set of clique motifs formed in epileptic seizure network models; (2) identify topological structure that have a long lifetime, which can be used to potentially differentiate brain regions that have high degree of participation in seizure activities over others; and (3) translate the summary statistics derived from ETDA to clinical research and patient care, such as improving the lateralization of the epileptogenic zone in patients refractory to medication during presurgical evaluation [24, 25]. The ETDA framework enables the development of a new approach for characterizing the complex dynamics of brain networks during epileptic seizure.

**Figure 1:** An overview of the Epilepsy Topological Data Analysis (ETDA) using clique complexes.
and also provides novel insights into the brain networks that underpin serious neurological disorders as compared to healthy individuals.

1.1 Background.

Directed network model of epileptic seizures from EEG data. Multiple signal analysis techniques have been developed to compute the coupling between signal data recorded from different brain regions, for example using linear cross-correlation and coherence functions. In particular, a method developed by Pijn et al. based on nonlinear regression coefficient \( h^2 \) has been widely used to effectively characterize the association between two EEG signals during seizure activity [22, 26, 27]. The directionality computed from EEG signal data is an important feature of the \( h^2 \) measure as it enables source localization in the epileptic network [26, 28]. The non-linear measure is maximized by taking into account all possible time lag values \( \tau \) between the two signals in the direction X to Y and using the maximum value of the measure, that is, \( h^2_{XY} = \max_{\tau_{\text{min}}<\tau<\tau_{\text{max}}} h^2_{XY} \). We use the resulting directed graph with nodes representing intracranial electrodes contacts and edges representing correlation (Figure 1) to compute simplicial complexes.

Topology data analysis. A clique in a graph epileptic seizure network graph \( SNG \) consists of a collection of all-to-all connected vertices and the set of all cliques in a graph \( SNG \) is called the clique complex of \( SNG \) and is written \( X(SNG) \) [18]. It is important to note that all subsets of a clique \( \Omega \) are also cliques, therefore \( X(SNG) = \{ \Omega \subset [M] | \Omega \text{ is a clique of } SNG \} \). Therefore, the cliques in \( X(SNG) \) consisting of \( n+1 \) nodes represent \( n \)-dimensional simplices [18]. The homology of the clique complex \( X(SNG) \) computes the relations between cliques in \( SNG \) and the homology counts the cycles in a clique complex. A cycle represents a collection of nodes which interact with one another and is a boundary when all of the nodes in that collection interact with all the other nodes. In this way, the homology of the clique complex represents higher-dimensional structures that are generalization of the number of cliques in a graph. The clique topology of a graph is computed using Betti numbers that track the dimensions of homology groups (we refer to the [23] and [29] for a detailed discussion on computation of Betti numbers). Therefore, the \( n \)-th Betti number of \( X(SNG) \), denoted by \( B_n(X(SNG)) \) is the rank of a \( k \)-vector space \( H_n(X(SNG);k) \) [18].

Summary Statistics of Topological Structures using Betti Numbers. The arrangement of cliques in an order complex of a matrix can be used to detect random or geometric structures. Clique topology studies the interactions (such as overlapping) between the cliques in the entire order complex. The topological structure of cliques in graph is quantified by “filling in” all cliques and counting non-contractible cycles (arrangement of cliques that bind the “holes”). A 1-cycle bounds 2D area, a 2-cycle bound a 3D volume. As the edge density \( p \) is varied, cycles may be created, destroyed, or different cycles might merge together. This information is tracked by computing the set of Betti numbers that count the independent \( n \)-cycles in each graph after all cliques have been filled in for a cycle. The Betti numbers across all graphs in an order complex yields a plot of the Betti curve.

2. Methods

There is an emerging consensus that the common characteristics of healthy brain networks such as a small world network structures are disrupted in neurological disorders; however, it is not clear how these disruptions occur and what is the effect of these disruptions on the core neurocognitive networks, such as the default mode network (DMN), salience network (SN), and central executive network (CEN), which are associated with memory, speech, or consciousness state [30-32]. The ETDA framework is an innovative approach to effectively address the challenges of: (1) Modeling the physiology of interactions in the aberrant brain networks to provide insights into how disruptions occur; and (2) Computing topological structures that are characteristic of clinical events to understand the effect of disruptions on neurocognitive functions. In addition to accurately modeling seizure networks, the clique topology model has applications in a variety of brain connectivity research, including: (1) identification of discriminating components of a seizure network for individual patients across multiple seizures to construct a patient-specific map of seizures; and (2) the metrics derived from the seizure network clique topology will be interpretable by clinicians for use at the point of care. In this section, we describe the approach used to compute the maximal simplices for the clique complexes formed during seizure events, the computation of Betti numbers, and bottleneck distance.

Study Data. We used a unique dataset of high-resolution stereotactic encephalograph (SEEG) recordings from a Level 4 epilepsy center at the University Hospitals Cleveland Medical Center (UH-CMC). The UH-CMC epilepsy center carries out pre-surgical evaluation of patients with drug-resistant epilepsy using multi-modal physiological parameters including EEG, EKG, video, autonomic, evoked potential, O2, CO2 and respiratory rate measurements. The EEG acquisition system is a Nihon Kohden (Japan) system, which is capable of simultaneously recording up to 192 channels of EEG at 1000 samples/second along with video recordings. The intracranial electrodes consist of platinum-iridium contacts with a diameter of 1.1 mm by 2.5 mm and each lead was 31 cm long with 10 - 12 electrodes that were placed every 5 mm, beginning from the tip. In addition to video-EEG recording, 16 analog input signals can be connected to the system. Table 1 gives the details of the five patients used in this study. Although multiple seizures were recorded for each patient, we selected two seizures with highest phase of ictal phases, that is, distinct phases in which seizure propagation was clinical identified to include additional brain regions [20].

2.1 Computation of Clique Complexes from SEEG Data. The fundamental unit of study in algebraic topology is the simplex; multiple simplices are then brought together in a “controlled” way to form a simplicial complex – this “control” is achieved by positioning simplices not arbitrarily, but by gluing them together in such a way that any two simplices are either entirely disjoint or have an intersection that is itself a simplex. These ideas can be developed entirely in the abstract so that they can be adapted to a variety of different constructs (see [23] for full details), but we will focus in this paper on a specific notion of a simplicial complex that is very well suited for graphs, namely the clique complex [15]. As suggested by the name, we define a simplex in the clique complex of a graph to be a network clique, i.e., a complete subgraph, or a subset of the vertices and edges of the graph such that any two vertices in the subset are connected by some edge. More specifically, since simplices are associated with a non-negative integer called its dimension, we define a simplex of dimension n, or an n-simplex, to be a clique on n+1 vertices. Note how this corresponds to the “gluing rule” above: any subgraph of a clique is itself a clique, and therefore the intersection of any two cliques must be empty or a clique, and hence a simplex.
Given a graph, we can identify its simplices inductively, starting with the list of the graph’s 0-simplices (i.e., vertices). From a list of the graph’s n-simplices, we can construct the list of (n+1)-simplices by iterating over the list of n-simplices and the list of vertices and creating a corresponding (n+1)-simplex if a given vertex is connected to each node of a given n-simplex; given the graph as an adjacency matrix, this lookup can be done instantly. This procedure explicitly illustrates how lower-dimensional simplices can be subsumed by higher-dimensional ones, and we would like to focus on the higher-dimensional simplices that demonstrate a greater interconnectivity of nodes. Therefore, at each step of the process above, we will also be discarding those n-simplices that are contained in a formed (n+1)-simplex (these n-simplices are traditionally termed the faces of the (n+1)-simplex). This gives a final list of lists of maximal simplices for the clique complex.

2.2 Computation of Betti Numbers. The homology of a clique complex computes the relations between cliques and the homology counts the cycles in a clique complex. This represents higher-dimensional structures that are generalization of the cliques in a graph. The clique topology of a graph is computed using Betti numbers that track the dimensions of homology groups (we refer to the [23] and [29] for a detailed discussion on computation of Betti numbers). Relative ordering of entries in a correlation matrix, $X_{ij} < X_{kl}$ whenever $Y_{ij} < Y_{kl}$ is called an order complex $\text{ord}(X)$ [18]. Order complex represented as a nested sequence of graphs where each subsequent graph includes additional edges corresponding to the next largest matrix entry $X_{ij}$. Any quantity computed from order complex is invariant under transformation as $\text{ord}(X) = \text{ord}(Y)$. The arrangement of cliques in an order complex of a matrix can be used to detect random or geometric structures. Clique topology is a measure of how cliques fit together and overlap across entire order complex. Topological structure of cliques in graph is quantified by “filling in” all cliques and counting non-contractible cycles (arrangement of cliques that bind the “holes”). A 1-cycle bounds 2-D area, a 2-cycle bound a 3-D volume. As the edge density $p$ increases, new cycles are created, modified, and eventually destroyed, which are tracked by computing set of Betti numbers that count the independent n-cycles in each graph after all cliques have been filled in for a cycle. The Betti numbers across all graphs in an order complex yields a plot of Betti curves. In the Results section, we illustrate the Betti curves computed from the five patients used in this study.

2.3 Persistence Diagram to Characterize Topological Structure Across Seizure Events. The lifetime of a topological structure can be plotted over filtration in horizontal and vertical axes to generate a persistence diagram [33]. A point at $(x,y)$ represents a generator born at an edge density of $x$ and filled in at an edge density of $y$. Since a generator cannot die before it is born, $y$ is always greater than or equal to $x$, so we draw the $y=x$ diagonal line (where $y-x=0$ persistence) and use the distance of a point from the diagonal as a handy heuristic to estimate persistence. If a point is close to or on the diagonal, it did not persist long after first appearing and can almost be treated as noise. If a point is far from the diagonal, the point persisted long after being born (i.e., many edges had to be added before it could be filled in). In the latter case, keep in mind that edges are added in order of weight, so persistence does not say anything about the size of a hole: for example, a small hole such as a square that is only two edges away from forming a clique/pyramid may prove to be "significant" in that there really aren't any weighty edges that could fill it in. In summary, persistence diagrams make important generators stand out from the rest at a glance.

After the generation of the persistence diagrams, we use the bottleneck distance measure, which characterizes the difference between two persistence diagrams. Therefore, bottleneck distance is used to find the best bijective matching between points of two persistence diagrams, that is, the best way to pair points while minimizing distance between them. The bottleneck distance between A and B can be thought of as assuming diagram B is an approximation (or noisy version) of diagram A and measuring the error in the approximation. In our table, there are blanks whenever the current phase has trivial homology (i.e., no points in the persistence diagram). If two diagrams have low bottleneck distance, it means the distribution of their generators/points is very similar. This is extremely useful for testing hypotheses: if we generate a diagram A which is known to uniquely describe a graph with a certain property P and we find that diagram B is at a low bottleneck distance from A, we can say with some confidence that the graph upon which diagram B was generated also has the property P. Likewise, a high bottleneck distance would support the claim that the graph of B does not have property P. This technique can also be used to show that our diagrams do not have the characteristics of diagrams generated from random, unstructured data. We discuss the results of computing the Betti numbers and generation of persistent homology diagrams from seizure events from the epilepsy patients in the following section.

3. Results

The objective of our evaluation approach is to characterize the lifecycle of clique complexes computed from EEG data recorded from the five epilepsy patients across different phases of epileptic seizure. In the first section, we describe the persistence diagrams for the patients and in the second section we discuss the bottleneck distance computed from the persistence diagrams.
3.1 Persistence diagram derived from EEG data in five patients. Due to space constraints, we illustrate the persistence diagrams for two patients corresponding to two seizure events with multiple phases, including seizure onset and ictal phases.

Figure 2: Persistence diagram for patient ID HHUG across multiple seizure phases during two distinct seizure events.
We also illustrate the persistence diagram of the second patient (study ID: DIMX) across different dimensions. It is interesting to note that no topological features were detected in the second seizure event for dimension = 3.

Figure 3. Persistence diagram for patient ID DIMX across multiple seizure phases in two distinct seizure events.
3.2 Bottleneck distance computed over the persistence diagrams in five patients. As we discussed in the Method section, bottleneck distance is used to compute the difference between two persistence diagrams corresponding to distinct seizure phases. In Table 2 we describe the bottleneck distance computed for different seizure stages across different seizures in each of the five patients.

Table 2: Bottleneck distance computed for the five patients across different phases of epileptic seizure.

4. Discussions and Limitations

We have shown that the ETDA framework enables the representation of organized geometric structures, and the topology of cliques that occur during epileptic seizure events, which often occur as abnormal brain activities propagate across different brain regions. The preliminary results demonstrate that the proposed EDTA approach is a promising method to accurately characterize changes brain networks during epileptic seizures.

In this paper, we did not discuss methods to characterize the geometric structures extracted from signal data during clinical events from randomly occurring structures. To address this challenge, we propose to extend previous work by Giusti et al. that discussed the potential use of clique topology to identify a correlation matrix representing functional connectivity metrics that is not random and derived from a geometric matrix (18). Given that a clique topology describes the distribution of order complexes in both random and geometric matrices with the properties of the Betti plots changing with N, we can use the Betti plots to distinguish a random matrix from geometric matrices. We propose to generate random correlation matrices by modifying and shuffling the matrix cell values corresponding to each seizure event in our result with distinct off-diagonal values. Previous studies have reported that the graph in order complexes are nested family of Erdos-Renyi random graph with unimodal Betti curves. The Betti curves of geometric order complexes have distinct characteristics (18). Similarly, we believe that the Betti curves computed from the directed graph models computed from signal data recorded during seizure events will also have distinct properties as compared to random matrices. Using our new persistent homology algorithms for directed graph model, we propose to use the persistence lifetimes to characterize the differences between Betti curves or random and geometric matrices for validating the soundness of the topological structures extracted from the correlation matrices.

5. Conclusions

Neurological disorders affect more than 100 million persons in the nation with significant adverse impact on the affected persons, including disability, morbidity, and economic costs of more than $800 billion per year. Improved understanding of brain connectivity networks that are adversely affected in neurological disorders, such as Epilepsy, Parkinson’s disease, and...
Alzheimer’s disease, can be used to develop more effective therapeutic approaches for patients. However, the interaction dynamics of brain networks in neurological disorders is poorly understood. Although there is increasingly availability of multi-modal data, there are critical limitations of existing graph models used in research studies as graphs are inherently binary representations of complex polyadic or n-ary interactions involving multiple brain regions simultaneously. The goal of this project is to develop new algebraic topology models and algorithms to characterize multi-dimensional interaction structures formed during events related to neurological disorders, such as epileptic seizures with multiple simultaneous foci of interactions. To validate the new algebraic topology structures in neurological disorders, we used high resolution stereotactic electroencephalogram (SEEG) data recorded from a cohort of five patients with refractory epilepsy. In particular, we used clique structured formed during seizure events to compute topological structured and using persistent homology we analyzed the changes in interaction between brain regions during seizure events. Using the metric of bottleneck distance, we compared the differences between persistent diagrams computed for the five patients in this study. The proposed ETDA approach showed promise in analyzing high-dimensional interactions between brain regions during seizure events.

Abstract

Effective communication between pre-hospital and hospital providers is a critical first step towards ensuring efficient patient care. Despite many efforts in improving the communication process, inefficiencies persist. It is critical to understand user needs, work practices, and existing barriers to inform technology design for supporting pre-hospital communication. However, existing research examining the ways in which patient information is collected and shared by pre-hospital providers in the field has been limited. We conducted a series of ethnographic studies with both pre-hospital and hospital care providers to examine 1) the types of information that are commonly collected and shared by the pre-hospital providers in the field; 2) the types of pre-hospital information that are needed by hospital-based teams for ensuring appropriate preparation; and 3) the challenges in the pre-hospital communication process. We conclude by discussing technology opportunities for facilitating real-time information sharing in the field.

Introduction

In high-risk, time-sensitive medical domains, such as emergency care, medical professionals must provide rapid treatment and manage potentially life-threatening illnesses or injuries (e.g., trauma injuries, stroke, medication overdose). Effective and timely information sharing between pre-hospital and hospital providers (also known as pre-hospital communication) is a critical first step for achieving this goal¹. Information collected in the field and en route to the hospital (pre-hospital information) can help the emergency care providers at the receiving hospital anticipate the severity of patient illness or injury, and make appropriate preparations and triage decisions². Despite its critical role, information sharing between the field providers and those at the receiving hospital remains challenging³, ⁴. For example, verbal reports given by pre-hospital providers during patient transport often lack detail⁵, ⁶ or accuracy⁷, ⁸, making it difficult for hospital teams to appropriately prepare. The highly dynamic nature of out-of-hospital encounters is also characterized by frequent interruptions, posing challenges on real-time data collection and leading to delayed and incomplete information dissemination from the field⁹.¹⁰.

Previous research has developed information and communication technologies (ICTs) to support data transfer from the field to receiving hospitals¹¹, ¹². Key examples include mobile electronic documentation systems¹⁰, ¹³ and ambulance-based telemedicine systems¹⁴⁻¹⁹. These systems, however, are rarely used in real-time due to portability and usability issues¹⁵, ¹⁹, ²⁰. Pre-hospital providers have to perform hands-on examinations and treatments on patients while managing information from multiple sources in short time periods. This work practice limits their direct interaction with handheld systems²¹. Prior research has highlighted that the development of ICTs for healthcare professionals should not only focus on technological aspects but also account for user needs and current work practices³, ¹². Although several studies have looked at information handover workflow between pre-hospital and hospital teams in the receiving care centers (e.g., emergency department)³, ⁸, ⁹, ²², limited research exists on the ways in which pre-hospital information is collected and shared in the field.

The long-term goal of our research is to design and develop novel technologies to better support real-time, seamless data sharing between pre-hospital and hospital teams. To achieve this goal, we first need to answer several fundamental research questions (RQs):

RQ1: What types of information are commonly collected and shared by pre-hospital providers in the field?
RQ2: What types of pre-hospital information are needed by hospital teams for ensuring appropriate preparation?
RQ3: What challenges and barriers exist in the pre-hospital communication process?

In this paper, we describe a mixed-methods ethnographic research conducted with both pre-hospital and hospital providers to answer these research questions and inform technological interventions for facilitating the acquisition and dissemination of pre-hospital information in the field.
Background: Pre-Hospital Communication Process

A typical pre-hospital communication process involves multiple geographically distributed and heterogeneous emergency care teams, including Emergency Medical Services (EMS), Emergency Communication and Information Center (ECIC), and Emergency Department (ED) (Figure 1). Depending on the patient needs, other care teams, such as trauma teams, neurology, and cardiology teams may also be activated and involved in the care process. Following an incident, EMS providers (e.g., paramedics and air-ambulance crews) are dispatched to the scene to provide urgent medical care and transport the patient to the nearest or most appropriate care center. EMS teams collect and manage a variety of information about the patient’s status and clinical needs, which inform treatment decisions in the field. Under certain circumstances (e.g., trauma or burn injuries, cardiac arrest, stroke), EMS teams need to notify the receiving hospital about the patient’s status. By protocol, EMS crews should provide a verbal report via radio (also known as pre-arrival notification) to the 9-1-1 communication center, where dispatchers collect the information and relay it to the ECIC teams—the first point of contact at the hospital for crews transporting patients to the hospital. In some cases, EMS providers would choose to contact ECIC or ED directly via phone. Upon receiving the pre-arrival notification, the ECIC staff (e.g., dispatchers or communication specialists) first call the ED charge nurse or physician on call to relay the reported information. If EMS providers request medical advice, ED physicians are added to the EMS-ECIC call to provide guidance and make decisions. If trauma team activation is needed, ECIC staff sends out a brief notification message to trauma team members via pagers. As the trauma team assembles in the resuscitation room, the ED physician relays known information about the patient and works with other trauma team members to prepare for the patient’s arrival. For other critical cases (e.g., stroke or cardiac arrest), care specialists will also be summoned to the ED for consultation, and the receiving teams (e.g., neurology and cardiology teams) will be notified to get ready.

Methods

Data Collection

Data collection occurred in different time periods. Between 2016 and 2017, we conducted semi-structured interviews with three different care teams in an urban pediatric teaching hospital with a Level I trauma center in the east coast region. Participants included six ED physicians, eight ECIC team members, and 16 trauma team members (five emergency medicine physicians, eight senior surgical residents, one surgical fellow, one respiratory therapist, and one nurse practitioner). The interviews focused on their work practices, pre-hospital information needs, and concerns about receiving and using pre-hospital information. The length of interviews varied depending on their availability (ranging from 15 minutes to one hour). This interview study helped us uncover pre-hospital information types that are critical to the work of emergency care professionals at the point of care. We also gained an in-depth understanding of the challenges faced by hospital-based teams in acquiring and using pre-hospital information. These results informed our following studies with EMS teams.

To understand how pre-hospital information is collected and shared by EMS providers, we first reviewed video recordings of 25 simulations performed in an urban fire-based EMS agency in the mountain region. The simulations were conducted for training purposes. Participants in the simulations were paramedics and emergency medical technicians (EMTs) recruited from the EMS agency; all participants were experienced providers and met local and state authority requirements for staffing an Advanced Life Support (ALS) ambulance. Each simulation team consisted of 4–6 members with a designated team leader, carrying out three different scenarios over a period of 6 months in 2019. The scenarios involved a 15-month-old seizure, a 1-month-old with hypoglycemia, and a 4-year-old clonidine ingestion. The simulations were conducted in a mobile simulation laboratory resembling the back of an ambulance,
using high-fidelity patient mannequins. All simulations were captured by three video cameras: 1) the patient’s overhead view, 2) the foot side of the patient, and 3) a zoom-out view of the entire scene.

To augment the findings from video review, we conducted 45-90-minutes long semi-structured interviews with 13 EMS practitioners, 11 of whom are paramedics, and the other two are EMTs. The interviews were conducted via Zoom between 2020 and 2021. The participants were recruited from four hospital-based EMS agencies, which are part of the 9-1-1 system in an urban area in the US Northeast region. Years of experience range from 7 to 30 years, with two participants being EMS directors. The interviews focused on their work experience and backgrounds, job responsibilities, data collection in the field, communication process with physicians, and challenges in sharing data with the receiving hospital.

All interviews were audio-recorded and transcribed for further analysis. The videos were transcribed using excel sheets to provide a linear list of conversations and activities. Both the university and hospital Institutional Review Board (IRB) approved the studies.

Data Analysis

In reviewing the videos, we used an open coding technique to uncover common information types collected in the field and work practices related to data collection and sharing. Two researchers coded the video transcripts. They first reviewed four randomly selected videos to develop a codebook in an iterative manner (e.g., codes and codebook disagreements were discussed through regular meetings). The codebook defines a set of codes related to types of collected and shared information, types of verbal communication (e.g., inquiry, clarification), instances of non-verbal communication (e.g., note taking, gazing, pointing), and artifacts used. The codebook was then used by the researchers to standardize the coding process. The inter-rater reliability between the two researchers was substantial (Cohen’s Kappa coefficient value is 0.7). We also compared the information collected in the field to the information reported to the hospital. Because EMS verbal reports were omitted in 3 simulation sessions, our analysis focused on the remaining 22 simulations. This video review helped answer the first research question (RQ1).

Data from semi-structured interviews were also analyzed using an open coding technique to answer RQ2 and RQ3. The EMS interview analysis focused on the challenges faced by EMS practitioners in communicating patient data to the receiving facility, while the analysis of interviews with hospital teams focused on their needs and concerns in acquiring pre-hospital information from the fields. All the codes generated through the interview analysis were discussed among researchers to determine which codes to keep, merge, or discard. We then used affinity diagrams to generate high-level themes, followed by identifying representative quotes to support the claims.

Results

We report the results in three parts. First, we describe the information types that are collected and shared by EMS providers in the field. Second, we report the needs and challenges of acquiring pre-hospital information by emergency care professionals at the receiving hospital. Finally, we present the challenges and barriers that EMS providers face in communicating patient data to hospital teams.

Types of Information Collected and Shared by EMS providers in the Field

Of 25 simulations, EMS providers verbally reported the information via radio to the receiving hospital in 22 sessions. The analysis of these 22 simulations showed that EMS providers collected and shared about 18 types of information during pre-hospital care. We grouped these 18 information elements into five high-level categories: demographics, mechanism of injury, physical findings, injuries, and treatments (Table 1). Below we discuss each high-level information category in greater detail.

Demographics: Commonly collected demographic information included patient age, gender, name, weight, and medical history. In particular, age and medical history were inquired by EMS providers in all simulations (22/22), while gender and name were asked in 19 and 13 out of 22 sessions respectively. Because the simulations were situated in the context of pediatric emergency care, demographic information was mainly collected through verbal communications with the patient’s parents or guardians. Among these demographic information types, patient age (22/22) was always included in the EMS pre-arrival notification. In contrast, medical history (1/22) and weight (1/8) were rarely shared with the hospital teams.

Mechanism of Injury (MOI): To come up with an appropriate patient management plan, it is critical for EMS providers to know how the patient got injured or what type of incident occurred. EMS providers specifically asked for this information from the patient’s parents or guardians in almost all simulations (20/22): “About 30 minutes ago I heard
him kind of banging around, and then I walked in just a few minutes ago, and then he was just lying there.” Of the 20 simulations where this type of information was collected, EMS crews shared injury mechanism with the receiving hospital in 16 sessions.

Injuries: Because the simulations were medical resuscitation cases, EMS providers only collected injury information in 6 out of 22 sessions. Their focus was primarily on whether the patient presented any signs of trauma (e.g., swelling, bruises, and lacerations). In the simulations, this information was identified either by talking to the patient’s parents or when a certain injury was reported during physical examination. The injury information was reported to the hospital in two cases.

Physical Findings: The information types collected in this category included vital signs (e.g., heart rate, blood pressure, and respiratory rate) (22/22), breathing (21/22), patient neurological status (e.g., alertness, consciousness) (22/22), pulse (8/22), airway status (8/22), symptoms (7/22), and change of status (13/22). Some physical findings were almost always reported in the notification to the hospital, such as vital signs (19/22) and neurological status (16/22). However, other physical findings were rarely shared with the hospital, e.g., such as breathing (11/21), pulse (0/8), airway (0/8), and change of status (2/13).

Treatments: Commonly collected information related to treatments included IV (intravenous) or IO (intraosseous) access and administration (22/22), oxygen (18/22), and treatment outcome (11/22). But only IV/IO administration (20/22) was consistently reported by EMS providers to the hospital.

Our analysis also showed that the collected information was only reported briefly or partially in many cases (Table 1). For example, vital signs information was only fully reported in 7 sessions, but partially reported in 12 sessions. In those partial reporting cases, only one or two physiological data points (e.g., blood pressure) were shared with the

Table 1. Types and frequency of pre-hospital information collected and shared by EMS providers in 22 simulations.

hospital while other vital signs were excluded from the verbal report. Another example of partial reporting is related to the mechanism of injury, with many details missing from the pre-arrival notification.

During the interviews, we asked EMS practitioners to explain why the information was only partially shared with the receiving hospital. They stated that the purpose of pre-arrival notifications is to “let the hospital know you are coming, not just give them very comprehensive report” [EMS-P1]. Also, they are concerned that the notification receiver (e.g., dispatcher or ED nurse) could get overwhelmed if they report too much information: “I try to keep it super tight because usually if you give too much information, the person who’s taking the call might not remember all of it. So, we just try to keep it to about 30 to 45 seconds if we can” [EMS-P11].

Similar to previous work\(^1\), we also found that EMS providers already follow a relatively stable structure to construct the pre-arrival notification: “The first thing that I share is usually what I’m rolling in—what the diagnosis is that necessitated us calling ahead of time. And then the patient’s demographics, age, gender, their associated medical history, usually any interventions that I’ve performed, and things that are out of the ordinary. And lastly what the ETA [estimated time of arrival] is to the hospital” [EMS-P12].

**Types of Pre-Hospital Information Needed by the Hospital Teams**

The semi-structured interviews with three different hospital-based teams (ECIC, ED, and trauma teams) helped us identify commonly needed pre-hospital information types by emergency care providers at the point of care (Figure 2). Based on these data, findings from the physical examination were considered the most critical type of pre-hospital information. For example, patient neurological status (e.g., loss of consciousness) and vital signs were viewed as critical by most emergency care professionals because this information helped them anticipate the level of patient acuity. Hospital teams also considered mechanism of injury as an important pre-hospital information type because this information helped them “picture” what happened to the patient: “In addition to vital signs, getting an impression about the patient [is also important]. So, impression could be respiratory distress, or motor vehicle crash. I would like to know what happened first” [ED-P5]. Many care providers also wanted to know what treatments were completed en route, and if any medications were administered. As an ECIC staff explained: “So, like, if they have started a [IV] line, and gave morphine, and if they gave other treatments, I would definitely let ED nurse know, so it does not overlap with ED work. In that way, the ED doctor knows at what time they gave morphine […] If they just gave morphine 5 minutes ago, you don’t want to give it once again” [ECIC-P5].

Information needs, however, could also vary across different professions (Figure 2). For example, ED physicians expressed more interest in knowing details about patient injuries (e.g., the type, severity, and location of the injuries) than other teams. We also observed differences in information needs even among the members of the same team. For

---

\(^1\) Similar to previous work, we also found that EMS providers already follow a relatively stable structure to construct the pre-arrival notification: “The first thing that I share is usually what I’m rolling in—what the diagnosis is that necessitated us calling ahead of time. And then the patient’s demographics, age, gender, their associated medical history, usually any interventions that I’ve performed, and things that are out of the ordinary. And lastly what the ETA [estimated time of arrival] is to the hospital” [EMS-P12].
example, several ED physicians expressed the needs to know injury mechanism, however, it is interesting to see that one ED physician had different opinion on the importance of the mechanican: “Mechanism doesn’t matter. Mechanism increases risk about certain injuries, if you use seat belt, if you get hit by a car, but it is still a matter of what. It just increases your risk, but it doesn’t mean any injury. I’ve seen a kid fell from 70 feet from an apartment building, and he is fine: and I’ve seen kids fell from 10 feet, lay on concrete, then he has major head injury. So, mechanism is useless information but it doesn’t really help you” [ED-P4].

Even though the hospital teams may have different opinions on the importance of different types of pre-hospital information, they all expect a well-structured and clearly articulated EMS report: “I want a short, sweet assessment of three criteria that I need. I need to know is there a physiological change in the patient, is there an obvious fracture, and is there a mechanism. They are pretty objective assessments. […] I don’t need that ‘live in the home,’ all that nuanced information. Give me what I need, and I don’t know if EMS really knows what it is we are looking for. […] As you may see, I am rolling my eyes over and over again, I am like just give me the information” [ED-P3].

Our results also showed several concerns and unmet information needs related to receiving the pre-hospital information from EMS providers. First, four ED physicians and trauma team members indicated the desire to receive more contextual information from the accident scene (e.g., photos and videos) to better anticipate the patient’s needs. They considered visual information such as photographs and videos as a helpful addition to the summary of the patient’s status because they visualized augmented the brief EMS reports. However, this information need is not well supported by current communication mechanisms. Second, not all information types considered necessary were available at all times; even when available, information was not always accurate. Third, the level of detail about certain information needed by the hospital-based teams was not clearly established between pre-hospital and hospital teams, leading to some tensions. EMS teams sometimes did not know how important certain types of information about patients were to the hospital teams. It was therefore challenging for them to prioritize these information items in communicating with hospital teams, causing EMS reports to be either too short or overwhelmingly detailed.

**Challenges Faced by EMS Teams in Sharing Information with the Receiving Hospital**

EMS teams are well aware of the importance of communicating accurate and essential patient information with the receiving hospital: “We are sometimes the only eyes and ears for the physician and the hospital. So, the story that we provide may sometimes be the only story that the clinicians at the hospital have to take care of the patient” [EMS-P4]. However, EMS providers face many challenges in accomplishing this important task, including limitations on collecting and reporting patient data in the field, ineffective communication mechanisms, overloaded EMS systems, and intermediary communication links. Below we describe each challenge in greater detail.

**Limitations on Collecting and Reporting Patient Data in the Field.** It is common that EMS providers cannot always obtain sufficient information in the field due to time pressure or the patient status (e.g., unconscious), limiting their ability to report the needed information to the hospital teams. In those situations, they announce their arrival to the hospital teams with only a fraction of the patient information. As one participant explained: “If the patient is unconscious or the patient might be too critical to be able to answer questions, and there might be nobody with the patient, we can’t get their name or any information on demographics. […] We may just guesstimate [guess and estimate] the patient’s age” [EMS-P1]. In other cases, EMS crews may not even have the capability to notify the hospital as their hands are occupied with stabilizing a critically injured or ill patient: “In some critical cases, like if I’m doing CPR to patient, I can’t take out my phone and start calling the charge nurse” [EMS-P10].

**Ineffective Communication Mechanisms.** EMS providers primarily rely on radio or cellular link to communicate with dispatchers and hospital teams. However, the radio signal is often unstable and fails to work in many areas, causing challenges for efficient and accurate pre-hospital communication: “There are dead zones in the city where your signal is poor, so you might not be able to get through in a timely fashion where you might have to move somewhere, either away from the patient or move the patient to somewhere where you have a stronger signal” [EMS-P8]. The COVID-19 pandemic has exacerbated this challenge, as explained by another EMS participant: “What comes to my mind first is that because it’s a different world right now with COVID. We are wearing N95 respirators, and it’s really, really difficult to speak to anyone over the phone, let alone that you have to request orders from that” [EMS-P12].

Due to the system integration issues, the portable radio carried by EMS providers on the scene cannot be used for pre-arrival notification, forcing the EMS crews to use the radio inside the ambulance. Because of this limitation, the EMS provider driving the vehicle is usually the one giving the notification to the hospital. The driver may not necessarily know the most current patient status since they have difficulty communicating with the co-workers in the back of the ambulance: “If you have a real serious patient and you have two paramedics in the back and an EMT who doesn’t
necessarily know what’s going on is driving. And then that EMT has given the notification, they might not get the right information because they don’t know what’s going on or they might forget something” [EMS-P8].

The limitations of the current communication mechanisms also pose significant challenges in communicating contextual information from the field to the receiving hospital, leading to not only time-consuming verbal descriptions but also misinterpretations of the patient status: “I think the biggest issue is the fact that it’s all verbal and they can’t generally see the patient” [EMS-P4]. To work around this issue, a few participants mentioned that they would take a picture of the accident scene for trauma cases to help ED and trauma teams understand the severity of the accident and consider potential internal injuries: “When I showed up to the scene of a really bad accident, I would take pictures of the accident, and then when I got to the hospital, I would show the trauma doctors because they can see if it was a head-on collision, then they know what kind of injuries they’re expecting and what could be wrong with the patient. [...] I find that could be relevant information to doctors and assisting them” [EMS-P11].

Overloaded EMS Systems. An organizational-level challenge is that the EMS system is usually overloaded. The entire system could become extremely busy in peak hours, especially in large cities. For example, EMS providers need to call the emergency communication center to give the pre-arrival notification, but establishing connection with the dispatcher is sometimes challenging: “It’s only one dispatcher. So, if two ambulances are trying to give notification at the same time, one is stuck in limbo. And they might not ever get through because he’s hung up on details on one call. I can’t even talk to him yet about my call and I’m going to get to the hospital before I get through” [EMS-P8].

To address this challenge, EMS practitioners sometimes call the receiving hospital directly using their personal phones: “Because I’m working in a hospital-based EMS system, I have the phone number for the ER, if I have to give a notification to the specific ER that we work at, I will call them on my phone personally, rather than having to go through the dispatcher” [EMS-P12]. Another participant confirmed this “unofficial” yet effective work practice: “There are times where I can’t get over the radio to the dispatcher. So, I do have to call the hospital notification line directly and speak with the nurse in the ED and let them know we’re coming. That’s like more unofficial way of getting a notification. Meaning it’s not technically the correct way to do it, but I think it’s more efficient” [EMS-P9].

EMS practitioners may also need to consult a physician about treatment plans en route or patient destination. Almost all of our EMS participants have experienced difficulties reaching out to ED physicians: “Common problem that has occurred is that there is a long delay to actually speak to the physician sometimes. Sometimes, it can take anywhere between 15 minutes to half an hour, and that can be frustrating. And obviously it delays patient care. [...] What you’re supposed to do is just wait, because otherwise you get in trouble for doing something without speaking to the physician” [EMS-P1].

Intermediary Communication Links. When giving a notification, EMS practitioners have to communicate with a 9-1-1 or ECIC dispatcher who takes the information and relays it to the next recipient in the communication chain. Our results showed several issues in the EMS-dispatcher communication process. First, some information could get miscommunicated or lost during this transition process, as described by an EMS participant: “A lot of information gets lost in translation. I’ve had plenty of times where we show up and the hospital’s ready for a patient in ‘cardiac arrest.’ And we’re like, ‘wait, we did not say that.’ Or we show up and they’re like, ‘we didn’t get a notification about what you’re talking about.’ So, the game of telephone, I think, is a big hindrance in getting notifications. [...] The dispatcher has to understand 100% when you say over the radio and then they have to say it again to a person [ER nurse or physician] on the other end of the phone. And they don’t really have the opportunity to call you back and ask further information. Because as soon as they’re done with that one, there’s another ambulance who’s on the radio waiting to get connected” [EMS-P13].

Second, the dispatchers often asked the EMS practitioners about unnecessary information, which delayed the notification process. An EMS crew member explained: “They [dispatchers] tend to follow a protocol. [...] It’s ingrained in them that they need this and that information or they can’t continue on, even if the information really isn’t going to make a difference. If you call about a stroke patient, they will ask if it is the left side or the right side. It doesn’t matter. Or exact numbers on a set of vitals. [...] If it’s normal, it doesn’t matter. It’s not going to affect the main goal for a notification, which is to have a team ready and the right sources. [...] But they’ll get hung up on those details and that’ll just delay them” [EMS-P8].

Given those challenges, EMS participants expressed their interest in sharing original patient data directly with the receiving ED department: “It’d be great if we are able to send our notes to the hospital, so they could know what’s going on even before we get there” [EMS-P10]. However, this need is not fully supported by the current system architecture and communication mechanisms.
Discussion

We found that EMS providers collected a variety of information from multiple sources in a short time period, including patient demographics, mechanism of injury, physical exam findings, injuries, and treatments. Due to the time pressure, EMS providers were only able to provide a very brief verbal report to the receiving hospital. Our results showed that only a few information types (e.g., patient age, neurological status, vital signs, and IV/IO administration) were always shared by EMS providers, while other types (e.g., details of mechanism of injury, airway, breathing, and change of status) were rarely reported. Even when available, much information, including the essential parts such as vital signs, was often partially reported. A possible reason for this limited or partial reporting may lie in the purpose of the EMS verbal report, which is to quickly announce the patient arrival to get the hospital teams and resources ready. However, these limited or partial reports could also lead to challenges in establishing common understandings between the pre-hospital and hospital teams.

Interviews with different hospital-based teams uncovered information types that are critical to their work. We found that the pre-hospital information needs of hospital teams match what is typically reported by EMS teams. However, hospital teams need contextual information from the accident scene (e.g., photos, videos) to better anticipate the patient’s needs. The challenge, however, is that EMS teams currently lack effective mechanisms by which context-specific information is accrued to allow for rapid integration and sharing. Even in this era of modern communications, EMS providers still rely on radio or phone to communicate with hospital teams. Theses outdated mechanisms make it challenging for EMS providers to not only describe complex patient cases in words but also for hospital teams to understand the symptoms and status of the patient. The limitations of current communication mechanisms pose challenges to efficient information sharing between pre-hospital and hospital teams, requiring further studies.

Despite being aware of the importance of pre-hospital communication, EMS teams face many challenges in delivering accurate information to the receiving hospital in a timely manner. One prominent barrier is related to the limited ability to notify hospitals when dealing with a critical patient in the field, as EMS providers need to perform hands-on examination and treatments on patients. As a result, they often experience high physical and cognitive workload, limiting their abilities to use handheld radio or phone for notification. Another significant challenge is the difficulty of communicating with the dispatchers at the emergency communication centers. Sometimes dispatchers are overloaded, forcing EMS providers to wait in a queue to get connected. This challenge could severely delay the notification process and ultimately patient care. In other cases, miscommunication or information loss could occur in the notification process due to various reasons, such as unstable radio signal or inaccurate interpretation. Because of this issue, the information delivered to ED physicians is not always accurate, hindering their decision-making process (e.g., which specialist to call, what resources and equipment to prepare, and what labs to order).

Given these challenges, it is critical to consider novel technology interventions to support seamless, real-time pre-hospital information sharing in the field. For example, Schooley et al. reported the design and evaluation of an Android-based smartphone application to support the communication of patient information from the field to the receiving hospital. EMS providers can use this application to take photographs, record digital audio notes, and capture video of the patient and scene. Such data can be relayed to and reviewed by ED physicians via a web application. An ambulance-based telemedicine system is another key example of technology being tested over the past decade to enable real-time, audio-video pre-hospital communication. The system is installed in the ambulance with video cameras to capture a designated area’s view (e.g., patient body) and transfer data to the hospital. Despite the benefits, various challenges hinder the effective use of these technologies. For example, given the size and weight of the ambulance-based telemedicine unit, this system is not portable enough to be used outside of the ambulance where a great portion of urgent patient care occurs. As a result, these handheld systems have rarely been used in real time, becoming a hindrance to the user.

Recent work has shown that “smart glasses” have a high potential for supporting pre-hospital information transfer, because this novel technology offers touchless interaction mechanisms, such as voice control, to minimize the intrusiveness of these tools. These head-mounted, wearable devices with a transparent screen and a video camera that can project first person, point-of-view data to a remote viewer are hands-free, allowing care providers to focus on patients in many hands- and eyes-busy medical contexts. This novel technology could also reduce the likelihood of cross-contamination and patient infections since care providers do not have to handle the device physically.

Smart glasses also allow EMS providers to capture and share videos and pictures in real time, which are considered useful by emergency care professionals in the hospital. By doing so, EMS providers can easily share specific information about a patient (e.g., injury location and severity, symptoms) instead of spending a significant amount of time describing the patient situation with words. In addition, pre-hospital and hospital providers can connect via...
videoconferencing applications within the smart glass for more effective care coordination. In this case, ED physicians can see and hear what the EMS providers see and hear through the smart glass application, allowing them to offer medical advice as EMS crews manage and stabilize a severe patient during patient transport. All these promising features of smart glasses make this technology of interest to EMS professionals, allowing them to have faster access to expert advice anywhere (e.g., outside of the ambulance). In our future work, we will look into how to design and develop smart glasses and hands-free interaction mechanisms to support real-time and effective pre-hospital information collection and sharing in the field. As prior work pointed out, smart glasses may introduce cognitive burden and human factor issues. These limitations require considering how smart glasses could be designed for seamless integration into the workflow of pre-hospital care while accounting for physical and cognitive limitations of emergency care providers. Also, social, organizational, and policy factors that can facilitate or impede the use and uptake of smart glasses will be explored in our future studies with various stakeholders.

This study has several limitations. First, we mainly relied on video review of simulated EMS interventions to understand the types of pre-hospital information being collected and shared in the field. It is possible that video recordings of simulations may not have clearly captured all work practices. Despite this limitation, this video review allowed us to analyze the data offline and capture detailed communication and work practices. Also, simulations provide a safe environment without the risk of loss of patient confidentiality. Second, the video recordings we analyzed were simulations with only 3 medical resuscitation scenarios. This limitation might affect the generalizability of the results to other domains (e.g., stroke or trauma). In our future work, we will conduct additional field studies with EMS providers to cover as many patient scenarios as possible for a more comprehensive understanding of the pre-hospital data collection and sharing practices in real-world situations. Third, there is a five-year gap between the interviews with hospital teams and EMS teams. However, since the work practices and communication technologies (e.g., radio signal) haven’t changed during this time period, we believe the impact of this gap on our findings is limited. Lastly, the video data and interview data were collected from different EMS agencies in different regions. However, these EMS agencies follow similar protocol and regulation, making the results generalizable. In addition, their different characteristics (e.g., fire-based vs. hospital-based EMS agency, east coast region vs. mountain region) can further strengthen the generalizability of the results.

Conclusion

In this study, we conducted a series of mixed-methods ethnographic studies with both pre-hospital and hospital care providers to examine user needs, work practices, and existing barriers in the pre-hospital communication process. We described the types of pre-hospital information commonly collected and shared in the field and whether the shared data meet the information needs of emergency care providers in the receiving hospital. We also discussed the issues and challenges related to real-time information sharing during pre-hospital encounters from both pre-hospital and hospital teams’ perspectives. Finally, we used these findings to discuss potential technology solutions that could address the identified challenges and support seamless information sharing between pre-hospital and hospital teams.

Abstract

During the coronavirus disease pandemic (COVID-19), social media platforms such as Twitter have become a venue for individuals, health professionals, and government agencies to share COVID-19 information. Twitter has been a popular source of data for researchers, especially for public health studies. However, the use of Twitter data for research also has drawbacks and barriers. Biases appear everywhere from data collection methods to modeling approaches, and those biases have not been systematically assessed. In this study, we examined six different data collection methods and three different machine learning (ML) models—commonly used in social media analysis—to assess data collection bias and measure ML models’ sensitivity to data collection bias. We showed that (1) publicly available Twitter data collection endpoints with appropriate strategies can collect data that is reasonably representative of the Twitter universe; and (2) careful examinations of ML models’ sensitivity to data collection bias are critical.

Introduction

The coronavirus disease (COVID-19) pandemic has put tremendous strain on the society. As of March 9, 2021, more than 29.1 million Americans have been diagnosed with COVID-19 and more than 526,000 have died.1 Governments worldwide are trying their best to contain the spread of the virus. Preventative measures, such as social distancing, school closures, and work-from-home policies, implemented by national, state, and local governments, have affected the daily routines of billions of people worldwide and forced many activities and social interactions to be moved online.2,3 Social media platforms are a way for people stay connected during this pandemic. Individuals are increasingly sharing a large amount of personal health information, including their COVID-19-related sentiments and comments. Officials such as health organizations and government agencies have used social media to share COVID-related policies, progress of vaccine development, and Q&A towards COVID-19 issues to help the public stay safe and informed.4 These social media data provide unique insights into public health events.

Among the popular social media platforms, Twitter, initially a microblogging platform, has well-constructed Application Programming Interfaces (APIs) for obtaining the data that are publicly available. Therefore, it has become a popular source of social media data for researchers. In the short time since the pandemic began, Twitter has been used to study various topics around COVID-19. For example, Kouzy et al. (2020) manually identified and quantified the magnitude of misinformation that is being spread on Twitter regarding the COVID-19 pandemic which can served as an early warning for unexpected events.5 Xue et al. (2020) used latent Dirichlet allocation (LDA) to identify popular topics and sentiments from 4 million COVID-19 tweets.6 Mackey et al. (2020) used the Biterm topic modeling to identify individual reports of COVID-19-related symptoms, testing, and recoveries that appeared on Twitter.7

Twitter provides new opportunities for health-related research. However, the use of Twitter data for research also has drawbacks and difficulties; the potential for bias appears at every stage of the process, from data collection to modeling. Tools for collecting social media data often result in biased samples. For example, Twitter APIs only return a subset of the tweets from Twitter’s data warehouse; but the relative size of a subset as a proportion of the whole is unknown, as are the sampling strategies used by Twitter to produce the subsets.8 Further, social media data (e.g., tweets) are mostly unstructured free-text data. To study health information on Twitter, researchers often use inference models such as machine learning (ML) and topic modeling methods to process and identify insights from these free-text tweets. However, supervised ML models (e.g., models used to identify genuine laypeople discussions from health-related discussions on Twitter9–11) require annotated training samples. If ML models are trained on

---

a Corresponding: Jiang Bian, PhD; bianjiang@ufl.edu
potentially biased subsets of data, it is not clear how well those models will perform when analyzing other samples from the whole datasets. Biases of social media data and analysis methods have yet to be rigorously addressed, particularly in public health surveillance studies such as those for COVID-19. Overlooking these biases in health-related social media studies can lead to wrong or inappropriate results with severe unintended consequences.

Thus, in this study, we used six different data collection methods available to collect COVID-19-related Twitter data and developed three machine learning models. This study had two primary aims, listed below with three corresponding research questions (RQs):

Aim 1: Assess data collection bias.
- RQ1: What proportions of each dataset data collection method returns?
- RQ2: How representative of the data collected with each of the 5 data collection methods to the gold standard dataset (i.e., from the Twitter full archive)?

Aim 2: Measure ML models’ sensitivities to data collection bias.
- RQ3: How does data collection bias (i.e., models trained on different subsets) impact models’ performance when applied on other subsets?

Methods

Figure 1 shows the overall process of our study, where we (1) collected COVID-19 related tweets using 6 different data collection methods, (2) estimated the data collection biases in two-fold: i) assessing the overlapping portions between each pair of the six datasets, and ii) assessing the data representativeness using rank correlation based on the top keywords comparing each of the other 5 data collection methods against the full archive data, and (3) explored ML models’ sensitivity to data bias in terms of model performance by training and testing prediction models on samples selected from different datasets.

Data collection

From February 21st, 2020 to May 1st, 2020, we collected COVID-19-related tweets using three different Twitter APIs: (1) Twitter search API (i.e. “GET search/tweets”), (2) Twitter sampled stream API (i.e. “GET statuses/sample”), and (3) Twitter filtered stream API (i.e. “POST statuses/filter”) using a list of keywords (e.g. “#coronavirus” and “covid”). The list of keywords was developed through a snowball sampling process, where we started with a list of seed keywords collected from online information sources such as news sites and Wikipedia. We then iteratively queried sample tweets from the Twitter website using these keywords and manually reviewed the content of the tweets to discover new COVID-19-related keywords (i.e., words that co-occur with one of the existing keywords but that were not in the existing keyword list) until no new keywords were found. Through this process, we initially found 36 COVID-19-related keywords initially.

As the COVID-19 pandemic progressed, using a similar process, we further extended our 36 keywords to a total of 86 keywords based on a new round of sampling of relevant tweets and Google search results. Since Twitter APIs have rate limits (e.g. for the search AP, only 450 requests are allowed in a 15-minute time window for each crawler and restricted by IP), we split the 86 keywords into 4 groups and used 4 crawlers making 4 sets of Twitter search API requests separately (a.k.a “Twitter multi-search” in our experiments) from May 14, 2020 to July 17, 2020.

On April 29, 2020, Twitter released a new streaming interface that is designed for COVID-19 data collection (a.k.a a “Twitter COVID-19 stream” in our experiment). This COVID-19 endpoints allow approved developers to access COVID-19 related tweets across languages. Nevertheless, the exact mechanism of how Twitter decides that a tweet related to COVID-19 is unclear. Thus, to make this COVID-19 streaming dataset comparable to our other Twitter...
data collection methods, we filtered the dataset using the same set of keywords and the same time range as in our multi-crawler data collection method.

In January 2021, Twitter made its full archive data available to academic researchers; however, the full archive APIs are still constrained by the rate limits.16,17 Ideally, the full archive dataset should contain all tweets of the Twitter universe and thus can be used as the gold-standard dataset for calculating the data coverages of the different data collection methods described above. Because of the rate limits, we collected 200 random samples of a full-minute of tweets from the “Twitter full archive” based on the corresponding keywords and the time ranges that we used for the other data collection methods accordingly.

In summary, we used six Twitter data collection methods resulting in six different datasets: (1) "Twitter search", (2) "Twitter filtered stream", (3) "Twitter sampled stream", (4) "Twitter COVID-19 stream", (5) "Twitter multi-crawler search", and (6) "Twitter full archive". Figure 2 (A) shows the time range of each dataset; and as shown in Figure 2 (B), we divided the datasets into two groups based on the data collection time ranges. Group 1 includes four datasets (i.e. "Twitter search", "Twitter filtered stream", "Twitter sampled stream", and "Twitter full archive") collected from February 21, 2020 to May 1, 2020; and Group 2 includes three datasets (i.e. "Twitter COVID-19 stream", "Twitter multi-crawler search", and "Twitter full archive") collected from May 14, 2020 to July 17, 2020. As shown in Figure 2 (B), ideally, each of the other Twitter data collection methods returns a subset of the "Twitter full archive" dataset, while overlaps with the other datasets collected from the same time period and with the same list of keywords. However, since we collected the full archive data in January 2021, tweets that have been deleted or from accounts that have been suspended were no longer accessible, resulting in other datasets having tweets not in the full archive. The eight circles in Figure 2 (B) represent eight random samples that we used to train our ML models. The results of the training sample annotations and associated ML model performance will be detailed in the result section.

Bias in social media data collection methods
The underlying mechanisms of the Twitter APIs’ sample selection strategies are unknown. We first assessed the data collection bias in terms of overlaps among the datasets within the two groups (as shown in Figure 2 (B)). We then compared the overlapping of tweets by considering the top relevant keywords and measuring the Kendall correlations for each dataset against the full archive dataset.

Originally, we thought that the Twitter full archive API could reliably be used as the gold-standard dataset; however, since we collected the full archive data in January 2021, tweets that had been deleted and tweets from suspended Twitter accounts were no longer available. Thus, when we compared each dataset with the full archive, these tweets had to be removed from our calculations.

In addition to comparing the first five data collection methods with the "Twitter full archive" dataset over the span of a minute, we also measured the overlapping among the first five datasets within additional time spans, including a minute, an hour, a day, and a week. To do so, we first randomly selected 100 random time periods at the lengths of a minute, hour, day, and week. We then calculated the overlapping proportions of the datasets generated from each data collection method and reported the mean overlapping proportions and associated confidence intervals across 100 random samples. For Group 1, we calculated the overlapping proportions among the datasets using the total of the first three datasets (i.e., “Twitter search”, “Twitter filtered stream”, and “Twitter sampled stream”); and for Group 2, the denominator consisted of the total of the “Twitter multi-crawler search” and “Twitter COVID-19 stream” datasets. In addition to calculating the global overlapping proportions among these five datasets, we also aimed to answer RQ2:
“how representative of the data collected with each of the 5 data collection methods to the gold standard dataset (i.e. from the Twitter full archive)?”. To make a fair comparison, we first identified the top 10 keywords of each dataset. We then measured the overlapping proportions between each of the first five datasets and the gold-standard dataset, only considering tweets containing the top 10 keywords. To measure the representativeness, we performed Kendall correlations for each comparison.

**Machine learning models’ sensitivity to data bias**

To test machine learning modes’ sensitivity to data bias, we considered a prediction task that classifies task, based on our past work,\(^9\) that classifiers each tweet into two categories: promotional information and consumer discussions.

**Training sample selection.** We randomly selected 600 English tweets from eight different sampling points (4,800 total tweets) as shown in Figure 2 (B). Those 4,800 tweets were manually sorted into the 3 groups (i.e., irrelevant, promotional, and consumer discussions) by three annotators (kappa = 0.73). Even if a tweet contains keywords related to COVID-19, the tweet may not be relevant or meaningful (e.g., “#SIRC$WORL$DNEWS #Coronavirus #CoronavirusOutbreak -- BREAKING - <URL>”); thus, we categorized those tweets as irrelevant. Within the relevant tweets, we further categorized those tweets into promotional information (e.g., from a health organization “CDC Denies Delaying Testing of California Coronavirus Patient; Over 100 CA Hospital Workers in Home Quarantine <URL>”) and consumer discussions (e.g., “My cousin just died of Coronavirus <URL>”).

**Tweet text preprocessing.** To build the classifiers, we first preprocessed the sampled tweets following the preprocessing steps used by GloVe:\(^8\) (1) removed hyperlinks, (2) removed mentions, (3) replaced hashtags into English words with hashtag sign (e.g., convert “#COVID” to “<hashtag> COVID”), and (4) replaced all emojis, URLs, and mentions (e.g., @username) with signs of “<emojis>,” “<url>,” and “<user>” respectively.

**Machine learning model sensitivity to data bias.** We explored three commonly used classification algorithms: convolutional neural networks (CNN), random forest (RF), and gradient boosting trees (GBT).\(^{19-21}\) We implemented the CNN models in Keras on top of the Tensorflow framework. We initialized the embedding layer with the GloVe pre-trained 100-dimension Twitter word embeddings. We implemented the RF and GBT via the scikit-learn library and used the Term Frequency-Inverse Document Frequency (TF-IDF) scheme to convert each tweet into a feature vector.

Regarding our research question about “model sensitivity to data collection bias”, our hypotheses were: (1) prediction models that were trained on samples selected from one dataset may not achieve consistent performance when they are applied on data from other datasets; and (2) prediction models trained on samples selected from the “Twitter full archive” dataset should achieve relatively higher performance and higher consistency compared to the models trained by samples from the other collection methods, since these are theoretically samples of the full archive.

To test our hypotheses, we trained each model 10 times on each of the eight annotated samples and then tested the model’s performance on the other samples. The performances were measured in terms of mean F-1 score and the 95% confidence intervals (CI) were reported across 10 runs.

**Results**

**Data collection**

In total, we collected more than 750 million tweets using six different Twitter APIs across two different time periods.

**Data collection bias analysis**

**RQ1: What proportions of each dataset data collection method returns?**

We randomly selected 100 random time periods at the minute, hour, day, and week scales within each of the two datasets. We first compared each dataset against the gold standard dataset at the minute scale by calculating
the overlapping proportion between each dataset and the “Twitter full archive” dataset. The denominator used for this comparison was the total number of tweets in the “Twitter full archive” dataset. We then compared the overlapping portions of the datasets within each group, using the combination of all available datasets within each group as the denominator. We also identified the top 10 keywords of each dataset as shown in Table 2. Except the “Twitter full archive” data in Group 1, the other datasets collected at the same time period have the same top 10 keywords within its group. The “Twitter full archive” data in Group 1 has 9 keywords that are the same as the other three datasets within that same group, with the exception of "#viruscorona" which only exists in the top 10 list of the other sample datasets.

Table 5 shows the overlapping proportions of each pair of datasets from Group 1. As shown in Table 5, the "Twitter search" dataset captured most of the relevant tweets (i.e., a larger portion than the others). The overlapping between the "Twitter search" dataset and the "Twitter filtered stream" are slightly increased at all time scales, comparing only the tweets with the top 10 keywords.

Table 6 shows the overlapping proportions between each pair of the datasets in Group 2. As shown in Table 6, "Twitter multi-crawler search" covers a higher proportion than "Twitter COVID-19 stream". The overlapping between "Twitter multi-crawler search" and "Twitter COVID-19 stream" is over 50% at all time scales. When comparing only the tweets containing the top 10 keywords, the overlapping between these two datasets increased to almost 60%.

Another interesting finding is that the "Twitter multi-crawler search" covered 98.4% of the tweets with the top 10 keywords, which shows that using multiple Twitter search crawlers and multiple queries can increase the data coverage.

\(^a\)The denominator is the "Twitter full archive" dataset.
\(^b\)The denominator is the union of "Twitter COVID-19 stream" and "Twitter multi-crawler search" datasets.

Figure 3 visualizes the data overlap in different scenarios across the data collection methods.

Figure 3. Data overlapping across data collection methods.

RQ2: How representative of the data collected with each of the 5 data collection methods to the gold standard dataset (i.e. from the Twitter full archive)?

We measured the representativeness of each dataset to the "Twitter full archive" dataset in terms of the Kendall correlations based on ranking of keywords. As shown in Table 7, all the data collection methods in Group 1 have moderate correlations with the "Twitter full archive". The two streaming APIs (i.e. "Twitter sampled stream" and
In this study, we aimed to assess data collection bias among different data collection methods provided by Twitter, identify the representativeness of each data collection method compared with the "Twitter full archive", and test ML models’ sensitivities to data collection bias, through answering three research questions (RQs).

For RQ1, we found that, first, the "Twitter multi-crawler search" can effectively collect more tweets than a single "Twitter search" crawler, even with the same set of keywords, in terms of both data volume and overlapping...
proportions (i.e. covering more samples of the Twitter universe), suggesting that (1) Twitter's internal subsampling strategies might not be consistent across different endpoints due to rate limits, and (2) using multiple crawler and multiple queries is a way to work around the API rate limits. Nevertheless, using multiple crawlers requires researchers to have multiple Twitter accounts, and as Twitter has strengthened its identity verification process, especially for developer accounts (e.g., each phone number can only register a single Twitter account), this presents a challenge. We also found that overlapping proportions between the “Twitter filtered stream” vs. “Twitter search” in Group 1 and the “Twitter COVID-19 stream” vs. “Twitter multi-crawler search” in Group 2 increased when we compared only the tweets that included the top 10 keywords, leading to our RQ2, the representativeness of the tweets collected by different data collection methods.

To answer RQ2, we assessed the Kendall correlations between the "Twitter full archive" benchmark dataset and each of the other five datasets. Among the five other datasets, the “Twitter filtered stream”, "Twitter sampled stream", and "Twitter search" datasets all have moderate correlations, which indicates that even though these crawlers only collect subsamples of the tweets in Twitter data warehouse, these subsamples are still representative and can be used to "identify and track trends, monitor general sentiment, monitor global events, and much more" as claimed in a Twitter API document. Somewhat surprisingly, the "Twitter multi-crawler search" (τ = 0.89) has the same level of correlation to “Twitter full archive” as the "Twitter COVID-19 stream" (τ = 0.89), which shows the effectiveness of the multi-crawlers and multi-queries strategy. The "Twitter COVID-19 stream" was designed based on Twitter's internal COVID-19 Tweet annotation and parameters, which they "believe deliver a comprehensive view of the conversation around this topic." The effectiveness of the "Twitter multi-crawler search" gives us some level of confidence that studies that use the "Twitter multi-crawler search" for other public health studies, where an endpoint like "Twitter COVID-19 stream" does not exist, can still be conducted.

To answer RQ3, we randomly selected eight training samples for building ML models from different parts of the datasets as shown in Figure 2 (B). Among the eight training samples, seven samples were selected either from a single dataset or from overlapping portions within each group, and one sample was selected from the “Twitter full archive” dataset covering the time ranges of both Group 1 and Group 2. We found that (1) in general, models trained on one dataset cannot perform well on the samples from the other group (i.e., time shifts have a significant impact on model performance); (2) CNN models can achieve the highest average performance with relatively reliable consistency when using sample from the “Twitter full archive”. These results suggest that it is necessary to selection training samples from a representative dataset, and as the time progress, it is important to retrain of ML models with new datasets; and (3) traditional ML models such as RF and GBT can only achieve reasonable performance on the samples that they trained with. This indicates that compared with CNN models, RF and GBT are more easily to be overfitted. Thus, when conducting social media analyses, more thorough experimentation and testing of the selected models and their underlying assumptions of the data is necessary.

We also recognized the limitations of our study. First, we cannot recover the “Twitter full archive” dataset back to the time when we collected the other datasets, because of issues such as deleted tweets and suspended accounts. Thus, our measures of overlapping between other datasets to the full archive are only approximates. Second, many other factors that may affect the Twitter data collections such as the number of crawlers running on a single machine (i.e., competing of CPU cycles), and the reliability of the Internet connections among others. Third, many other factors may affect the ML model performance as well such as the sample size of the training samples, data preprocessing methods, hyper-parameter tuning, and data imbalance issues. Fourth, there are many other types of biases in Twitter studies, such as demographic bias and keyword bias. Weeg et al. (2015) mitigated demographic bias of Twitter data by stratifying Twitter users based on geographic distributions. Kim et al. (2016) measured the quality of data collection in two aspects: 1) retrieval precision (i.e., “precision measures how much of the retrieved data is not garbage” and 2) retrieval recall (i.e., “recall measures how much of the relevant data is retrieved”) and proposed a conceptual framework for the filtering and quality evaluation of social data. Those biases and potential methods are worth investigating in future research.

In conclusion, our study assessed the data collection bias, evaluated the representativeness of multiple data collection methods, and tested ML models’ sensitivity to data collection bias. Data and model bias issues are often ignored in social media studies. However, to really use social media such as Twitter as a reliable data source for future research, we must find ways to address (or at least assess) data and model biases.

Towards Digestible Digital Health Solutions: 
Application of a Health Literacy Inclusive Development Framework for 
Peripartum Depression Management

Alexandra Zingg, MPH, MS, Tavleen Singh, MS, Sahiti Myneni, PhD

University of Texas Health Science Center at Houston, School of Biomedical Informatics, Houston, Texas, USA.

Abstract
Women of low income and education have lower levels of peripartum depression (PPD) literacy, limiting their ability to recognize symptoms and make informed healthcare decisions. Existing digital solutions and underlying development frameworks for PPD lack an integrative approach addressing health literacy and related disparities. Therefore, we develop an integrative framework for digital content engineering in PPD self-management consisting of (a) user needs analysis, (b) inclusion of eHealth literacy principles (science and health literacy), and (c) mapping user needs to the Behavioral Intervention Technology model. Results revealed that perinatal women seeking mental health care prefer information in multisensory formats, and knowledge needs were identified in areas such as medication management and coping with abnormal results. Results were mapped to eHealth literacy features of whiteboard videos covering essential PPD knowledge, and social media features where patients can articulate information needs. Initial evaluation of proposed features against existing PPD self-management solutions are discussed.

Introduction
Peripartum depression (PPD) affects approximately one out of 10 women in the United States [1], and may cause significant maternal and neonatal morbidity [2]. PPD can affect any woman, but those with characteristics such as belonging to minority groups or of low socioeconomic status (SES) are the most vulnerable [3]. Additionally, women of minority groups such as African-Americans and Latinas are likely to experience disparities in accessing and completing adequate treatment [4]. Digital health technologies have been touted as a viable solution that can improve access to PPD care, and previous research has tested such solutions in the areas of PPD screening [5] and remote delivery of therapy programs [6]. Other areas of PPD care where digital interventions have been explored are self-monitoring of mental health status [7], and providing of social support during pregnancy [8]. Results from these previous interventions show that digital solutions can improve the management of PPD and lead to better mental health outcomes for perinatal women [9].

The indispensable role of health literacy in reducing disparities related to PPD is well-established. For example, low health literacy can adversely impact women’s ability to correctly recognize depression symptoms [10] and to proactively initiate the seeking of help and information for depression and other mental health disorders [11, 12]. Low health literacy is also associated with less understanding of PPD treatment options [10]. And, it has been shown that women with low literacy are likely to experience adverse socioeconomic conditions such as employment insecurity [13], making it more difficult to access mental health care resources. Within the context of PPD, existing work that evaluates digital health technology interventions includes randomized controlled trials [14], feasibility studies [15], and qualitative studies [16, 17] regarding interventions such as applications and text messages. Some of these studies have shown that health literacy is an important factor in women’s engagement with digital information sources. For example, Guendelman and colleagues [17] explored the role of eHealth literacy in disadvantaged perinatal women’s engagement with digital-health-seeking activities, and found that it was positively correlated with higher web-based seeking activities. A qualitative study by Pineros-Leano and colleagues [16] also indicated that clinic staff viewed reduction in literacy barriers as an advantage of having women complete PPD screening evaluations through an electronic tablet format. Clinic staff specifically mentioned the abilities to swiftly adapt screening questions to multiple languages, and to have them read aloud to the patient, as unique literacy components offered by the tablet. Although some of these studies briefly mention examples of how digital tools can address health literacy factors, existing literature underexplores the development and application of content engineering methods guided by health literacy principles for PPD digital health solutions.
While previous research shows that digital interventions can improve PPD health outcomes for vulnerable populations [9], it is now well known that sometimes digital health technologies themselves can create new disparities or exacerbate existing ones [18]. This phenomenon has been termed a “digital divide” in healthcare [19], and it refers to how the benefits of digital health solutions do not always reach all populations, including the ones who can benefit the most from them. In the case of PPD, existing literature [17] indicates health literacy barriers can prevent some women from fully enjoying the benefits of digital health technology solutions. In order to prevent such inequities and facilitate increased comprehension and engagement with digital information resources, the purpose of this study is to outline an integrative content engineering framework to supplement existing design and development processes of PPD digital solutions. To achieve this, we analyze women’s information and technology needs regarding PPD through the lens of health literacy theory. Our aim is to contribute new knowledge towards the production of easily digestible digital content that can increase women’s knowledge regarding PPD, and ultimately result in improved health outcomes for this population. We incorporate principles from the eHealth literacy framework (specifically, learning categories and the literacy domains of health and science) into the behavior intervention technology model. This allows us to propose and outline eHealth literacy features which present essential PPD information in an engaging and minimalist manner (examples: whiteboard videos and social media channels), and which can vastly improve women’s knowledge and understanding of this important condition.

Methods

Theoretical Rationale: eHealth Literacy

Health literacy is a term that has recently undergone a redefinition in August 2020 by the U.S. Department of Health and Human Services’ Healthy People 2030 initiative [20]. The term has been expanded to include both personal health literacy and organizational health literacy. Personal health literacy is “the degree to which individuals have the ability to find, understand, and use information and services to inform health-related decisions and actions for themselves and others” [20], while organizational health literacy is “the degree to which organizations equitably enable individuals to find, understand, and use information and services to inform health-related decisions and actions for themselves and others” [20]. This new definition is meant to highlight the important role of organizations in enabling individuals to reach optimal levels of health literacy.

With the rapid rise in use of digital health technologies, an additional separate term was created to reflect how health literacy fits into this new digital health landscape. The term is electronic health literacy (or eHealth literacy), and is defined as "the ability to search, locate, understand and use health information through electronic resources and use this knowledge to resolve health-related problems" [21]. Some theoretical frameworks have been derived to further elaborate on the concept of eHealth literacy. One of the earliest is Norman and Skinner’s “Lily Model” [21], which establishes six types of literacy (traditional, information, health, science, media, and computer) as its subcomponents. Chan and Kaufman [22] expanded on this framework and created the “eHealth Literacy Framework” by addition of cognitive elements from “Bloom’s Taxonomy” [23], which is extensively used to plan and execute educational objectives. It is a collection of action words that describe how a user processes and synthesizes new knowledge [23] and contains six categories of learning, from the simple level of remembering to the complex level of creating. Additional literacy skills and factors in predicting patient’s use of health information technology were also added to include privacy and security concerns, need for information and self-management, computer anxiety, and convenience and advantages of information from health professionals [24,25].

While there are multiple health literacy frameworks, Chan and Kaufman’s offers the most user-ready, systematic process of attributing different literacy domains and cognitive tasks to digital health features. It allows developers to determine at what cognitive level each health literacy domain is applied in digital features. In this paper, we utilize this framework in conjunction with our Digilego framework, which comprises of user needs analysis and BIT model [26] to develop theory-driven digestible digital solutions for PPD management.

Figure 1 presents an overview of our integrative framework. The main components of the framework - (a) mixed-methods needs analysis, (b) theory mapping, and (c) content specifications are as discussed below.
Figure 1- Incorporation of eHealth Literacy Framework into PPD-specific Digital Health Technologies

User Needs Analysis: We conducted a mixed-methods user needs analysis consisting of focus groups, interviews, and social media analysis. While these datasets were originally produced during previous work [27, 28], in this study we use them to inform the mapping of health literacy digital features to the condition of PPD. Two focus groups were conducted with a total of nine patients seeking prenatal care at a Maternal and Fetal Medicine clinic in Houston, TX. Each session lasted approximately thirty minutes. Additionally, ten patients were individually interviewed. The purpose of the focus groups and interviews was to discover themes regarding the use of digital technologies in the self-management of mental health during the peripartum period. They followed a semi-structured format in which question guides were used to facilitate open discussion. Question guides included the topic of educational content and design, the information they receive from currently available products, and their current knowledge of depression (example questions: “What kind of information do you actually get from these apps?”; “How would you like any educational materials of the app to be prepared?”). Ground theory analysis was used to extract themes from focus group and interview recordings, in which opening coding was done on a line-by-line basis to derive the concepts being brought up by the participant. This was followed by axial coding, in which patterns and relationships between concepts were delineated to produce major themes. Information from our focus groups and interviews was complemented with analysis from social media data. We chose to analyze online PPD forums from the websites of BabyCenter [29] and What To Expect [30]. Both of these websites are highly popular with pregnant women, and host very active social forums. While women do not have to be diagnosed with PPD in order to participate in the PPD market, a total of 5,532 posts were extracted from What to Expect, and 56,483 posts from BabyCenter. We manually labeled 850 user posts with the following five categories: Breastfeeding, Family and Friends, Medications, Symptom Disclosure, and Social Support. Similar to our focus groups and interviews, these categories were derived using grounded theory analysis. We then applied machine learning (ML) models to scale up the qualitative labels to the entire dataset. We specifically applied three ML classifiers to our labeled dataset: Logistic Regression (LR), Random Forest (RF), and Support Vector Machine (SVM). Our automatic text classification was multilabel, meaning multilabel categories were allowed per each user post. To achieve this, we applied the one-vs-the-rest multilabel strategy, whereby binary classifier is trained per category, and then categories are fitted against each other. Our automatic text classification was completed using Python’s sciKit-learn package [31]. The classifiers were evaluated with the measures of recall, precision, and F1 score. After evaluation, we applied the best performing model to the previously unlabeled dataset from BabyCenter.

Mapping Health Literacy to PPD: We then employed Mohr’s Behavior Intervention Technology (BIT) Model to incorporate health literacy principles into PPD digital features. This model asks the five questions of Why? How? What? and When? This model can be easily applied to not only the general technology development process but also to specific components of the technology [32]. To help us answer the question of How?, we have used the literacy skills and learning categories previously described as part of the eHealth Literacy Framework. We then finalized a set of PPD literacy features to be integrated with our digital solution, MomMind [28]. An example that illustrates this mapping process is: the task of articulating a question about perinatal mental health through the literacy feature of social media forums is related to the eHealth Literacy Framework cognitive task of analyzing information within the literacy domain of health.

Initial Evaluation: We have also conducted an initial market evaluation of our proposed features against literacy features in existing PPD applications, as measured by their reading grade level and cognitive task complexity. To
evaluate the reading grade level of the application’s content, we used the Flesch-Kincaid readability test [33]. This is a measure that is widely used, and it is based on a mathematical equation factoring the text’s total words, syllables, and sentences. Scores of the test range from 0-100, with lower scores indicating a more difficult reading level and higher scores indicating an easier reading level. Cognitive task complexity was determined through the six categories of learning described in the eHealth literacy framework (i.e., understanding, applying, evaluating). This evaluation can help guide future researchers and developers in assigning the appropriate complexity level of their health literacy content.

**Results**

*a) User Needs Analysis*

**Focus Groups and Interviews**

The majority of our focus group and interview participants were young: 10 were 25-34 years old, five were 18-24 years old, and four in the category of 35-44 years old. The ethnical composition of our sample was: seven identified as Hispanic, six as Black, four as White, one as Asian, and one as Other. One participant had an education level of some high school, three participants were high school graduates, five participants had some college credit, five had an associate’s degree, four had received technical training, and one had a bachelor’s degree. 14 out of 19 participants were low-income women. The main source of pregnancy information for participants was the internet (n=17). 11 participants reported seeking additional information from non-digital sources like their doctors or friends and family. Our focus groups and interviews revealed various literacy themes, including preferred formats for educational materials. The majority of participants preferred to consume educational content through dynamic formats (e.g., slide shows, videos, audio) that would make the process of understanding the content more amenable to them. This is illustrated in Comments 1 and 2. Such formats were also preferred because they are a good fit for the busy schedules of expectant and new mothers.

*Comment 1*: “… kind of like how it is now through a slideshow or, you know, just kind of something similar to that. Short videos.”

*Comment 2*: “If you could actually listen to them instead of reading, it’s better because I’m a mother so I don’t always have time to read.”

Participants also mentioned the importance of separating topics into sub-topics for a well-paced presentation of the material (Comment 3). This is in line with previous research that suggests separating information into blocks of about seven units makes it easier for the learner to retain information in memory [34].

*Comment 3*: “Well, when I was in school, I started off like the main topic and then I have bulletins that will help break down. You know, okay, like if it was for a symptom it brings it down to like, what I should do, or how I should treat it, any medication... broken down to the bullets or sections.”

Participants also expressed the at times frustrating experience of following up with their doctors after having read information from digital sources (e.g., social media). It was difficult for them to discern when to trust these sources, and when to contact their doctors if such sources indicated a possibly abnormal event in their pregnancy. This indicates a barrier for participants in using the information they receive from non-traditional sources, as Comment 4 shows.

*Comment 4*: “Sometimes I’ll come to my doctor (with the app) and show ‘Look, this says this is not normal’ and they’ll say ‘Oh no, don’t trust those things’. Well, then I don’t want to bug you every five minutes for the nine months we get to go through this. I was told this would not happen to me.”

**Social Media Analysis**

Evaluation of our selected ML models indicated that the RF model had the best performance (Table 1). Therefore, we applied this model to predict categories for user comments in our unlabeled dataset of 56,484 user posts from BabyCenter. The category used most by our chosen model was “Social Support” with 50,337 comments, followed by “Medications” with 10,499. “Symptom Disclosure” was applied to 6522 posts, and “Family and Friends” to 2275 posts. The least used category was “Breastfeeding” with 532 comments. The high frequency of the “Social Support” category indicates that women use channels such as online social forums both to receive and provide support regarding PPD at various levels: emotional (words of encouragement), informational (sharing of scientific and health concepts regarding PPD), and instrumental (practical tools to help manage PPD, such as relaxation techniques). Therefore, it is
important that discussion participants are able to critically process the information from such channels by having sufficient baseline knowledge about the condition. A specific health literacy component that we can derive from this result is that all women need a simple introduction to PPD that covers essential information such as its definition, symptoms, and possible treatments. The high number of “Medications” post also indicates that women who seek PPD care need educational materials that will help them understand practical topics such as how to better manage their medication (i.e., different medication options, usual dose, frequency) and the medication effects on breastfeeding and baby’s health.

**b) Theory mapping**

Table 2 shows our mapping of the BIT model to health literacy components for PPD. The goal of incorporating health literacy components into the content of our educational platform is to make our content as learnable as possible to the majority of women. Ultimately, this will allow them to use new knowledge to make the best decisions about their mental health (i.e., deciding to disclose symptoms to their doctors) and sustain positive health behaviors (i.e., routine mental health screening). To accomplish the goal of making our content highly learnable, we will follow results from previous research on education and psychology. For example, studies have shown that presenting content to the user in short segments helps improve long-term memory retention [34, 35]. Therefore, our content will be presented in brief whiteboard videos. As also indicated by our participant demographics, the education level of our participants ranged from some high school to a college degree. To assure that our materials are written at a literacy level that can be well understood by all, we have selected to write our educational modules at a reading level of eighth grade.

**c) Content specifications**
Table 3 shows a granular mapping of the eHealth literacy framework to proposed PPD digital modules in our MomMind digital platform. In this mapping, we have concentrated on the specific literacy domains of health literacy and science literacy. Our results indicate that our platform has the potential to improve our users’ literacy levels in these domains by helping them achieve the cognitive tasks of understanding important PPD health topics and science concepts.

d) *Initial Evaluation*

Our initial market evaluation of literacy features in our proposed digital platform for PPD management against five selected commercial applications for PPD management [36-40] showed that most applications addressed health literacy through educational modules and brief tips for PPD symptom management (Table 4). It was found that two of the applications had content written for the college reading level, one had content written for the high school reading level, and one had content written for the eighth-grade level. The content of MomMind was written at the sixth-grade level, making it the easiest to read. These results indicate that most available market applications for PPD management have content which will be most useful to women of high education levels. The application which had the highest level of cognitive task (applying) was PPD Act, which presented weekly practical tips to its users. Three applications (Postpartum Depression, Postpregnancy Recovery, and MomMind) had the lowest complexity level of cognitive task from the eHealth literacy framework by presenting PPD information that the user can recall from their long-term memory if needed.

**Discussion**

Our user needs analysis provided us with an in-depth dwelling into the world of perinatal women who are seeking mental health resources and the hurdles they face in their journey. Our target population (low-income women seeking mental health care) has an educational level of mostly some college, but the lowest education level achieved was some high school. Most were also low-income and of minority groups. Overall, these characteristics indicate to us that any educational materials presented to this population should be at a maximum reading level of 8th grade, to assure that the materials can be understood by everyone. We also found that this population was most interested in learning about topics that served as gateways into further discussion and information about mental health and PPD (breastfeeding, family environment, medications). Our user needs analysis could have been strengthened by including in our focus group and interview samples women of different backgrounds who have been diagnosed with PPD.

Our theory mapping of the BIT model and the eHealth literacy framework to literacy features for PPD allowed us to model the relationship between our target users, our content, and the digital environment. This mapping suggests that
cognitive tasks such as remembering, analyzing, and applying PPD information would increase our user’s PPD health and science literacy. From this mapping, we derived the following two categories of health literacy features that should be included in digital solutions for PPD self-management:

a) Brief, multimedia educational materials: As indicated by our participant’s focus group and interview comments, participants prefer to receive information in a manner that is not just text. They specifically mentioned video and audio as formats that are engaging. They also suggested information should be broken down into bite-size chunks that can be consumed in short spans of time. Another conclusion we can make from our user needs analysis is that many women lack essential knowledge on PPD, such as its definition, symptoms, and available treatment. Therefore, our proposed application will contain brief whiteboard videos that will present women with this essential knowledge on PPD.

b) Channels where the user can articulate and analyze information: The combined results of our social media analysis, focus groups, and interviews revealed that the ability to discuss PPD information with peers and providers was an important component in increasing women’s health literacy. For example, our social media analysis revealed that online PPD forums was a very important source of information where women would share knowledge on a wide range of PPD areas, from recommendations on clinical treatment to sharing of local support resources. For this reason, in our proposed digital platform we include the features of a social forum where women can interact with fellow patients from the clinic they are attending, as well as the ability to have bidirectional communication with their providers to ask questions about the peripartum period and PPD.

The strength of our mapping process is that it is based on well-established literacy and technology theories. However, a main limitation of our study is lack of extensive evaluation of our selected literacy features with PPD stakeholders, including patients and clinicians. Additionally, our literacy features should be evaluated across users with high and low levels of health literacy. As part of future steps in our research program, we will focus on implementing these features and evaluating them in formative and summative evaluation studies to understand the effects of our framework on patient engagement, psychosocial outcomes, and PPD self-management capabilities. Our study adds important knowledge that is currently missing in existing literature: it explores the theoretical application of health literacy principles in the development and application of content engineering methods for digital health solutions in PPD management.

Conclusion

Health literacy is an important factor in empowering patients to make the best health decisions and reaching optimal health outcomes. With the rapid rise in use of electronic sources to distribute health information, it is critical that developers and providers incorporate electronic health literacy factors into digital health solutions to assure that such sources can be easily understood and used by the intended target audience. Such literacy factors can range from media type through which the information is delivered to the reading level at which the information is written. The integrative framework we describe in this study allows us to guide the work of future researchers, digital health designers, and developers to determine the ways in which literacy principles and digital features should be engineered. Ultimately, this framework can result in digital health technologies that promote equity in access to health resources.

Acknowledgements

We would like to thank patients and staff at the UTPhysician’s Women’s Center at TMC who participated in this study for their time and insights. Introduction

Because skin disease appears visually different across skin tones, educational materials depicting diverse skin tones are required for a well-trained healthcare workforce1–5. However, dermatology textbooks, lecture notes, and published literature lack adequate diversity in skin color representations. Massie et al. analyzed skin tones in the New England Journal of Medicine from 1992 to 2017 and found that only 18% of the images represented non-white skin.3 Adelekun et al. assessed skin tones in the top general dermatology textbooks and found darker skin tones significantly under-represented.5 The lack of representation in educational materials may translate to the clinical realm, where skin cancer diagnoses (e.g., melanoma, squamous cell carcinoma) are significantly delayed in patients of color, leading to increased morbidity and mortality6. The COVID-19 pandemic has further highlighted inequities4; manually annotated published photos of COVID-19 cutaneous findings and found images depicting darker skin lacking. Unfortunately, manual skin tone annotation is not feasible for a large corpus of dermatology education materials due to its labor-intensive nature, operator visual fatigue, and intra-/inter-observer error related to category assignment for different skin tones1,4. Automatic assessment of skin tone representation would significantly aid in identifying bias in educational materials. Previous work7 used Individual Typology Angle (ITA) to approximate skin tones in curated image datasets used as benchmarks and found they under-represented darker skin tones. We extend this work to process images in the wild from off-the-shelf textbooks and output representations of skin tone, which allows domain experts (e.g., dermatologists) to visualize biases in the data.

Method

The overview of the method is shown in Fig. 1. The main components are automatic ingestion of traditional academic materials (e.g., textbooks in .pdf), parsing of different entities (e.g., figures), extraction of skin images, and estimation of skin tones.

Figure 1: Overview of the proposed framework. Academic materials (e.g., in pdf format) are fed as input to our pipeline, which are ingested using a corpus conversion service8 resulting document entities (e.g., images and tables) parsed into a structured format (e.g., JavaScript Object Notation - JSON). Images are then cropped out using the annotations, among which skin images are selected. Segmentation of skin pixels is done followed by estimation of skin tones using a pre-trained ResNet-18 framework with the last layer fine-tuned to output “light” vs “dark” skin tones.

Data and Results:

We evaluated our framework using images extracted from four dermatology textbooks: Rook’s textbook of dermatology9, Bologna 4e10, Fitzpatrick Color Atlas 8e11 and Fitzpatrick Dermatology in General Med 9e12 resulting 28159 images collected from 416 chapters. The detection of skin images is performed with a leave-one-textbook-out validation and results in AUC of 0.98 ± 0.02 and F1 score of 0.94 ± 0.03 using XGBoost classifier. After
skin image segmentation is employed using pixel-level intensity values and region information, we aim to identify the skin tone, i.e., light vs. dark. To this end, we employed both handcrafted (e.g., HOG, ITA) features and raw pixels to train the models. Both traditional tree-based classifiers (e.g., gradient boosting) and pre-trained ResNet are experimented with five-fold stratified cross validation. The best performance achieved by handcrafted features is using a Gradient boosting classifier with $0.85 \pm 0.03$ AUC and $0.89 \pm 0.01$ $F_1$ score. A ResNet framework (pre-trained with natural images and finetuned to output "light" vs "dark" skin tones) outperformed the baseline classifiers using selected pixels after masking, i.e., $0.89 \pm 0.01$ AUC and $0.95 \pm 0.00$ $F_1$ score.

Discussion: Disparities in dermatological outcomes may be related to inequities in dermatological education, particularly the lack of darker skin images in educational materials used to train dermatologists and primary care physicians. Thus far, efforts to quantify biases in these materials have been done by hand, which is labor-intensive and impractical for large-scale application. Thus, we aim to develop a standalone online tool that enables a domain-expert to upload a given academic material and obtain distribution of images across different skin tones. This provides first-hand awareness of potential bias existing in these materials and thereby a chance to improve the imbalance. Since all images from a dermatology textbooks or educational materials are not skin related, the first step aims to discard non-skin images. Skin tone estimation needs to also avoid lesions areas of the skin image (e.g., lesion pixels in light skin image might resemble dark skin tone) and unnecessary background and foreground components (e.g., clothes). Results show encouraging performance in detecting skin images and classifying skin tones. The findings confirmed the reports of lack of dark skin images from manual studies of dermatology materials as only an average of $10.15\%$ of dark skin images (compared to light skin images) is found in the four validated textbooks. Future work aims to pilot the developed tool in different geographical locations. We envision this technology as a tool for dermatology educators, publishers and practitioners to quickly assess their educational materials, which could be scaled to other domains (e.g., history) to automatically identify lack of representation in, e.g., race and ethnicity.

Feasibility of a Self-Administered Elder Abuse Digital Screening Tool for Use in Emergency Department Settings

Fuad Abujarad, PhD, MSc1, Esther Choo, MD2, Michael V. Pantalon, PhD1, Karen Jubanyik, MD1, James Dziura, MPH, PhD1, Chelsea Edwards, BSc1, Gail D'Onofrio, MD, MS1, Thomas M. Gill, MD1

1Yale School of Medicine, New Haven, CT, USA; 2Oregon Health & Science University, Portland, OR, USA

Introduction

Elder abuse is a complex, national problem where as few as 1 in 24 cases may become known to programs and agencies1. Existing methods for identifying victims are limited due to underreporting and varying rates of known reporting and there is a need for a feasible and acceptable solution to facilitate and improve identification of elder abuse cases2. We developed a web-based digital health tool delivered on tablets to assist older adults in self-identifying and self-reporting elder abuse3. The VOICES tool was created to be self-administered by the patients themselves and offers a private, personalized experience based on answers provided by the patient. The tool includes interactive multimedia elements such as animations, videos, and automated text-to-speech (Figure 1). VOICES aims to encourage self-disclosure of abuse by guiding the user through a screening process followed by educational and motivational modules. The educational module details common types of abuse, services available and what may happen after disclosure. The motivational module encourages the user to recognize potential harmful behaviors and conveys that the consequences of abuse could be avoided by reporting abuse to a professional. In this abstract, we will discuss results from our ongoing study to evaluate the feasibility of the digital health tool VOICES with older adults age 60 or older in the emergency department.

Methods

Design: We conducted a feasibility study of the digital health tool VOICES, as a self-administered elder abuse screening tool at a busy emergency department.

Settings: Participants were recruited from the St. Raphael Emergency Department in New Haven, CT. All procedures were approved by the Yale University Human Investigation Committee (IRB).

Participants: We recruited cognitively intact and community-dwelling individuals 60 years or older who read and spoke English. We sought diversity in age, race, and sex to match the diverse patient population that normally visit the study site. Participants were compensated $20 for their time.

Intervention: The entire study session was conducted privately for patient confidentiality. A research assistant (RA) was available and ready to answer any questions if necessary. The session (one visit) took on average 45 minutes to complete including: consent, demographics questioner, tool use on iPad, and post-survey. After obtaining consent the RA helped the older adult with putting the headphones; oriented them to the iPad and explained the process that followed. First, participants completed a demographic survey. Next, they engaged in the VOICES tool on the iPad. Following completion of the VOICES tool, participants were asked to answer a series of questions validated by our research team on a 5-point Likert scale gauging their feelings regarding feasibility, satisfaction, ease of use and appropriateness of the tool (Figure 2).

Measurement: The study data came from the following sources: (1) participant demographics data, (2) participant responses given to questions during VOICES (abuse screener, self-identification, self-reporting), (3) participant responses on the post-use-survey, and (4) observations made by the RA on enrollment, and VOICES use.

Outcomes: The study was focused on three important outcomes of feasibility including: acceptability, implementation, and practicality.
Results
The participants included 500 older adults ranging in age from 60 to 98.8 years with a mean age of 72.8 years. The majority of participants were female, white, not employed, with high school education or higher, and 65.4% used the internet at least 1-2 times per week. Out of all participants, 98.8% of patients used VOICES to completion. Participants completed the VOICES tool with an average of 8.25 minutes (SD=3.57) and 90.4% participants were satisfied (mean=4.5, SD=0.77) with the time needed to complete the VOICES tool, on a 5-point Likert scale ranging from 1 being “Very Unsatisfied” and 5 being “Very Satisfied”, and 94.4% of participants agreed that the tool was easy to use (mean=4.6, SD=0.64) on a 5-point Likert scale (1: “Strongly disagree”; 5: “Strongly agree”). When asked about the perceived appropriateness of using VOICES to learn about elder abuse, 94.4% agreed VOICES was appropriate to use (mean=4.6, SD=0.64). Also, 93.6% of participants (mean=4.6, SD=0.68) agreed digital screening would maintain privacy and anonymity, and 79.2% felt safer after using VOICES (mean=4.3, SD=0.85).

Conclusion
The results of the feasibility study show that older adults found the VOICES digital health tool to be acceptable, practical, and satisfying. Patient satisfaction was very high, a clear indication of the tool’s acceptability. We found that the tool can be highly implementable since we had a high rate of execution success when measured by the number of participants who used the tool to completion. Participants felt comfortable with the privacy given by the tool and were satisfied with how long it took to complete. Overall, we found that using VOICES to screen for elder abuse in the emergency department setting is practical and feasible. With an implementable, feasible tool to facilitate screening we aim to overcome current barriers with identification. We believe that the VOICES tool is best adapted into an existing emergency department workflow to complement existing protocols for identifying elder abuse, rather than acting as a replacement to current protocols. Further research is needed to evaluate the efficacy of the tool and to explore the use of VOICES in other health care settings outside of the emergency department, such as in primary care settings. Future work involving this tool will include cognitively impaired individuals as well as Spanish-speaking individuals to evaluate previously excluded populations from this study.

Exploring Automatic Summarization of the Hospital Course

Griffin Adams, MS¹, Emily Alsentzer, MS², Mert Ketenci, MS¹, Jason Zucker, MD¹,
Noémie Elhadad, PhD¹
¹Columbia University, New York, NY, US;
²Harvard-MIT Health Sciences and Technology, Cambridge, MA, US

Introduction

Automatic patient record summarization has been proposed to support clinicians in multiple scenarios, from making sense of a patient’s longitudinal record over long periods of time and multiple interactions with the healthcare system, to synthesizing a specific visit’s documentation. Here, we focus on hospital-course summarization, synthesizing a patient’s specific inpatient visit, from admission to discharge. A well-documented hospital course summary is crucial for continuity of care and patient safety post discharge. To motivate future research in multiple, self-contained directions, we distill task-specific characteristics to a few salient, standalone takeaways. For each, we provide evidence in the data and/or literature, before proposing implications of these findings on model development and evaluation.

Methods

Given the clinical documentation available for a patient hospitalization, our task of interest is to generate a text that synthesizes the hospital course in a faithful and concise fashion. The hospital-course summary tells the story of the patient’s admission; it conveys what was done to the patient during the hospital admission and why¹,². To carry out analyses, we create a large-scale summarization dataset, CLINSUM, using the notes from all hospitalizations between 2010 and 2014 at Columbia University Irving Medical Center (CUIMC). We extract the “Brief Hospital Course” (BHC) section of the discharge summary as the proxy (gold-standard) summary, while treating the preceding “Admission”, “Progress”, “Consult” notes as the source documentation. Table 1 shows corpus statistics.

To characterize the task and dataset, we develop several extractive baselines, and report performance in Table 2 on a held-out validation set. Oracle models have access to the ground-truth reference and represent a nice upper bound for extraction. Here, we define different sentence selection criteria for our oracle methods. ORACLE TOP-K: Take sentences with highest $R_{12}*$ vis-a-vis the reference until a target token count is reached; ORACLE GAIN: Greedily take source sentence with highest relative $R_{12}$ gain conditioned on existing summary. Extract sentences until the change in $R_{12}$ is no longer positive; ORACLE SENT-ALIGN: For each sentence in reference, take source sentence with highest $R_{12}$ score; ORACLE RETRIEVAL: For each sentence in reference, take reference sentence from train set with largest BM25 score; and ORACLE SENT-ALIGN + RETRIEVAL: For each sentence in reference, take sentence with highest $R_{12}$ between ORACLE RETRIEVAL and ORACLE SENT-ALIGN. We also provide three extractive baselines: RANDOM - extracts random sentences until summary reaches target word count (average summary length); LEXRANK - selects the top-k sentences with largest LexRank score until target word count is reached; and CLINNEUSUM - a variant of the Neusum model adapted to the clinical genre³. CLINNEUSUM is a hierarchical LSTM-based network trained on ground-truth labels derived from ORACLE GAIN.

Results

Below, we distill dataset characteristics into five standalone groupings. (1) Summaries are mostly abstractive with a few long segments of copy-pasted text. CLINSUM summaries appear extractive according to a coverage (0.83 avg / 0.13 std) and a very density (13.1 avg / 38.0 std)⁴. Yet, there is large variance within summaries. This directly affects the performance of a supervised extractive model, whose selection capability degrades as summary content transitions from copy-paste to abstractive. (2) Summaries are concise yet comprehensive. Hospital course summaries are dense with medical entities regarding disorders, labs, procedures, and medications. These entities are well-distributed across the source notes and relations are often not explicit. Collectively, this makes it a difficult multi-document task, which calls for a knowledge-intensive, domain-specific approach to assessing faithfulness and factuality. (3) Summaries have different style and content organization than source notes. Hospital course summarization involves not only

¹The average of ROUGE-1 & ROUGE-2 F-1 scores.
massive compression, but a large style and organization transfer. Source notes are written chronologically yet the way clinicians digest the information, and write the discharge summary, is largely problem-oriented. (4) Summaries transition abruptly from topic to topic without much cohesion. Clinical text, particular when arranged around a patient’s problems (problem-oriented), exhibits frequent, abrupt topic shifts, as demonstrated by very sparse entity grids (i.e., very few lexical chains). This leads to lower next-sentence prediction scores (NSP), as compared to summarization datasets in other domains (e.g., news articles). We also show that ROUGE is not correlated with local coherence. (5) The BHC sections are silver standard summaries. Discharge summaries and their associated BHC sections are frequently missing critical information or contain excessive or erroneous content.

Discussion and Conclusion

In this abstract, we construct a large-scale multi-document dataset of proxy summaries from the clinician-authored “Brief Hospital Course” section of the discharge note. Based on a comprehensive analysis of the dataset and the literature, we identify a number of implications for this complex task on future research: (1) BHC summarization models must handle abrupt transitions between extractive and abstractive text; (2) the presence of densely packed entities calls for a knowledge-intensive, domain-specific approach to ensuring and assessing the faithfulness and factuality of generated summaries; (3) our oracle analysis suggests that “retrieve-edit” frameworks are well-suited for the task of hospital course generation; (4) as opposed to coherence models based on lexical chains, we argue for the development of problem-oriented models of coherence, which are associative in nature, and reflect a deeper knowledge about the relationship between disorders, medications, and procedures; and (5) noisy reference summaries can harm model performance, but this could be mitigated by dataset filtering or reference-free evaluation approaches.

Abstract

In a multi-site retrospective study using electronic health records, we investigated longitudinal changes in ejection fraction (EF) values in patients diagnosed with heart failure (HF) and observed significant variations in comparison with a previous study based on HF registry data.

Introduction

Heart failure (HF) is a major public health problem in the US and around the world. Left ventricular ejection fraction (EF) is a critical measurement used in the diagnosis, prognosis, and treatment of patients with HF. Patients with HF have been categorized into three sub-phenotypes based on their EF: heart failure with reduced ejection fraction (HFrEF) with an EF value less than 40%; heart failure with preserved ejection fraction (HFpEF) with an EF value greater than 50%; and a borderline category called heart failure with mid-range ejection fraction (HFmrEF) having EF between 40 to 49% [1]. Previous studies on changes in EF over time in patients diagnosed with HF were mainly conducted through heart failure registry data or site-specific clinical trials involving limited patient cohorts. The widespread adoption of electronic health records (EHRs) has resulted in a dramatic increase in clinical research using EHR data, especially for phenotypic information and cohort identification. In this study, following a previously validated algorithm [2] for HF phenotype, we identified subphenotypes based on EF values, and studied the longitudinal changes in EF over time using a multi-site retrospective study design.

Methods

This multi-site study was conducted at three large academic medical centers: Weill Cornell Medicine (New York City, NY), Mayo Clinic (Rochester, MN) and Northwestern Medicine (Chicago, IL) following approval from corresponding institutional review boards (IRB). We denote these sites as Site-A, Site-B and Site-C in random order for anonymizing results from individual sites. Echocardiograms from site EHR systems were the source for patients’ EF values. Values were available either natively as structured data or extracted from echo reports through natural language processing. Inclusion criteria for the base patient cohort consists of (1) All patients 18 years or older from 2000-2019, (2) Current Procedural Terminology (CPT) code for echocardiogram, (3) International Classification of Disease-Ninth Revision (ICD-9) codes for diagnosis of HF (any 428.xx) or ICD-10 codes for diagnosis of HF (any 150*), (4) Either B-type natriuretic peptide (BNP) or pro-BNP (NT-proBNP) values recorded, and (5) Prescriptions for HF medication within 6 months of diagnosis. Subphenotypes of HF were identified by the EF value assessed at index date. From the above base HF population, we further identified patients with at least 2 consecutive EF assessments over a 1-year duration. Transitions from HFpEF to HFmrEF, HFpEF to HFrEF, and HFmrEF to HFrEF were pooled and defined as EF-

Decrease. Transitions from HFrEF to HFmrEF, HFrEF to HFpEF, and HFmrEF to HFpEF were pooled and defined as EF-Increase. Those patients with no change among EF subphenotypes were pooled and defined as EF-Stable.

Results

Table 1 lists metrics for HF patients at the three participating sites. Figure 1 shows 1-year longitudinal changes in EF values from the corresponding baseline values for HF patients who had at least 2 EF measurements available, across the three sites.

![Figure 1. EF changes in 1 year among HF subphenotypes at three sites. Each bar segment shows the proportion (%) of patients with changes with stable EFs in each category as references.](image)

Discussion

In this multi-site EHR based retrospective study, we sought to investigate the nature of longitudinal EF changes in HF patients treated for medical care at three multi-specialty hospital systems and compare them with previous studies that involve either a small cohort data or previously curated HF registry data. Using an HF registry data, Savarese et. al. [1] studied 4,942 patients (mean age 72 years, 31% female) for their EF changes during a mean follow-up time of 1.4 years, and a baseline EF distribution of 18% (HFpEF), 19% (HFmrEF), and 63% (HFrEF). During follow-up, 21% and 18% of HFpEF patients transitioned to HFmrEF and HFrEF, respectively; 37% and 25% of HFmrEF patients transitioned to HFrEF and HFpEF, respectively; and 16% and 10% of HFrEF patients transitioned to HFmrEF and HFpEF, respectively. These results were substantially different from our current observations at three sites. For all three sites, a smaller percentage of HFpEF patients reduced their EF values to HFmrEF and HFrEF. Similarly, a higher percentage of HFrEF patients improved their EF values to HFmrEF and HFpEF. Among other things, we attribute these differences mainly to patient characteristics at these centers, who are younger and have a higher proportion of females compared to the reported study. These results demonstrate the importance of replication studies to represent geographically distinct populations more broadly. Data gathered from this longitudinal study were further used to develop various machine learning models to predict EF changes in heart failure patients and will be the subject of a forthcoming manuscript.

Conclusion

While we observed differences in EF changes between the three participating sites, the observed results in general varied substantially from a previous study that employed HF registry data.

Toward phenotyping of ventilator-induced lung injury with a damage-informed pulmonary model of lung-ventilator interaction.

David Albers1,2,3, PhD, Deepak Agrawal1,3, PhD, Brad Smith3, PhD, Peter Sottile4, MD, Tellen Bennett1, MD MS, Jake Stroh1,3, and George Hripcsak2, MD MS

1Pediatrics, Section of Informatics and Data Science, University of Colorado, Aurora, CO, 2Biomedical Informatics, Columbia University, New York, NY; 3Department of Biomedical Engineering, University of Colorado, Denver, CO, 4Internal Medicine, Division of Pulmonary Sciences and Critical Care, University of Colorado, Aurora, CO.

Introduction
Mechanical ventilation is a life-saving therapy that is challenging to apply because of complex interplay between ventilator mechanics and settings, patient-ventilator interactions, disease processes, non-ventilator interventions (e.g. sedation), and the underlying pulmonary physiology[1], [2]. Mechanical ventilation can worsen lung injury through barotrauma (e.g., alveolar rupture due to pressure differences imposed by mechanical ventilation), volutrauma (e.g., overextension of alveoli), and atelectrauma (e.g., shearing forces from repeated collapse and re-inflation) that are referred to collectively as ventilator induced lung injury (VILI) [1], [2]. Clinicians attempt to minimize VILI but mortality from VILI-related syndromes, e.g., acute respiratory distress syndrome, remains unacceptably high [3].

Identifying ventilator settings that minimize VILI is challenging because the demands of gas exchange and lung protection are frequently in conflict; e.g. low pressures protect from VILI but may not provide sufficient gas exchange. Avoiding VILI is further complicated by the fact that it is difficult to understand and quantify lung injury. Both inter- and intra-patient heterogeneity is the norm. Injury is not homogenously [4] distributed within the lungs of a patient. Furthermore, the condition of the lungs change over time as injury worsens or resolves. Unfortunately, we currently lack the methodological ability to define quantifiable, interpretable phenotypes of lung function anchored to physiologic understanding that could be used to guide ventilator management. In addition to injury solely caused by the ventilator settings, VILI may be instigated and exacerbated by patient interactions with the ventilator, or ventilator dyssynchrony (VD). There are roughly seven types of VD that can occur at varying frequencies, with varying severities, and in varying confounding circumstances[1], [4], [5]. For example, the patient may inspire more than the prescribed tidal volume and cause volutrauma. While it is easy to imagine how VD may cause VILI, e.g., by straining the lung tissue, exact mechanisms and the types of VD that cause the worst injury are not well understood. Specifically: (i) the causal mechanics between types of VD and VILI are not well described, (ii) quantification of observable VILI in bedside ventilator data is missing, and (iii) quantitative understanding—e.g., a rank ordering—of types of VD regarding their level of damage and impact on outcomes does not exist. We do know that VD is strongly associated with mortality and that this association is believed to be causal. However, understanding of how, when and why VD drives VILI and mortality is missing. It has proven difficult to deeply and quantitatively investigate the relation between VD and VILI. To solve this problem and provide raw materials—knowledge extracted from data—for decision support, we need methods that can deduce new knowledge from ventilator data that can be synthesized into understandable phenotypes of degree and kind of lung injury without which clinical decision support is not possible. In this abstract we present a new mechanistic model-based method for estimating lung states from ventilator data. We show how the method can extract lung-damage information from the data not easily extracted otherwise. Similarly, we show how the new method compares to other state of the art lung-modeling efforts.

Methods
We use prospectively collected human ventilator and mouse-model data to validate a newly developed damage-informed lung model (DILM). The DILM is represented as 8 ordinary differential equations modeling pressure and volume, with four constraint equations and 20 parameters. The model, at baseline, models the healthy pressure and volume ventilation waveforms or signals. Damage or lung injury can be conceptualized as deviation from ideal pressure and volume wave forms. While there are many potential ways that an observed pressure or volume waveform can deviate from an ideal, there are particular deviations that are hypothesized to correspond to important types of lung damage. For example, some deviations indicate that a portion of the lung collapsed and only opened once it was forced open by elevated pressure. The DILM takes a healthy baseline and then adds functional terms that correspond to particular, damage specific, deviations, incorporating clinical and physiologic knowledge into the models via allowed pressure and volume diversity. This allows the model to accommodate and estimate deviation of the waveform...
Figure 1: Damage-informed lung model estimates two mouse breadths (top), and two human breadths (bottom) and a comparison of estimation error for single compartment vs. damage-informed lung models for 150 human breadths with mean squared errors of 0.25 and 0.09 respectively (far right).

estimate the same model for both humans and mice in similar situations—types of initial injury, types of VD, etc.—with the end goal of physical validation and explanation of the calculated phenotype by studying the mouse lungs. The preliminary work here includes estimates of 100s of breadths from 2 individuals and 8 mice. Evaluation of model error is quantified using the mean squared error between the data and the model.

Results
Figure 1 shows two different breaths from a mouse (top) and an ICU patient with ARDS (bottom), one healthy breath at the beginning of the experiment or middle of the ICU stay, and one injured breath at the end of the experiment or ICU stay, with MSE Volume<1.0E-5, Pressure<1.0E-2 and Volume<1.0E-3, Pressure<1.0E-1 respectively. The pressure-volume (PV) loops reveal different lung states (phenotypes). For the paralyzed mouse, the observed PV loops indicate a reduction in lung compliance and increase in hysteresis, characteristic of lung injury. The patient was sedated but not paralyzed and the ventilator was in pressure-controlled, patient triggered mode, minimizing patient-ventilator interactions. We observe lung compliance is substantially improved prior to extubation. These observations are quantified into computable phenotypes via the estimated parameters showing the ratio of tidal (peak) volume to peak pressure increased while the PEEP parameter was reduced. Finally, the bottom right panel of Fig. 1 shows the accuracy gain with the DILM versus the single compartment model via MSE for 120 sequential breadths: the damage informed lung model outperforms the single compartment model by a factor of 3 on non-VD breadths.

Conclusion
We developed a new model and used DA methods to estimate explainable and concordant lung phenotypes in mice and humans that differentiated health states using a single breadth. This provides a methodological pathway for personalized knowledge extraction and decision support for mechanical ventilation.

Introduction
Making informed health decisions is dependent on the ability to discern and interpret the information relayed. This becomes more challenging in patient-facing technologies that do not provide electronic health record integration, or direct provider communication, placing an even heavier burden on patients to interpret their health data accurately. Although probabilities of risk and benefit are often essential components of medical information, it is well established that many patients have low numeracy, which may impair their ability to understand or make decisions based on numerical information.1-5 As a result, many technology developers are concerned that patients will not be able to use numerical information or prefer words to numbers. Information technology standards emphasize the development of tools for interpreting and improving the quality of data, but there is limited guidance on how to accomplish this. Therefore, this study's objective was to assess patient interpretation and preferences for verbal probability information, such as the terms “rare” or “common”, which could be used to relay health risks and quantities such as laboratory data in patient-facing technologies.

Methods
We conducted a systematic review of the literature published through September 2020 following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA)6 statement to identify studies using verbal probability terms. Original studies conducted in English with samples representative of lay populations were included if they assessed health-related information and elicited either (a) numerical estimates of verbal probability terms and/or (b) preferences for verbal vs. quantitative risk information.

Data extracted included the main question or comparison, the outcomes measured (either numerical interpretation of the probability terms, format preferences, or both) and the population recruited. For the outcome of numerical estimates of a verbal probability, we recorded sample sizes, mean estimates, ranges, and either standard deviations or 95% confidence intervals. In the list of verbal terms, we did not distinguish between adjectival and adverbial forms (e.g., rare and rarely). For format preference, we recorded the proportions of subjects who reported preferring words, numbers, both, other, or no preference. To assess the risk of bias, we adapted criteria from the AHRQ Methods Guide for Comparative Effectiveness Reviews and Cochrane Handbook for Systematic Reviews of Interventions.7,8

Results
We identified 33 original studies that referenced 145 verbal probability terms, of which 45 were included in at least two studies, and 19 in three or more. Of the studies, 15 focused on medication side effects, 14 on disease risks, and 4 with no specified context. In 24 studies, numerical estimates were elicited for verbal probability terms. Table 1 reports weighted averages and ranges for 7 terms that were evaluated in at least four studies each. The term “rare” was estimated to mean an almost 10% risk, whereas the term “likely” averaged 72%. Variability of interpretation of these terms was high, both across studies (minimum and maximum study averages reported in column 5 and 6) and within study (ranges reported in column 7). For example, individuals estimated the term “rare” to mean anything from 0% to
80%, and “common” to mean anywhere between 10% and 100%. Among 2 large studies of European Commission guidance (EC) verbal labels, including 1,053 participants, an average of 70.1% misinterpreted the EC risk label.

In 12 studies, participants’ preference for verbal versus numeric information was captured. In 9 of the 12, majorities preferred numeric risk information alone or in combination with verbal labels. In the 5 studies that permitted a choice between verbal, numeric and combined formats, about one-third of respondents preferred the combination of numeric with verbal descriptions.

Discussion
Since 1967, 33 studies have examined lay interpretation of and preferences for verbal probability terms in health contexts. These studies show numeric interpretations of verbal terms are extremely variable and highly overlapping, providing no assurance that patients will perceive a health outcome described as “common” as more likely than one described as “rare.” The literature suggests that patients prefer numeric risk information, alone or in combination with verbal labels, therefore designing patient-facing technologies that use verbal-only risk descriptors may not be meeting patients’ preferences, resulting in poor communication. A bigger emphasis should be placed on evaluating numerical representation formats of health data and developing evidence-based guidelines on communicating probabilistic health information to empower patients to make their best-informed medical decisions.

Spillover Effects from the HITECH Act on Innovation in Medical Informatics

Nate C. Apathy, PhD¹, A Jay Holmgren, PhD², Shane Greenstein, PhD³
¹University of Pennsylvania, Philadelphia, PA; ²University of California – San Francisco, San Francisco, CA; ³Harvard Business School, Cambridge MA

Introduction

The Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 stimulated the United States economy and digitized the health care delivery system via generous subsidies.¹ Beyond this first-order goal, the HITECH Act was projected to generate an important second-order effect: an ecosystem for digital health innovation built on digitized clinical data and broad adoption of information technology systems among provider organizations.² While some progress has been made, broader economic indicators of the growth of the industry are less well-understood. Furthermore, the breakdown of how any returns were distributed across geographies, incumbent firms, academic innovators,³ and major EHR vendors is largely unknown, leaving the winners and losers of the HITECH Act unclear. In this study, we analyzed the second-order innovation returns to the HITECH Act in the form of medical informatics patenting activity to determine HITECH’s overall impact on innovation as well as any distributional effects across a variety of dimensions.

Methods

We used detailed patent-level data from two databases spanning the US and European patent offices from 2001 to 2017. For our first research question examining the impact of the HITECH Act on overall innovative activity in medical informatics, we compared medical informatics patenting in the US to Europe using a difference-in-differences study design, leveraging the PATSTAT database of global patent applications. For our subsequent research questions analyzing the distribution of innovation returns within the US, we compared US medical informatics patents to US non-medical informatics patents using the USPTO PatentsView database, which includes information on all granted US patents. We analyzed only granted patents, and stopped our data as of 2017 to account for multi-year patent approval timelines. We identified medical informatics via the PATSTAT International Patent Classification or PatentsView Cooperative Patent Classification (CPC) Subclass of G16H, Healthcare informatics (i.e., information and communication technology specially adapted for the handling or processing of medical or healthcare data). Informatics patents for our non-medical comparison group were identified as CPC Subclass G06Q, Data processing systems or methods specially adapted for managing, promoting or practicing commercial or financial activities.

In our analyses, we used ordinary least squares multivariate regression models and a difference-in-differences specification \( Y = \beta_0 + \beta_1\text{TreatmentGroup} + \beta_2\text{PostHITECH} + \beta_3\text{TreatmentGroup*PostHITECH} + e \) to estimate the causal impact \( (\beta_3) \) of the HITECH Act on 1) overall innovative activity in medical informatics, 2) innovative activity in new economic areas, and 3) innovative activity among new firms. We used OLS multivariate regression models and an interrupted time series (ITS) specification \( Y = \beta_0 + \beta_1\text{StudyMonth} + \beta_2\text{PostHITECH} + \beta_3\text{StudyMonth*PostHITECH} + e \) to estimate the impact of the HITECH Act \( (\beta_3) \) on the rate of change in innovative activity among 4) academic organizations and 5) major EHR vendors. For analysis (1), we made two comparisons. First, for our international comparison, our outcome \( Y \) is the logged number of monthly medical informatics patent applications and the treatment group is US patent applications. Second, for our within-US comparison, our outcome \( Y \) is the logged number of monthly medical informatics patents and the treatment group is US G16H patent applications (vs. US G06Q applications). For both models, the post period is defined as Feb. 2009 through Dec. 2017. Analyses (2) through (5) use outcomes defined as aggregated monthly proportions of patents attributable to the dimension of interest (e.g., % of patent applications in new economic areas). New economic areas are defined as BLS Economic Areas that were not in the top 10 most common medical informatics areas prior to HITECH. New firm entrants are defined at the firm-year level, with firms identified as “new entrants” if they have no previous medical informatics patent applications. Academic assignees were defined as those with a university or academic medical center affiliation (e.g., Regents of the University of Texas or the Mayo Clinic). Finally, major EHR vendors were defined as any of the top 10 ambulatory or inpatient EHR vendors as of 2017, per the Office of the National Coordinator for Health IT.
Results

Overall innovative activity in the US medical informatics industry increased in the years following the HITECH Act’s passage. From 2001-2008, the US averaged 602 annual medical informatics patent applications, compared to the 2009-2017 period, which averaged 1,338 annual applications, a 122% increase (Figure 1). In difference-in-differences analyses comparing the rate of innovative activity growth in the US to Europe, we found a 68.0% greater rate of growth in medical informatics innovative activity in the US as a result of the HITECH Act ($\beta$=0.519, $p$=0.001). Within-US estimates for the law’s effect on innovative activity were similar (41.1%, $\beta$=0.344, $p$=0.001). In our within-US comparisons to non-medical informatics patenting, the HITECH Act was responsible for an increase of 4.1 percentage points in the share of innovative activity in new economic areas ($\beta$=4.10, $p$<0.001), but did not have an effect on new firm share of innovative activity ($\beta$=2.54, $p$=0.07). We found more new firms annually on average after HITECH – 39% more than pre-HITECH – but new firms’ share of innovative activity did not increase as a result of the law. In interrupted time series analyses comparing the rate of growth in academic and major EHR vendor patenting, we found that the HITECH Act had a positive effect on the share of academic patenting ($\beta$=0.034, $p$=0.02), but did not affect vendor innovation ($\beta$=0.028, $p$=0.09). These two groups accounted for 2.1% -7.8% annually of all medical informatics innovation during the study period (Figure 1).

Discussion

We found substantial returns to innovative activity in medical informatics following the passage of the HITECH Act. While the HITECH Act led to major increases in US medical informatics innovation, our distributional findings of those innovation returns are noteworthy. First, rather than exacerbating geographic disparities in innovation activity, the HITECH Act’s innovation returns accrued in non-traditional technological hubs. This may be in part due to activity from academic medical centers and the local nature of health care markets. Second, while new economic areas were brought into the fold as well as a large number of new firms, the share of innovation from new firms did not change as a result of HITECH. This may be due to the high barriers to market entry in medical informatics, including high regulatory burdens put in place by HITECH itself. Third, we do not find a cooling effect among academic informatics innovators, a concern raised by the informatics community as more academic centers have transitioned to vendor EHR systems. On the contrary, our results imply that as a share of overall patenting, academic innovators have seen an increase in innovation since HITECH. Finally, the large infusion of cash to EHR vendor balance sheets does not appear to have resulted in substantive increases in innovation from these organizations. As vendors have increasingly needed to provide support and maintenance services, the influx of EHR adoption driven by HITECH may have crowded out development activities, a concern given the substantial innovations required to improve EHR usability.

Conclusion

The HITECH Act’s adoption incentives had a large, positive second-order effect on innovation in medical informatics. The distributional composition of those effects suggest that future innovation needed for usability improvement may be more likely to come from non-traditional innovation centers and academic innovators, rather than EHR vendors.

A Generalizable Framework for Cost-Effectiveness Analysis of Antihypertensive Drugs Leveraging Real-World Evidence

D. Arneson, PhD¹, R. Vashisht, PhD¹, V. A. Rudrapatna, MD PhD¹, A. J. Butte, MD PhD¹
¹University of California, San Francisco, CA

Introduction
Hypertension is a chronic disease that affects one in three adults in the United States with an estimated annual direct cost of $47.3 billion and annual patient cost of $733¹. Despite the widespread incidence and financial burden of hypertension, there does not exist a standardized set of prescription guidelines. What exists is a multitude of guidelines from different countries, agencies, and associations with varying recommendations spanning multiple drug classes and active ingredients leading to prescription tendencies which may not be optimized for cost-effectiveness.

To bypass the technical limitations imposed by the reanalysis of randomized controlled trials (RCTs), we capitalized on the vast and growing wealth of prescription drug data residing in electronic health records (EHRs). These data were the basis of our novel generalizable framework to conduct cost-effectiveness analysis of prescription drugs using real-world evidence (RWE). This framework allowed us to directly compare the cost-effectiveness of all antihypertensives to propose a new set of guidelines as ranked lists of effectiveness per dollar based on sets predefined factors.

Methods
For a given drug class, we obtained the deidentified EHR records of all patients who were treated with that drug class and met a prespecified set of inclusion criteria. The inclusion criteria for this study were: first time user of antihypertensive monotherapy, prior diagnosis of hypertension with blood pressure (BP) ≥ 130/80, prescription occurred during an outpatient visit, at least 1 year of medical history in the EHR prior to the prescription, at least 1 year of follow-up in the EHR after the prescription, each consisting of at least two visits with a physician with primary care as their primary specialty, and at least 60 days of consecutive use of the prescription.

To evaluate the cost-effectiveness of antihypertensives on patients commonly seen in the health care system, cohorts were specified for exhaustive combinations of demographics (age, sex, race, etc.) and comorbidities (type 2 diabetes, chronic kidney disease, heart failure, etc.). The resulting cohorts were 1:1 propensity score matched for all pairwise combinations of antihypertensive drug classes. We considered a number of outcomes to evaluate the relative cost-effectiveness of each drug including quality-adjusted life year (QALY), incremental cost-effectiveness ratio (ICER), ΔBP per dollar, and incidence of secondary outcomes per dollar (e.g. heart failure, stroke, dementia, etc.). QALY and ICER utility values included days as inpatient/outpatient, acute stroke, chronic stroke, myocardial infarction, acute unstable angina, coronary heart disease, and death and were assessed at 1-, 3-, and 5-years post-treatment. The follow-up for other outcomes was at the first incidence of: outcome, 5 years follow-up, 12-31-2020, discharged dead, and stopped or changed antihypertensive. Based on the selected outcome, drugs were ranked by benefit per dollar using national average drug pricing obtained from the IBM Micromedex RED BOOK.

We first built our framework using EHR data from the UCSF OMOP Deidentified (DEID) Clinical Data Warehouse (CDW) which uses the OMOP Common Data Model (CDM). This standardized data format allowed us to validate our findings using EHR data from four other academic medical centers which are part of the University of California Health system (UC Davis, UCLA, UC Irvine, and UCSD). The UC Health System EHR is ~5x the size of the UCSF EHR which allowed us to evaluate an additional ~30,000 patients who met our inclusion criteria.

Data was queried from the UCSF OMOP DEID CDW using SQL and from the UC Health Data Warehouse (UCHDW) through the UC Data Discovery Portal with Apache Spark and Databricks. All downstream analysis was conducted using R statistical software. Reported p-values have been adjusted for multiple testing using Bonferroni correction. Code will be made available to facilitate reproducibility and dissemination of the framework.

Results
We first applied our framework to 3,203 antihypertensive treated patients from the UCSF OMOP DEID CDW who met our inclusion criteria. To identify the antihypertensive drug class which produced the greatest change in blood pressure per dollar, we considered all pairwise combinations of drug classes and matched the cohorts with 1:1 propensity score matching to adjust for potential bias.
To evaluate the generalizability of both our framework and these findings, we extended our analysis to the UCHDW which included four additional academic medical centers (Figure 1). We observed a similar effect on change in systolic blood pressure between diuretics and three of the four other antihypertensive drug classes, with few statistically significant differences (Table 1 top). However, ACE inhibitors provided a greater reduction in systolic blood pressure across all five sites with a significant difference at UCLA and close to significant at UCD, UCI, and UCSF (adjusted $p$-value = 0.056, 0.05, and 0.068) compared to a matched cohort of diuretics users. These absolute changes in systolic blood pressure were then normalized to cost per day for a 10 mm Hg decrease in systolic blood pressure using cost and frequency information (Table 1 bottom). Diuretics provided the lowest cost per day for a 10 mm Hg reduction in systolic blood pressure (range of average values: $0.10$-$0.18$) versus the other four reported antihypertensive drug classes (range of average values: $0.58$-$1.63$). This is largely attributable to the similar effect of diuretics on the outcome of change in systolic blood pressure versus other antihypertensive drug classes and the low average cost of diuretics versus the average cost of the other drug classes.

**Table 1.** Results of cost-effectiveness of antihypertensives from UCHDW. Pair-wise comparisons for drug class (each row) versus diuretics across 5 sites in the UC Health System (columns). The top half of the table reports changes in systolic blood pressure after antihypertensive treatment and the bottom half reports the normalized price for a 10 mm Hg change in systolic blood pressure. For each site, the two columns give the average change in systolic blood pressure (cost per 10 mm Hg decrease) with the left number corresponding to diuretics and the right number corresponding to the drug class indicated in the row. Bolded numbers have adjusted $p$-value $< 0.05$ from a Wilcoxon rank sum test between matched cohorts of diuretics and the indicated drug class. ARBs (Angiotensin Receptor Blockers), CCBs (Calcium Channel Blockers).

**Discussion**

We developed a flexible framework that can be used to evaluate the cost-effectiveness of all drugs for a given indication. This framework was used to systematically evaluate the benefit-per-dollar of all commonly prescribed antihypertensives using RWE. Our findings were robust across multiple hospital centers in the UC Health System. The outcomes of this study can be used to inform new prescription guidelines for patient populations treated with antihypertensives. While cost-effectiveness is an important consideration in the medical decision-making process, other factors which may not be modeled by our framework also contribute (e.g. patient insurance status, side effects, medication adherence, etc.). The framework we introduce here highlights a new use for RWE that can make an immediate impact on clinical prescription guidelines for any drug class it is applied to.

Design for Health System Resilience in Challenging Times: 
A Framework for Remote Cancer Care Through Community Codesign

Eliah Aronoff-Spencer, MD PhD¹, Melanie McComsey, PhD¹; Alexandra Hubenko, MBA¹, Mingyuan Chih, PhD², Timothy W. Mullett, MD MBA FACS², Corey E. Baker, PhD², John Kim, EdD MPH³, David K. Ahern, PhD³, Michael C. Gibbons, MD MPH⁴, Joseph Cafazzo, PhD⁵, Pia Nyakairu, BID⁵, Robin C. Vanderpool, DrPH⁶, Bradford W. Hesse, PhD⁷  
¹University of California San Diego, La Jolla, CA; ²University of Kentucky, Lexington, KY; ³Brigham and Women’s Hospital, Boston, MA; ⁴Johns Hopkins University, Federal Communications Commission (FCC) Connect2Health Taskforce, Washington, DC; Baltimore, MD; ⁵University Health Network, Toronto; ⁶National Cancer Institute, Bethesda, MD; ⁷Retired (National Cancer Institute), Kailua-Kona, HI

Introduction
During the COVID-19 pandemic, screening and diagnostic testing have been significantly curtailed or delayed, resulting in projections of a substantial rise in excess deaths from cancer¹. An opportunity exists to redesign systems of cancer care in a virtual world that are more inclusive of stakeholder input and resilient through participatory design, community engagement, and iterative collaborative development of robust and sustainable solutions. This study describes a human-centered, participatory design approach to engage stakeholders in solving a community-defined problem: here, the problem of serving rural patients experiencing distress during cancer treatment. The effort represents the work of a public-private partnership referred to as the Linking and Amplifying User-centered Networks through Connected Health, or the L.A.U.N.C.H. Collaborative². In L.A.U.N.C.H., priority areas are framed where stark differences in cancer burden and resources present an opportunity for innovation. Data from the national cancer registry and Federal Communications Commission has pinpointed Appalachian Kentucky as an area experiencing a “double burden” of poor cancer outcomes and lack of access to broadband. It is here that we focused the L.A.U.N.C.H. work with the hypothesis that codesign of solutions prioritized by, and built with diverse local stakeholders, would be more effective, scalable and resilient than traditional approaches. We describe the codesign and co-creation processes in developing the MyPath app for remote cancer distress management in Appalachian Kentucky and present results from formative evaluation of the new service model as compared to the gold standard, paper-based cancer distress monitoring tool, the National Comprehensive Cancer Network Distress Thermometer (DT).

Methods

People, Context and Design. Following the Institutional Review Board approval, cancer patients, family caregivers, providers, payers, technologists and broadband providers were engaged across Appalachian Kentucky and within the University of Kentucky Markey Cancer Center. A formal design process with roots in Human Centered Design for Complex Sociotechnical Systems³⁴ was adopted. We developed the “L.A.U.N.C.H. ROADMAP” as a guiding framework of both innovative and proven approaches. The overall approach is outlined in prior work²⁵.

Designing, Prototyping and Testing. The L.A.U.N.C.H. ROADMAP contains seven Phases: Identify, Discover, Define, Ideate, Refine, Implement, and Test. In the Identify phase, existing data was analyzed, and stakeholders provided input to identify cancer distress management in Appalachian Kentucky as the key issue. In Phase 2, the stakeholders were engaged in Kentucky using ethnographic fieldwork to understand the cancer experience and to develop a network of local stakeholders for subsequent codesign activities. With stakeholder input, the problem was redefined in Phase 3. In Phase 4, ideation sessions were introduced to help participants constrain solutions but allowed for local innovation based on resources that had not been considered prior. In Phase 5 and 6 (the 72-hour co-design sprint), prototypes were described verbally, then refined with low-fidelity methods such as post-it notes. In parallel, a professional designer (Toronto, Canada), a mobile application developer (Berlin, Germany) and a design support group (San Diego) worked together to translate low-fidelity concepts to working digital applications. These working prototypes were tested and iterated in real time with participants in Kentucky. In Phase 7, two booths in Kentucky were staged to collect feedback about the codesigned instrument (MyPath), as compared to the DT. Participants were introduced to the paper version of the two instruments first, then followed by the app version. Providers were invited to evaluate the digital dashboard. Participants were given an opportunity to use these prototypes and asked to complete a 10-item System Usability Scale (SUS) to evaluate the respective prototypes. Participants and stakeholders in all
these activities are cancer patients, caregivers, providers, and other community stakeholders, including broadband Internet providers and healthcare payers.

Results

**Design Activities.** Problem Identification, contextually Discovery and problem Refinement set the stage for participatory design work. The Ideation phase was initiated with a codesign booth where participants stop and go in Pikeville and the 1st design studio where participants sit and work in Lexington, KY, to frame problems in cancer care and conceptualize new solutions. This work contextualized the 2nd design studio in an Appalachian Kentucky county (Jackson) where community members, patients and caregivers were encouraged to brainstorm granular solutions to problems or make practical those solutions that had been considered. These concepts were presented in a subsequent 72-hour co-design sprint in Lexington to select a lead candidate. A prototyped was created and Refined for the concept of cancer distress management and was rapidly Implemented as an intervention to test with patients, providers, caregivers, and others. The outcome of this work was a new software application and service model, call MyPath, developed with participants and delivered to stakeholders for implementation and formal testing.

**Prototypes and Testing.** As the existing DT is paper based, in our 3rd design studio (Oct 7-8, 2019), a comparable paper tool based on codesign and co-creation work from prior studios was developed first. Key findings from these sessions produced the following requirements (and potential pitfalls of the current approach): (a) compelling user experience; (b) framing the problem from patient perspective (my wellness and my path vs distress thermometer); (c) framing questions positively; (d) adding patient centered questions; (e) giving feedback and actionable information upon completion of the survey. Certain feedback from the design studios could not be implemented using paper-based methods alone and required digitization, e.g., to get feedback based on answers, and to communicate patient distress with providers in a timely manner. On the second day (Oct 8, 2019), participants designed a digital version of the paper app (named MyPath by the participants) as well as a digital version of the DT to assess incremental improvement from added functionality, but also to discern the role of digitization alone. Highlighted user requirements for MyPath included: compelling colors, content from the paper app, new summary screen giving immediate feedback upon completion, and actionable insights with instructions and connection to providers. A provider-centric dashboard was prototyped and designed to integrate with user generated data in the MyPath app.

**Prototype Testing.** On October 9-10, 2019, 38 participants (5 patients, 8 caregivers, 11 providers and 14 others) evaluated the paper version of MyPath and DT, 27 participants (7 patients, 4 caregivers, 8 providers and 8 others) evaluated the app version, and six evaluated the MyPath dashboard. Among instruments, the MyPath app had the highest mean SUS score (82), and followed by the DT app (78), the DT paper (74) and the MyPath paper (73). The MyPath app had a higher usability subscale score than the gold standard, the DT paper (t(63)=2.611, p=0.01) and a better overall SUS score than the MyPath paper (t(63)=2.35, p=0.02). Providers rated all instruments higher when compared to how patients rated. However, patient-rated scores increased through our iterative development path from the DT paper, to a reworded version of the MyPath paper, to the DT app, and finally to the MyPath app. Providers, on the other hand, appeared to be less satisfied with the earlier iteration of the MyPath paper than patients did. This finding may be related to clinical staff having more familiarity with the traditional language in the DT. Nevertheless, providers responded with higher usability and learnability ratings than patients did when exposed to the final MyPath app. Providers also highly rated the MyPath dashboard (mean SUS=90). It appears clinical staff grew more appreciative of the form and intent of the project the closer it progressed to its final operable format.

Conclusion

A human-centered codesign approach such as described here can address the global need for rapid health system innovation that generates effective and locally sustainable solutions, and which can scale laterally to promote resilience in the system. A pilot study is currently testing MyPath as a remote cancer monitoring tool in Kentucky.

Accurately and Privately Reporting Crowdsensed COVID-19 Data

Hafiz Asif, Ph.D., Periklis A. Papakonstantinou Ph.D., Stephanie Shiau, Ph.D., Vivek Singh, Ph.D., Jaideep Vaidya, Ph.D.
Rutgers University, New Jersey

Introduction

In the early months of the COVID-19 pandemic, testing for COVID-19 remained insufficient. This resulted in a lack of crucial information necessary to track the spread of the disease. To fill this information gap, many symptom-tracking apps were developed to collect self-reported health and demographic data – which is both personal and sensitive – and generate insights about the pandemic, e.g., current and emerging hotspots. However, these apps have two major limitations: (i) the insights are released for prefixed regions (e.g., counties) and do not allow reporting for smaller localities (e.g., neighborhoods), where outbreaks typically occur; or for regions spanning administrative boundaries; (ii) though insights are released as aggregates, no privacy is guaranteed for the people reporting data.

To address these issues, we propose a data-driven spatiotemporal partitioning based approach to develop privacy-preserving symptom-tracking (or crowdsensing) apps. Our approach provides the ability to answer, with a provable privacy guarantee, any number of arbitrarily and adaptively chosen spatiotemporal range (SR) queries to gather insights about the spread of COVID-19, without sacrificing utility. In this context an SR query asks for the number of data points in a given region and a time period, e.g., “How many people reported experiencing COVID-19 symptoms in NYC in the past 14 days?” is an SR query. The method was implemented and deployed via COVID Nearby platform.

Method

The basic idea is to create differentially private (DP) spatially and temporally indexed partitions of the space (e.g., the USA) using spatially and temporally partitioned data, and then compute the DP count of the reports (e.g., the number of symptomatic people) in each partition. These indexed partitions with their corresponding DP counts are used to answer SR queries. While it may appear to be trivial to answer queries (i.e., provide DP counts), in actuality it is significantly complex to create the right partitions to provide both privacy and utility given the arbitrary and adaptive nature of the queries. Note that here for any SR query, at any given day, we consider the past 14 days as its time period.

We propose a hybrid of data-agnostic and data-dependent approaches (in isolation, neither can simultaneously guarantee reasonable privacy and accuracy). First, we partition the space data-agnostically, based on administrative units, e.g., counties – call them divisions. Then, every day for each division, we temporally partition the data of the past 14 days (reported from the division) into k groups (i.e., partitions), and use them to create k different data-dependent partitions of the division by building k-many (ε/n)-DP quadtrees over the same division. Each of these k quadtrees uses the data from one of the k groups and is only built if it has not been built before (here k = ⌈14/n⌉ and n is chosen such that 1 ≤ n ≤ 7). We develop a novel data-partitioning (da-parti) algorithm to create the temporal partitions (every day), ensuring that no report will be included in more than n groups created over time. Thus, the overall privacy risk remains at most ε. To choose n over time, we give an empirically supported heuristic. We also give a heuristic to limit the privacy risk incurred by multiple reports by a user.

To answer any SR query on any given day, we first find all the divisions overlapping the query region. Then, for each of these divisions, we use the k quadtrees (identified by da-parti algorithm) to compute the partial answers, which are aggregated to give the final answer. Since quadtree-based spatial partitioning works for rectangular regions, it introduces some distortion for many of the divisions (i.e., counties). Therefore, we also consider the actual overlapping region (computed via polygonal approximation) of the division to better approximate the answers.

Results

Our method has been validated via an extensive empirical evaluation over spatially disaggregated real-data of confirmed COVID-19 cases. The results show that the DP answers, computed via our method, are highly accurate (Fig. 1(a), (b), (d), (e)). This is true even for the arbitrarily picked region within a division (Fig. 1(b)). Note that our approach yields a much lower error than a baseline approach that provides the same DP guarantee (Fig. 1(c)). Additionally, we can calculate moving averages (Fig. 1(d)) and rank regions very accurately (Fig. 1(e)). We used ε = 6.
Figure 1: Private counts are DP answers to SR queries computed by our method from the actual COVID-19 case count. (a) depicts the stacked bar-chart of the case counts of the 5 NY counties with the most cases. For each day: (i) two stacked bars are given, the first for the actual counts, and the second for the private counts; and (ii) each bar gives the total COVID-19 cases for the 14 days period leading up to that day. (b) juxtaposes the heatmaps of the actual and private 14 day case counts (on a log scale) for NY counties and regions within Richmond county, on 3/20/2020 and 4/13/2020. (c) compares our approach to a naïve approach (i.e., DP data aggregation over partitions created by a fixed grid with cell size of 1 Km²) guaranteeing the same level of privacy. Since both the methods are probabilistic, the boxplots are computed over 100 iterations. (d) plots the 14 days moving average for NY, TX, and the USA. (e) plots the ranking score (i.e., Kendall rank correlation coefficient) in terms of the cases in the past 14 days (i.e., SR queries) for all counties (score = 1 means the data from DP SR queries produces the same ranking as the original data).

Discussion & Conclusions

To use our approach in a similar future pandemic/epidemic, one needs to find the corresponding heuristic to select the parameter \( n \) (for the da-parti algorithm). This can be done by generating synthetic data for the new daily cases by, for example, using SIR model⁵, estimating \( d \) (which for COVID-19 is 14 days), and then following our approach.

The proposed approach can be used to create crowdsensing platforms that guarantee privacy and allow queries across arbitrary space and time bounds. Lack of privacy guarantees has been cited as a leading cause of concern by experts and non-governmental organizations. Hence, the proposed approach can be vital to allaying the concerns of experts and end-users alike. Its support for tracking across administrative boundaries is almost cognizant of the ground realities of the pandemic. Also, the approach can be generalized and applied for crowdsensing information about other health symptoms or adoption behaviors (e.g., vaccination rates). On the whole, this approach paves a way forward for countering pandemics without compromising individual privacy.

Applying Real World Data to CDISC Standards through the Joint FHIR® to CDISC® Mapping Document

Rebecca Baker, MS, MHA, BSN, RN1, Rhonda Facile, MS1, Bess LeRoy, MPH1
1CDISC, Austin, Texas, USA

Introduction

As healthcare data has increasingly become digitized, there has been a desire in the research community to harness this information to enhance and assist data collected for clinical research. [1] Clinical Data Interchange Standards Consortium (CDISC®) has a complete suite of standards supporting clinical and non-clinical research processes from planning, data collection, tabulation and analysis [2] all supported by controlled terminology maintained by the National Institute of Health (NIH) National Cancer Institute (NCI) Enterprise Vocabulary Services (EVS). [3] The HL7® Fast Healthcare Interoperability Resources (FHIR®) is a relatively new standard for exchanging healthcare information electronically. The Joint HL7 FHIR to CDISC Mapping IG leverages prior work started by the EHR to CDASH team (E2C) and the TransCelerate Biopharma Inc. to move the needle on achieving greater interoperability and exchange of data from EHRs to clinical research submission-ready datasets. Using FHIR to harness the data for clinical research using CDISC standards has been proposed as a way to capture ‘real world data’ (RWD) where clinical data not directly captured for clinical trial purposes can be used to support regulatory applications. This solution, the Joint FHIR to CDISC Mapping IG, [4, 5], is a step towards making it easier to harness RWD data and leverage it for case report forms (CRFs) and direct capture of data within systems rather than having separate data entry occur in each system.

Methods

CDISC reignited the E2C team to further define the mappings that were created when FHIR was at an early maturity level. A gap analysis was performed on the previous work for completeness and adherence to the current FHIR resources for the SDTM domains of interest: Adverse Events (AE), Concomitant Medications (CM), Demographics (DM), Laboratory (LB), Medical History (MH), Procedures (PR) and Vital Signs (VS). The focus was on FHIR resources with a maturity level of 4 and 5. Gaps were identified and FHIRPath was used to further the mapping. FHIRPath is a path based navigation and extraction language used to express terms of logical content of hierarchical data models in a platform-independent, model-independent expression. A team of FHIR experts did the bulk of the mapping work with insights and direction provided by the E2C team. The mapping was based on FHIR R4 and the latest CDASH version (CDASH IG v2.1, which corresponds to SDTMIG v3.2, SDTM v1.4).

The E2C team performed the reviews in addition to the CDISC community during an Internal Review (IR) process. Once the draft was ready, a simultaneous CDISC Public Review (PR) and HL7 Ballot Review Process occurred with the support of the HL7 Biomedical Research and Regulation Work Group. Feedback was provided from both the CDISC and HL7 communities through this mechanism. Initially the mapping was maintained in an Excel spreadsheet. Once ready for the Public Review, the content was placed in the FHIR GitHub in XML format enabling different viewing formats. This became the “source of truth” for the mapping document. The aim is to publish both the HL7-FHIR IG and the CDISC IG simultaneously as the “Joint FHIR to CDISC Mapping IG”. The publication will include a PDF rendered version of the FHIR IG with supporting mappings and FHIR IG XML source to facilitate loading into the CDISC Library.

Results

There were 153 comments received during the CDISC IR, and a total of 95 comments as part of the joint CDISC and HL7 Public Review process (37 from the CDISC PR and 58 as part of the HL7 ballot process). Once comment resolution is complete, the document will be published simultaneously through CDISC and HL7. The mapping was done at a high level using a vendor agnostic approach with FHIRPath. The mapping deliverable will provide an informative FHIR IG, supplemental mapping document with associated references. A machine-readable version also will be included in the CDISC Library.
Discussion

The community expressed enthusiasm for the project and there were many comments about mapping explicitly end-to-end to promote optimal interoperability.

The rationale for using FHIRPath was that each health system/hospital/clinic has different data elements available in their EHR system and the IT queue in health systems has historically been quite lengthy. Another factor is that each clinical trial has different data requirements that may influence what is collected. As implementers use this document, they will need to be aware of the data they are mapping to and from and the idiosyncrasies within each system.

Challenges identified were (a) the limited pool of experts’ proficient in both FHIR and CDISC standards, (b) limitations of the comprehensive view of the clinical research workflow and (c) a desire expressed to have explicit instructions for the mapping to ensure interoperability. First, there is a small minority of informatics experts with both CDISC standards knowledge and FHIR knowledge. Having a robust review was difficult because expertise was either stronger on one side or the other. Second, understanding the clinical research workflow is important. The data entry workflow means how the data flows from case report form (CRF) to an electronic data capture (EDC) system then submitted for regulatory approval. Team members questioned what the regulation would look like around the mapping and how the data could potentially be traced from entry point to submission. “When does the mapping occur?” and “what are the implications to the end result?” were concerns voiced by some team members. The third challenge noted was the ongoing request for detailed mapping. The community expressed a desire throughout the review process to have a more explicit solution and a more granular approach. The impediment to this is the current ecosystem where each health system has different data elements available for mapping. [6] Future work to make the mapping more explicit would depend on the alignment of healthcare systems worldwide in general to a more consistent standard. This explorative project served to highlight the challenges while also providing a general approach for mapping HL7-FHIR resources to CDISC standards to create compliant datasets, and mapping EHRs to EDC systems.

Conclusion

Real world data can enhance clinical research data by using the HL7-FHIR and CDISC standards. The Joint FHIR to CDISC Mapping IG provides a high-level vendor agnostic approach for implementers to map electronic data to formats used by the clinical research community for submission. Use of this mapping document can support the interoperability of clinical research data from RWD and decrease redundant data entry processes.

Toward Patient-Centered Informatics Solutions: The Role of Intersectionality

Emily Bascom¹ & Reggie Casanova-Perez, MS¹, Harshini Ramaswamy², Deepthi Mohanraj¹, Janice Sabin, PhD, MSW¹, Wanda Pratt, PhD¹, Andrea L. Hartzler, PhD¹
¹University of Washington, Seattle, Washington; ²University of California San Diego, San Diego, California

Introduction
Before informatics systems can support equitable, diverse, and inclusive healthcare, we need to understand the impact of intersectionality on people’s experiences. Intersectionality is “the complex, cumulative way in which the effects of multiple forms of discrimination (such as racism, sexism, and classism) combine, overlap, or intersect especially in the experiences of marginalized individuals or groups.” Thus, experienced oppression is not based on a single axis of identity but rather on the interwoven aspects of identities. Coined by Kimberlé Crenshaw in 1989, the term originally referred to the unique oppression that the intersection of race and gender brought to individuals. Today, the term has expanded to include other identities (e.g., ethnicity, gender identity, sexual orientation, religion, body weight, height). Incorporating the concept of intersectionality in the clinical environment, including clinical information systems, acknowledges the whole person and the complexity of patient-provider interactions. This helps to dismantle the cisnormative privileges that are present in the healthcare system, which assumes things such as a person’s gender identity is their sex assigned at birth (i.e., cisgender) and that they are sexually attracted to people from the opposite gender (i.e., heterosexual). These privileges inform providers’ implicit biases, which can contribute to unjust medical treatment of patients with historically marginalized intersectional identities and is perpetuated by health information technology. In this podium abstract, we will present the intersectional identities that Black, Indigenous, People of Color (BIPOC), and/or Lesbian, Gay, Bisexual, Transgender or gender diverse (LGBTQ+) patients shared in their stories related to unfair treatment, elaborate on what we learned from those stories, and discuss the importance of intersectionality for developing solutions to enhance patient-centered care.

Methods
To investigate the lived experience of bias towards race, sexual orientation and gender identity experienced by patients from marginalized groups, we collected twenty-five stories from patients who are BIPOC, and/or LGBTQ+. Patients shared stories in which they not only experienced bias towards their race, sexual orientation, or gender identity, but also simultaneously toward their body weight, age, or height.

Results
We interviewed twenty-five BIPOC and LGBTQ+ participants, ages 19-60 to investigate how they experience biases in healthcare. Eleven participants were BIPOC, three were LGBTQ+, and ten were BIPOC and LGBTQ+. One participant did not report being BIPOC or LGBTQ+ but described themself as an “older Asian woman.” As we expected, seventeen participants brought up racism, seven participants shared discrimination based on sexual orientation, and four participants shared discrimination based on gender identity throughout the stories they shared. Half of the participants (13/25) also shared other types of discrimination; six mentioned sexism (i.e., assumptions made based on biological sex), four mentioned sizeism (i.e., assumptions made based on the person’s weight), three mentioned ageism (i.e., assumptions made based on the person’s age), one mentioned discrimination based on their height, and one mentioned discrimination based on legal, recreational drug use. For example, PT12 explained, “I get mistaken for a high school student or an intern a lot of times at my workplace and it's a struggle... I’m not sure if that's something that's coming slowly from a patient-doctor dynamic or; you know, it's just physical attributes like skin color and height and race that lead to such biases.” These findings provide insight into how the healthcare system fails to adequately and fairly treat the diverse health and wellness needs of patients with intersectional identities. Understanding how intersectional identities play a role in unfair treatment experiences is crucial for ensuring that patients are treated holistically and with fairness in their clinical interactions and in clinical information systems.

Discussion
Although we originally focused on race, gender identity, and sexual orientation, over half of our participants, without probing, shared other types of discrimination. We realized that focusing on racism and LGBTQ+ discrimination was myopic - that understanding the whole person requires acknowledging that there are multiple layers to and many types of discrimination. This brought to our awareness that in healthcare in particular, the impact of many layers and types of discrimination are often left unexamined because they have not yet received the same
attention as medical racism, which can result in gaps in traditional training devoted only to implicit race bias in healthcare. Thus, providers may not recognize or know how to address patients’ intersectional identities. As PT16 commented, “Just in every way that I am different from [my doctor], I think, is a barrier; honestly, the more things we have in common, the more welcomed I have felt so even if that’s just gender sometimes that is even just a huge difference.” This limited understanding doctors have can leave marginalized patients feeling as though they have been taken advantage of and like they are not receiving the best care possible. For example, PT11, a Black queer woman, explained “I complained about knee pain all the time and doctors always said ‘lose weight, lose weight, lose weight’... I got injured on a [theme park] ride and... when the x-rays came back the doctor was like ‘you have arthritis in one of your knees and also your kneecap is misaligned’... I have been dismissed for a decade... maybe I wouldn’t have arthritis in my knee right now had doctors listened to me previously when I expressed pain.” The complexity of PT11’s identity greatly limited the care she received, demonstrating the opportunity for innovative health informatics solutions that can represent patients in their entirety to support doctors in providing equitable, patient-centered care.

Recommendations for the field
How can we, in the biomedical informatics community, move towards patient-centered informatics solutions that empower patients with intersectional identities and encourage holistic treatment? We must prioritize conversations that work to establish what intersectionality means in our field and how we can make intersectionality an expectation rather than an afterthought in our informatics research and practice. Intersectional identities are under-researched as a whole. For example, current demographic categories that inform patient-centered healthcare methods restrict consideration of a patients’ identities to dichotomized dimensions; women versus men, Black versus White, young versus old. These binary categories fail to account for individuals with multiple identities that influence the care they may need. The health informatics community should prioritize ways to reinvent our conventional methods of categorizing individuals in our tools--from Patients Reported Outcomes to Electronic Health Records--and in our research and informatics interventions. Patient-centered informatics solutions can only be successful by considering the entirety of who a person is, as complex as that can be, and not by who they are assumed to be based on their physical characteristics and historic privilege.

Acknowledgements
The study is supported by #1R01LM013301. We want to thank Erin Beneteau, Cezanne Lane, Drishti Vidyarthi, Calvin Apodaca, Steven Rick, Dr. Nadir Weibel, and the rest of the UnBIASED team for their invaluable contribution to the hours of conversations we had surrounding this work and important topic. Most importantly, we would like to thank our participants for sharing their stories.

Beyond Absolute Acuity: Changes in Relative Acuity Direct Proactive Rapid Response Teams toward Meaningful Interventions

Joseph Beals, PhD¹, Kathy Belk, BA¹, Sheila Coonan, RN², Jacqueline Laird, RN³

¹PeraHealth Inc., Charlotte, NC; ²Yale New Haven Hospital, Saint Raphael Campus, New Haven, CT; ³Bridgeport Hospital, Bridgeport, CT

Abstract

Early warning technologies increasingly support pro-active clinical rounding on hospitalized patients, but often generate alerts of questionable utility. Simply identifying the most acute patients is unlikely to provide net new information to caregivers. SWAT nurse interventions prompted by the Rothman Index mobile application at Bridgeport Hospital and Yale New Haven Hospital demonstrate that alerts triggered by changes in patient acuity have value that is unrelated to the patient’s overall acuity level. Pro-active rounding teams may be more effectively directed to patients using alerts based on changes in a patient’s acuity without reference to fixed acuity thresholds.

Introduction

As part of the 100,000 Lives Campaign in 2004, the Institute for Healthcare Improvement recommended that hospitals deploy rapid response teams (RRTs), or groups of critical care clinicians trained to act quickly when a patient’s condition declines. By 2010 over half of US hospitals had implemented an RRT.¹ However, the last decade has shown these efforts to have mixed results.²³ Specifically, commonplace failure of the afferent limb – the ability to detect at-risk patients – undermines RRT effectiveness.³ Advances in technology have improved the availability of track-and-trigger early warning score (EWS) systems, however over-alerting from such tools can lead to inefficient use of clinical resources and alert fatigue.⁴ The majority of EWS systems trigger an alert when a pre-defined acuity threshold is crossed.⁵ While threshold-based alerts may correctly identify patients with significant physiological impairment, the condition of such patients is often already known to caregivers and hence the alert provides little incremental value.⁶ Conversely, changes in acuity, even among modestly impaired patients, may not have been appreciated and may be meaningful. This work shows that alerts based on a patient’s relative change in acuity has clinically actionable value across the acuity spectrum.

Methods

SWAT nurses at Bridgeport Hospital (BH) and the Yale New Haven Hospital, Saint Raphael Campus (SRC) used a secure mobile app to receive real-time deterioration alerts for patients on adult, non-ICU inpatient units.⁷ Alerts were based on relative changes, rather than threshold values, of the Rothman Index⁸ (RI) acuity score (PeraHealth, Inc., Charlotte, NC). An RI score of 100 corresponds to no impairment, with decreasing scores implying increasing acuity; RI scores around 40 are typical of patients being considered for ICU level care. Two alerts based on acuity changes were defined: High Alerts for patients whose RI scores dropped by 40% or more over a 12-hour period, and Medium Alerts for patients whose RI scores dropped 30% or more over a 24-hour period. If score changes met both sets of criteria the patients were assigned the High Alert status. Patients with RI scores below 20 were covered by a different alerting rubric so Medium/High warning criteria did not apply. As part of the clinical response protocol, nurses identified actions taken using a structured list, which included over half a dozen resultant interventions spanning a range of urgency from discussion of the patient with the medical team, to the initiation of orders for changes in treatment or additional diagnostics, to calling the full rapid response team to the bedside, calling a code blue, or transferring the patient to a higher level of care. Data from 7,796 alerts from Jan-Oct 2020 were analyzed to determine (a) the acuity level of patients at the time of the alert and (b) how the utility of the alerts (measured by whether or not there was a resulting clinical intervention) varied as a function of patient acuity at the time the alert was triggered.

Results

Owing to alert definitions requiring either a 30% or 40% drop in score over a specified timeframe, RI values of 70 and 60 are the highest scores that can be associated with Medium and High alerts, respectively, of which there were few or no instances. As shown in Figure 1, the preponderance of alerts occurred at lower RI scores (e.g., 96% of High
and 73% of Medium Alerts were associated with RI scores below 45). This is a function of both the baseline (pre-deterioration) acuity of the population as well as the fact that patients with minimal physiologic impairment are generally less prone to significant deterioration.

As shown in Figure 2 the proportion of alerts resulting in an intervention (i.e., alerts with the clearest value) was remarkably consistent across the acuity spectrum, over the RI range of 20 to 60. That is, for a given alert type at a given facility, the likelihood that the alert prompted a change in patient care did not vary with patient acuity.

**Discussion**

Threshold-based acuity alerts implicitly assume that higher acuity patients should be flagged, and that they will benefit from additional clinical attention. In most cases, nurses and physicians are aware of which patients are the sickest, and alerting on these patients provides no new insights. In contrast, deteriorating patients, whether of high or moderate acuity, are the patients whose evolving condition may not be easy to recognize. If it were true that higher acuity patients are more likely to receive interventions on the basis of proactive review, then alerts associated with lower RI scores should show a higher rate of interventions than alerts on less acute patients (those with higher RI scores). In fact, what we see in Figure 2 directly supports the contention that it is the change in a patient’s acuity, regardless of their overall acuity level, that is important to identify.

**Conclusion**

We show that the utility of EWS alerts, as determined by the rate of meaningful subsequent interventions, is independent of overall patient acuity. It is the relative change in any given patient’s acuity, and not alerts focused on absolute acuity thresholds, which can most effectively guide pro-active SWAT or RRT nurse rounding. This is consistent with clinical intuition, and helps explain why alerts using only fixed acuity thresholds are likely to provide an excess of unhelpful alerts on higher acuity patients, while missing important changes in lower acuity patients.

A Framework to Support Diversity, Equity, and Inclusion within AMIA Through Strengthened Pathways, Support and Leadership

Oliver J. Bear Don’t Walk, IV MS¹; Kevin Wiley, Jr., MPH²; Lois Walters-Threat, DNP, MS, RN-BC³; Rebecca L. Rivera PhD, MPH, CPH²; Martin C. Were, MD MS, FIAHSI, FAMIA⁴; Tiffrani J. Bright, PhD, FACMI⁵

¹Columbia University, New York, NY; ²Indiana University, Indianapolis, IN; ³American Nurses Credentialing Center, Silver Spring, MD; ⁴Vanderbilt University Medical Center, Nashville, TN; ⁵IBM Watson Health, Cambridge, MA

Introduction

In June 2020, the AMIA Board of Directors established the Diversity, Equity, and Inclusion (DEI) Task Force (now Committee) to advise AMIA on specific, actionable steps addressing DEI matters for strategic planning. An immediate charge of the DEI Task Force was to recommend a framework to support workforce diversity, exposure to biomedical informatics, awareness of AMIA, and improved recruitment and retention of students and faculty. Objectives were to strengthen pathways into biomedical informatics and address the unmet needs of AMIA members who are part of marginalized or historically excluded groups. This was in recognition that achieving a diverse and inclusive organization and environment would enable better and bolder decision-making while improving outcomes for the organization. Philips states, “Diversity jolts us into cognitive action in ways that homogeneity simply does not⁴.” Successful implementation of the proposed framework would ultimately benefit all members through collaboration.

Methods

To develop the framework, DEI sub-committee members conducted desk-reviews of available literature. Additionally, a brief scan of comparable professional association reports and programs for DEI initiatives was conducted for comparison. Scanned professional associations were of similar size to AMIA, focused on STEM and/or medicine, and had task forces or committees drafting actionable DEI strategies. Iterative sessions of brainstorming, editing and organizing activities were conducted over nine months to identify potential activities. A consensus-based approach was then used to prioritize identified activities needed to meet the specified objectives. Activities were represented using logic models⁵, which ensured that activities, resources, outputs and outcomes were comprehensively considered. Outputs are direct, tangible results of the activities. Outcomes are the desired results of actions. Logic models flow from activities to outcomes. Activities represent concrete steps AMIA can take to improve DEI.

Results

Comparable organizations have developed diversity initiatives to improve overall representation of marginalized or historically excluded members. Many DEI efforts were recently initiated and usually emphasized one point of the DEI triad. A common theme among scanned organizations was a focus on improving pathways into their respective fields by targeting students and trainees. These efforts directed organizational resources to develop strategies and committees to organize and mobilize members to improve DEI within each discipline. In all, the DEI initiatives of five other professional organizations were compared to the proposed framework.

Overall, there are 23 activities spread across three logic models: (a) Recruitment & Retention, (b) Supporting workforce diversity, and (c) Exposure to Informatics. The Recruitment & Retention activities contained 12 recommendations; Supporting workforce diversity contained eight recommendations; and Exposure to Informatics contained three recommendations. Recruitment & Retention activities pertain to building mutually beneficial partnerships with and pathways into AMIA for institutions and organizations that serve marginalized and historically excluded communities. It also brings into focus intentional leadership and mentorship for marginalized and historically excluded members. Supporting Workforce Diversity domain has an initial aim of building transparency and knowledge about the diversity climate within AMIA. Exposure to Informatics has one main goal to fortify existing and creating new outreach programs with broader scopes and partnerships. Here, two action items are presented for each of the three logic models outlined in Tables 1, 2, and 3.

Conclusion

The logic-model-based framework developed here provides a roadmap to guide AMIA in actualizing its goal of promoting diversity, equity, and inclusion of its membership. Making AMIA a welcoming home for all would take thoughtful and targeted actions to correct barriers that continue to keep many communities from being represented in informatics more generally. Some activities will have outcomes that can be realized within a year, and others may
take years for measurable results. A commitment to DEI is an ongoing process of unlearning these systems of oppression and then learning alternatives that promote the wellbeing of all. The proposed recommendations align with our field’s commitment to the ethics outlined in the Belmont Report\(^1\). To authentically realize these principles, they need to extend beyond the lab setting. How can respect for persons, beneficence, and justice be truly realized in our research without first addressing systems of oppression which violate these principles within our own community? Even if one is only concerned with ethics in research, a commitment to these principles necessitates a diverse, equitable, and inclusive community as a foundation.

Forecasting Inpatient Bed Demand to Respond to the COVID-19 Pandemic

Biplab Sudhin Bhattacharya PhD1, Debdipto Misra MS1, Eric Reich MSHI1, Jason Puckey BS1, David Vawdrey PhD1
1Geisinger Steele Institute for Health Innovation, Danville, PA, USA

Introduction – The COVID-19 pandemic caused extreme swings in hospital occupancy across the United States. Expecting a surge in COVID-19 cases in the spring of 2020, our institution canceled elective surgical procedures, made surge beds available, and redeployed staff. As the first wave of COVID-19 cases receded, a large backlog of non-urgent surgical cases needed to be scheduled—a proposition that threatened to overwhelm inpatient bed capacity. As we faced a second COVID-19 wave in the fall and winter that was 3-4x more severe than what we experienced in the spring, managing bed availability by titrating scheduling of surgical cases became even more important.

To help with short- and long-term management of inpatient capacity and operating room scheduling, we developed a time series Seasonal Autoregressive Integrated Moving Average (SARIMA) model. At the early stages of the pandemic, predicting COVID-19 specific admissions was a difficult task1. We used this model to produce 7-day occupancy forecasts for all medical, emergent surgical, and non-emergent surgical inpatient census for eight hospitals. The occupancy forecasts were distributed daily to clinical and operations leaders to aid decision-making in areas of discharge planning, staffing and surgical scheduling.

Methods – Each day for eight hospitals, the forecast models were retrained using the most recent inpatient occupancy counts. Occupancy was calculated as the number of medical, emergent surgical, or non-emergent surgical patients occupying inpatient beds, plus the number of patients that were being held in alternate locations such as the emergency department, post-anesthesia care unit, or cardiac recovery suite. The occupancy data were obtained from the bed management system in the institution’s electronic health record (Epic Corp., Verona WI).

There are various methodologies that can be used to predict occupancy2. Before the pandemic the analytics team at Geisinger had been developing a LSTM (Long Short-Term Memory) neural network approach which was selected after being tested against other time series models (ARIMA, exponential smoothing and SVR). The pandemic changed the statistical characteristics of hospital occupancy and the LSTM approach started performing poorly (Table 1). SARIMA models are univariate models, that are more responsive to unexpected fluctuations in the data, and are easier to implement and deploy.

We implemented three SARIMA models to predict occupancy 1-7 days in the future for: 1) medical, 2) emergent surgical, and 3) non-emergent (elective) surgical patients. The seasonal component of the model accounted for weekly patterns in bed occupancy (e.g., more inpatients on weekdays vs. weekends). Figure 1 shows an example of high variation in occupancy at one of our hospitals at the outset of the pandemic (beginning mid-March 2020). Such variation is indicative of non-stationarity in the input data, caused here by mass cancelation of surgical cases, declining medical inpatient census for non-COVID-19 patients, and unpredictable volumes of COVID-19 admissions. To account for this non-stationarity, an auto-parametrizing technique3 was implemented, which selected the optimal parameters for the SARIMA models each time they were run. Model performance was measured using mean absolute error (MAE) and mean absolute percentage error (MAPE).

It is vital that predictive models produce actionable insights4. The framework we used for deployment is shown in Figure 2. The models ran on an on-premise Hadoop Cluster which houses the institution’s enterprise data warehouse. An automated daily process tabulated medical, emergent surgical and non-emergent surgical occupancies that were used as model inputs. An automated report was generated (Figure 3) and sent by email to several hundred stakeholders, including executives and clinical and operations leaders. Additionally, the forecast data were included within other dashboards across the health system.

Results – Table 2 shows the SARIMA model performance for total bed occupancy from September 01, 2020 to October 30, 2020 for Geisinger Medical Center, an academic medical center with 367 adult beds. The MAE (actual bed occupancy vs. predicted) was between 13.7 and 16.8 beds for 1-7 days in the future. Overall MAPE for the evaluation period was 4.7%.

Discussion – Simple ARIMA models were among the first tools to predict bed occupancy5. Using a seasonal variant to account for weekly fluctuations along with the auto-parametrizing feature based on the stepwise algorithm1 enabled the model to adjust itself to the wide fluctuations in occupancy we observed during the COVID-19 pandemic. This model adapted to these fluctuations much better compared to a more sophisticated neural network model.

There are significant costs associated with overstaffing, while suboptimal patient care and dissatisfaction occur because of understaffing. The daily distribution of occupancy forecasts generated by our models allowed clinical and operations leaders to make data-driven decisions in planning for resources, staffing, discharges, and surgical scheduling. The availability of accurate
Forecasts of 7-day census became a key tool for Geisinger in battling the COVID-19 pandemic, and we expect the models to be equally valuable in the future to manage bed capacity in an increasingly challenging healthcare delivery environment.

LVHNet: Detecting Cardiac Structural Abnormalities with Chest X-Rays

Shreyas Bhave, MA1 Pierre Elias, MD2, Victor Rodriguez, MPhil1, Timothy Poterucha, MD3, Simi Mutasa, MD2, Jay Leb, MD3, Nir Uriel, MD2, Adler J Perotte, MD MA1
1Columbia University, Department of Biomedical Informatics, New York, NY, USA; 2Columbia University Irving Medical Center, New York, NY, USA

INTRODUCTION. Early identification of structural changes to the heart such as left ventricular hypertrophy (LVH) and dilated cardiomyopathy (DCM) is critical to improving outcomes in heart failure. Initial signs and symptoms of early stage heart failure can be nonspecific, and there will often be a delay in diagnostic echocardiography while fast, inexpensive chest X-rays (CXRs) are much more frequently performed. In the same way breast cancer screening mammograms evolved from chest radiographs, there is promise that CXRs can form a basis for early heart failure detection. Deep learning models utilizing CXRs have lacked both variety and quality in cardiac labeling. Prior models have primarily focused on detecting cardiomegaly, a catch-all term for an abnormally enlarged heart and often the only statement radiologists will make about the heart. Despite this, the radiologic comment of cardiomegaly is known to be poorly predictive of cardiac disease and does not trigger meaningful clinical action. We sought to replace cardiomegaly with more accurate and clinically actionable labels of structural abnormality derived from gold standard echocardiograms. These structural abnormalities lead to enlargement of the heart and are the key changes that occur before the development of overt heart failure. The detection of structural abnormalities consistent with LVH and DCM phenotypes could lead to earlier diagnosis of cardiac pathology, improving the management of heart failure.

DATASET AND LABELS. We created a dataset of 88,769 echocardiograms and 49,620 posteroanterior (PA) CXRs performed within 12 months of one another on 16,579 unique patients from Columbia University Irving Medical Center. CXR images and tabular data from echocardiograms were extracted, including LV end-diastolic dimension (LVEDD), end-diastolic interventricular septal thickness (IVS), end-diastolic posterior wall thickness (PWT). We constructed three gold standard labels using the echocardiogram data corresponding to each CXR: LVH, Severe LVH (SLVH) and DCM. The presence of positive labels was: 13,156 for LVH (26.3%), 4,326 for SLVH (8.6%) and 1,583 for DCM (3.2%). From this data, we constructed a train (N=38943, P=13059), evaluation (N=4767, P=1632), and test (N=4648, P=1633) split.

MODEL ARCHITECTURE, PREPROCESSING AND FEATURE MAPS. CXR images were cropped to a 1:1 aspect ratio, downsampled using bicubic interpolation, and normalized using contrast limited adaptive histogram equalization and minimax normalization. In order to improve the generalization performance of the model, we augmented our dataset by adding Gaussian noise (mean=0, var=0.05). All experiments were conducted using DenseNet-121. We devised two separate tasks: (1) multi-task binary label prediction on all three labels and (2) prediction on a single composite label which represents presence of LVH, SLVH or DCM. We used gradient-weighted class activation maps (Grad-CAM) to produce heatmaps visualizing areas of the images which were most responsible for driving prediction.

![AUC-ROC and AUPRC Curves for both multi-task and composite models](image)

*Figure 1 AUC-ROC and AUPRC Curves for both multi-task and composite models*
**COMPARISON TO RADIOLOGISTS.** We compared LVHNet's performance on detection of cardiac structural abnormality to radiologists commenting on presence of cardiomegaly via radiology reports with the label being extracted on the entire test set via CheXbert. We manually reviewed a random sample of the test set radiology reports to confirm accuracy of the labeler and remove ambiguous cases. Cardiac structural abnormality was defined as the presence of LVH, SLVH or DCM as identified via echocardiography. In discussion with chest radiologists, consensus was achieved that the fairest comparison to the radiologist label of cardiomegaly would be the composite label.

**RESULTS: MODEL PERFORMANCE.** We report the ROC and PR curves for the model in the multi-task and composite label setting (Figure 1). The multi-task model exhibits the best AUC-ROC on DCM (0.833) and strong performance on LVH (0.778) and SLVH (0.795) as well. The model performs best overall on the LVH label as the AUPRC is significantly better (0.554) in comparison to the other labels. The model maintains a relatively good AUC-ROC (0.774) and AUPRC (0.603) on the composite task.

**RESULTS: FINDINGS FROM GRAD-CAM.** The multi-task model Grad-CAM heatmaps demonstrate that for true positives, the model consistently focuses on structures of the heart across all structural abnormalities. Meanwhile, the true negative heatmaps highlight areas in the thoracic/abdominal cavities with no propensity for focusing on the heart.

![Figure 2 Grad-CAM heatmaps for targeted cardiac diseases. Blue borders: true positives, Orange borders: true negatives](image)

**RESULTS: PERFORMANCE COMPARED TO RADIOLOGIST CARDIOMEGALY READS.** Lastly, we compared the model’s ability to accurately detect cardiac structural abnormalities versus the official diagnostic read from a radiologist (Table 1). LVHNet outperforms radiologists in detecting structural abnormality on accuracy and F1 score. The accuracy of radiologist reads of cardiomegaly with CXRs was 70.5% while echocardiography has been consistently shown to have accuracy in excess of 97% at diagnosing structural abnormality. Our model is able to achieve closer to ground truth accuracy by training on these higher quality labels. These results demonstrate a significant advancement in the ability to detect cardiac structural abnormality from chest X-rays and the benefit of leveraging labels which are more specific indicators of cardiac pathology than cardiomegaly. Since state-of-the-art deep learning models using CXR data all depend on the cardiomegaly label, LVHNet represents an important step towards detecting actionable cardiac structural abnormality from CXRs.

Multi-Channel LSTM for Modeling Irregularly Sampled Time Series

Shreyas Bhave, MA1, Adler J Perotte MD MA1

1Columbia University, Department of Biomedical Informatics, New York, NY, USA

INTRODUCTION. Multivariate irregularly sampled time series data are ubiquitous in many data modalities across healthcare including principally Electronic Health Records (EHR) data. They are defined in the context where a dataset contains a set of time series where there are D distinct features, the time intervals between successive observations are irregular and all D features are not always present at each successive time point. Deep learning approaches that deal with modeling time series data such as RNNs and LSTMs have achieved state of the art results on many prediction tasks. However, these models are primarily used for regularly sampled data and are based on regular sampling assumptions. Furthermore, they are known to struggle in modeling signals that occur at different timescales simultaneously. In particular, they struggle to capture long-term dependencies in the data which may inform prediction. EHR data consists of data streams observed at very different rates along with hospital visits which occur at irregular intervals. Moreover, important downstream prediction tasks of interest such as in-hospital mortality, decompensation, and length of stay rely on effectively modeling the full history of a patient’s visit. In order to address these issues, we propose the Multi-Channel LSTM which consists of D separate LSTM channels, one for each feature, which are tasked with learning the irregular dynamics of each signal separately and combining all the signals to produce a prediction. We tackle the challenge of irregular sampling within each signal by incorporating information about the time gaps between data points directly. We show that this model outperforms baselines on a decompensation prediction task using MIMIC-III data.

PAST WORK. There are broadly two approaches that past work has taken: (1) Discretize the irregularly sampled sequence into equal bins and develop an interpolation model for data that is missing prior to using a standard RNN1,2 (2) Incorporate the time gaps between subsequent data points directly in the RNN by modeling the dynamics of the hidden state3,4. We propose an approach which is closer to (2) with the main distinction being that we model each feature separately, incorporating time differences between subsequent observations of the same feature.

METHODS: Multi-Channel LSTM (MC-LSTM). An unrolled representation of this model is shown in Figure 1. In this figure, there are three separate channels (one for each feature) which have their own LSTM. Each channel is trained using both the data observed at each time as well as the time difference between the current and previous timestep. Outputs can be predicted at any time. For prediction at any given time, we extract the hidden states of all channels which encode a representation of the entire history of the irregular time series and use a feed forward neural network using the concatenated hidden states to combine the signals. Such a model has a number of theoretical advantages: (1) It is amenable to modeling features which occur at vastly different timescales, mitigating the problem of vanishing gradients that is typically a challenge for such time series models. (2) It does not require building an imputation model which can be challenging especially when data are missing not at random.

METHODS: Hierarchical Multi-Channel LSTM (H-MC-LSTM). The principal drawback of the MC-LSTM is that it does not directly model dependencies across the features overtime as a model which leverages a multivariate vector representation and a single LSTM does. In order to remedy this issue, we introduce a hierarchical version of MC-LSTM which collects the hidden states across all channels and uses them as input to a regularly-spaced LSTM. This regularly-spaced LSTM contains information about the relationships between features and the overall dynamics of the hidden states across all channels. An unrolled representation of this model is shown in Figure 2. In this figure, there are three separate channels and one higher-level regularly spaced channel. This regularly-spaced channel incorporates all of the latest hidden states and times since they were observed for all the channels at a user-specified regular interval. Subsequently, this regularly-spaced channel’s hidden state is used along with the channel-specific
hidden states for prediction at any given time.

**DATA AND EXPERIMENTS.** In order to evaluate the model, we make use of the mimic benchmarks\(^5\) task of decompensation. The task is to predict whether a patient’s health will rapidly deteriorate in the next 24 hours. In particular, the task is a binary prediction task at each timestep from admission to the end of the ICU stay, where a positive label occurs in all timesteps 24 hours prior to death. Here, death is used as a proxy for decompensation as it is a relatively easy outcome to accurately label in the MIMIC-III\(^6\) database. We chose this task because it is widely used in the community, is of particular interest for early warning scoring and is supervised at each timestep. It also consists of a set of 17 physiological features which are sampled at varying timescales (e.g. heart rate, glucose, pH). The baselines we compared against for this task were a channel-wise LSTM, a discretization strategy used in the original mimic benchmarks paper (their best model) and our own vanilla LSTM model which is discretized and imputed using fill forward imputation.

**RESULTS AND DISCUSSION.** The results in Table 1 show that the MC-LSTM and H-MC-LSTM both outperform the two baselines on the AUC-PR metric. The channel-wise LSTM has the same model capacity as MC-LSTM but uses a discretization strategy. This shows that the performance improvement is not a result of a difference in the number of model parameters. The MC-LSTM is better able to capture the signal from each individual time series and avoids introduction of noise due to discretization and imputation techniques. Thus, the MC-LSTM shows great promise for modeling irregularly sampled data. In the future, we hope to further test this model in other risk prediction settings where both short and long term signals may be important.

**Table 1 Results on two baselines versus MC-LSTM and H-MC-LSTM (bolded results significantly outperform baselines)**

Latinx Acculturation Scales: Scoping Review and Novel Scale Selection Tool

Anweysha Bhowmik*, MS1, Logan Cameron*, BS1, Julia Ivanova, MA1, Stanley Haynes, MAS1, Ariana Cano, MAS1, George Runger, PhD1, Anita C. Murcko, MD1
1Arizona State University, College of Health Solutions, Scottsdale, AZ
*These authors contributed equally

Introduction: “Acculturation” has been defined as the process by which cultural groups adopt the customs and behaviors of a culture²³. The concept of acculturation is dynamic, moving from linear constructs like assimilation, into complex multivariate concepts such as biculturalism, multiculturalism, and cultural pluralism. Though numerous scales in multiple domains now exist, few studies quantify and categorize acculturation scale usage, so researchers seeking scales specific to their discipline or population are often limited to the validation study or a qualitative analysis. This study applies the National Institute on Minority Health and Health Disparities (NIMHD), a framework¹ that facilitates analysis of minority health and health disparities research portfolios to assess progress, gaps, and opportunities. Visualizations are based on the Sankey diagram popularized by Tufte⁴, correlating proportion to the diagrammed flows of information.

Method: PubMed, Scopus, and PsycInfo were searched using an optimal Boolean search string for articles published in the US 2015-2020. Books, editorials, and literature reviews were excluded. After eligibility screening, 32 articles remained. Multidisciplinary researchers categorized articles and acculturation scales using the NIMHD framework¹. Zotero was used for data storage, organization, and data preprocessing. Using a contingency table of domains, population size and acculturation scales, a Sankey-based tool for selection of acculturation scales was created using Tableau⁵.

Results: From the scoping review we identified and categorized 17 validated Latinx acculturation scales. We note that such scales must be interpreted in the context of geographic influences, generation of immigration, and other socioeconomic factors⁵. This standardized data on validated acculturation scales (click here⁷ for table) was transformed via the Tableau Sankey diagram software, as illustrated in Figure 2. A novel decision support tool, Latinx Acculturation Scale Selection Tool, was created based on Sankey Tableau software that permits users to input population and research domains, apply filters for influence and health outcome domains and identify patterns in their area of interest, thereby optimizing Latinx acculturation scale(s) selection.

Conclusion: Using the NIMHD framework, we analyzed the past 5 years of Latinx acculturation scale literature to create the novel, interactive, Tableau-based Latinx Acculturation Scale Selection Tool with filters for influence and health outcome domains. Researchers and health plans can use the Tool to retrieve acculturation scale use patterns in their area of interest, thereby informing tool selection based on user-defined parameters.
Figure 1. Flowchart of literature search and screening process.

Augmenting Barbershop Initiative Health Promotion with Wearables in African-American Populations
Lisa Anne Bove, DNP, RN – BC, Stephanie Turrise PhD, RN-BC, APRN, CNE, CHFN-K, FAHA and Rachel Carroll, PhD University of North Carolina Wilmington, Wilmington NC, United States

Introduction
According to the 2019 American Heart Association Heart Disease and Stroke Statistics, non-Hispanic African-American men have higher rates of hypertension (HTN) and the highest rate of HTN-related deaths of any racial, ethnic, or gender group in the United States. African-Americans develop cardiovascular disease (CVD) at a younger age than other ethnic groups, and because they remain undiagnosed longer, they experience increased morbidity (heart disease, kidney disease, eye disease) and mortality. Reducing systolic blood pressure (SBP) significantly reduces the risk of CVD and all-cause mortality. Exercise is significantly associated with blood pressure (BP) reduction regardless of the individual’s initial BP level, gender, physical activity level, type of exercise performed, or exercise training program.

A number of studies have demonstrated health improvements due to monitoring health through activity trackers such as Fitbits®. Increased physical activity reduces BP and activity trackers have been shown to increase activity. Thus, wearing an activity tracker may reduce BP. While 19% of Americans reported using an activity tracker such as a Fitbit® or a smartwatch, low income, African-Americans are least likely to use them.

Health promotion interventions have been implemented in barbershops to help reduce risk factors and promote health. Barbershops are often community centers serving diverse populations. Barbers and stylists are willing participants in health promotion activities and help enroll their customers in research studies. Victoria and colleagues found significantly higher rates of HTN control in the experimental group than the control group at the 10-month follow-up of their barbershop intervention. Likewise, Hess and colleagues found that when barbers offered encouragement and told their success stories, their clients who received the increased exposure also demonstrated higher rates of HTN control. While this form of health outreach is becoming more common, there are no studies reporting on combining health promotion with the use of wearable activity trackers as part of a barbershop initiative.

The purpose of this study was to determine feasibility of an activity tracker intervention to measure heart rate, steps, and sleep in African-Americans to determine 1) if the use of these activity trackers impacted health behaviors and BP, 2) the relationship among wearing patterns, steps, heart rate, sleep, and BP, and 3) any technical or wearability issues with the Fitbits®.

Methods
African-American barbers and stylists who are part of a regional medical center’s Barbershop Initiative were recruited from three shops. Participants signed consent, completed an initial survey, and were provided assistance setting up their Fitbit Inspire HR®. Participants wore the Fitbit® for a month collecting heart rate, steps, and sleep data. Weekly BPs, wearing patterns and health questions were collected. Upon study completion participants completed another survey describing their wearing patterns and perceived impact to health. Descriptive and inferential statistics including multiple linear regression and t-tests using R® were conducted.

Results
Out of 14 participants, the majority were males (71%) with known HTN (64%), although only 29% took antihypertensive medications. Age ranged from 25-75 years (M=46, SD = 17) and body mass index (BMI) ranged from 19–46 (M=30, SD =8.5). Preliminary results suggest that over the 30-day period, users averaged 7876 steps a day with an average resting heart rate of 72 beats per minute. The average change in systolic BP ranged from -22 to 34 (M=2.46) and diastolic BP ranged from -11 to 13 (M=3.6) where negative values indicate worse blood pressure compared to baseline. All but one participant reported wearing the device all or most of the time. All participants wore the device to sleep, though not every night. Nearly 30% (N=4) wore a tracker before, but admitted they did not monitor the results.
Participants also reported they were exercising more (N=7, 50%), getting more sleep (N=5, 36%), and felt they had better blood pressures (N=10, 71%). Anecdotally, participants reported that they ‘paid attention’ to the automated reminders and alerts and some reported increasing exercise based on the reminders.

Discussion

While there were no statically significant changes in BP, participants reported more activity and a focus on improving their risk factors for CV disease. Researchers were able to access information from the trackers while the participants were part of the study. While HR and sleep data was captured, it was difficult to correlate without hourly data extracts. Since participant's smartphone minutes were not unlimited, they often turned off Bluetooth, and so needed reminders to synchronize their Fitbits with the application on their phone each time we met with them. Adding an application program interface (API) to extract the data will improve quality of data for statistical analysis for meaningful interpretation about the relationship between HR and sleep.

Developing an Academic-Industry Internship to Train Next-Generation Biomedical Informaticians

Tiffani J. Bright, PhD, FACMI1, Allison B. McCoy, PhD, FAMIA2,
Dilhan Weeraratne, PhD1, Kim M. Unertl, PhD, FACMI2
1IBM Watson Health, Cambridge, MA; 2Vanderbilt University Medical Center, Nashville, TN

Introduction

Academic-industry partnerships are vital for enabling scientific discovery and for workforce development. One of the most beneficial aspects of these partnerships is the opportunity for joint industry-academic internships. Internships allow students to apply theoretical knowledge, gain insight, and learn key job skills. Particularly for undergraduate students with an interest in the science, technology, engineering, and math (STEM) fields, these experiences can help to inform career decisions and develop research skills. Today, students pursuing biomedical informatics and data science internships are faced with a wealth of opportunities across career sectors. However, siloed experimental learning experiences can leave students inadequately prepared to learn how to transfer foundational knowledge and skills across domains. Formal academic-industry internships that cross-train students within a discipline can expand students’ career preparation, benefitting both the individual and the scientific ecosystem. Despite these benefits, formal academic-industry biomedical informatics internships are rare. We describe an academic-industry internship between Vanderbilt Medical Center University (VUMC) and IBM and early lessons from its implementation.

Methods

Student Selection. The internship was created as part of the established Vanderbilt Biomedical Informatics Summer Program (VBISP), with additional positions funded through the IBM-VUMC academic research collaboration to advance artificial intelligence (AI) in healthcare. The VBISP internship was open to undergraduate students from across the USA; underrepresented minorities were encouraged to apply. Candidate applications included personal information, transcripts, reference letters, and a resume. Due to COVID-19, VBISP was significantly scaled back for summer 2020, leading to a need for a novel approach to continue the joint IBM-VUMC internships. Rather than hosting IBM-VUMC funded students in the summer, the internship resumed virtually during the 2020-2021 academic year. VUMC reviewed applications from individuals who had applied for the summer as well as additional applications to identify potential candidates for this academic-year program. The VUMC principal investigator (PI) screened applications according to the VBISP process, identified candidates with related skills for the IBM-VUMC projects, and sent applications to the IBM PI for review. When possible, both PIs interviewed and discussed the candidates to make the intern selections. PIs developed projects to align with intern skillset and interest; when IBM solutions were involved, the IBM scientist took the lead, and VUMC faculty were matched based on expertise and research interests.

Program Components. Internship objectives were to: 1) expand knowledge of biomedical informatics and research skills in academia and industry, 2) provide experiential learning through direct research and industry engagement, 3) establish next steps in the field, and 4) provide opportunities for professional development. The program lasted between 7-10 weeks. Interns gained insight into academic career paths by participating in research and methodological training workshops, twice-weekly seminars, one-on-one mentorship in student research projects, and intern group events. Exposure to life as an industry scientist, which was unique to the IBM-VUMC interns, included participation in the IBM Center for AI, Research, and Evaluation (an industry research team), bi-weekly research meetings, a visit to IBM Watson Health headquarters in Cambridge, MA, and access to IBM scientists. In lieu of the IBM visit due to pandemic travel restrictions, the PIs increased opportunities to receive broader exposure to multi-disciplinary industry sectors by including additional IBM research seminars.

Governance. The joint internship was overseen by one PI from IBM (TJB) and one from VUMC (KMU). The VUMC PI provided oversight for the VBISP, serving as the main contact for the IBM-VUMC Internship. The PIs were assisted by a VUMC staff member who aided with tasks such as program announcement, student recruitment, logistical arrangements, and program evaluation. Interns were guided throughout the research process and co-mentored by a
VUMC faculty mentor and IBM scientists via weekly meetings and ad-hoc meetings, as necessary. Lastly, debriefing sessions were held at the conclusion of the internship.

Results

Since 2019, the program has hosted six undergraduate interns: two in 2019 and four in 2020. Across the cohorts, the majority have been female (67%), Asian (67%), rising seniors (50%), and Vanderbilt University students (67%). One intern was a first-generation college student. The 2019 cohort interns collaborated on a systematic review evaluating the impacts of implemented AI-enabled clinical decision support; both gave an oral presentation at the VBISP Presentations Seminar, presented posters at the Vanderbilt Summer Science Academy Annual Research Symposium, and had poster abstracts accepted at the AMIA 2020 Informatics Summit. The 2020 cohort projects focused on: 1) disparities in genomics testing for lung cancer; 2) sociodemographic disparities in access to and use of telemedicine before and during the COVID-19 pandemic; 3) user interpretation and processing of ambiguous text in clinical notes; and 4) machine learning to assist with COVID-19 resource allocation. At conclusion, each intern gave an oral presentation for IBM and VUMC and submitted a conference abstract. Interns developed research skills, obtained work experience, and learned how scientific research informs product development and evaluation.

We observed several key lessons. First, administrative processes and contractual details required considerable time and needed to be addressed early in the process. Discussions were required to identify roles and responsibilities; align university, medical center, and industry human resources and onboarding policies; determine policies regarding data and intellectual property provisions; and negotiate indemnification and liability. The existing infrastructure for VBISP assisted with navigating these process-related program aspects. Once processes were established in 2019, the subsequent year only required minor modifications, even with the changed format and timing. Second, coordination across academia and industry was necessary to facilitate successful program execution. This was achieved by defining and adhering to responsibilities, regular communication, use of collaborative tools for project management and data sharing, and weekly meetings. Each mentor-mentee team also completed and submitted a project agreement and project plan, providing additional structure and alignment. Lastly, ample financial and personnel resources were essential. IBM sponsored the internship, and VUMC provided support for VUMC personnel for the additional effort required for execution of the joint internship. Small, but key levels of effort should be allocated for project management administration. Budgetary flexibility is also necessary to accommodate unplanned events and necessities.

Discussion

Biomedical informatics and data science internships have typically been siloed, requiring students to choose one sector over another, often pitting academia against industry. Yet, biomedical informatics is an interdisciplinary, fluid field where knowledge transformation and innovation often occur through the intersection of academia and industry. There is a need for future informaticians and data scientists to possess this important aspect of cross-sector. Through the IBM-VUMC Academic Partnership, we created a novel internship that introduced undergraduate students to the biomedical informatics and data science fields through academic and industry experiences. Through this internship, interns gained interdisciplinary training and research skills applicable in both academia and industry; professional skills including scientific writing, public speaking, team science, and leadership; and networking opportunities to help them envision their place in the future of biomedical informatics. The development of an academic-industry internship in the biomedical informatics and data science fields was a worthy and successful investment in training tomorrow’s scientists and informaticians. Future efforts include a formal program evaluation.

Acknowledgment. The authors wish to thank Shilo Anders, PhD, Hu T. Huang, PhD, Allison B. McCoy, PhD FAMIA, Molly McKillop, PhD, Travis Osterman, DO MS, Rubina F. Rizvi, MD PhD, S. Trent Rosenbloom, MD MPH FACMI FAMIA, and Dilhan Weeraratne, PhD, for serving as mentors.

Learning Objectives

At completion of this activity, participants will be able to (1) State the value of joint academic-industry internships and (2) Understand the processes in developing a successful academic-industry informatics and data internship.

How Will AMIA Lead? An Environmental Scan of Diversity, Equity, and Inclusion Activities within the Healthcare and Health IT Space

Tiffani J. Bright, PhD, FACMI1, Carolyn Petersen, MS, MBI, FAMIA2, Karen Wang, MD, MHS3, Clair Kronk, PhD4, Patricia C. Dykes, PhD, RN, FAAN, FACMI5
1IBM Watson Health, Cambridge, MA; 2Mayo Clinic, Rochester, MN; 3Yale School of Medicine, New Haven, CT; 4University of Cincinnati School of Medicine, Cincinnati, OH; 5Brigham and Women’s Hospital, Harvard Medical School, Boston, MA

Introduction
In June 2020, the AMIA Board of Directors established the Diversity, Equity, and Inclusion (DEI) Task Force (now Committee) to advise AMIA on specific, actionable steps addressing matters of racial diversity, equity, and inclusion for strategic planning. An immediate charge of the DEI Task Force was to conduct an environmental scan of DEI activities in similar associations and societies. Environmental scans are efficient for assessing how organizations have acquired data and information to establish actions but also set strategic direction1. Objectives were to: 1) identify activities that other associations in the healthcare community were undertaking to advance DEI within their membership and the broader community; and 2) build a knowledge base on which to draw for strategic planning.

Methods
Web searches were undertaken to find organizations and societies serving health care and health information technology professionals in September 2020. Each website was searched for relevant results using the terms “diversity,” “equity,” “inclusion,” and “DEI.” Items that resulted in direct policy/position statements and/or activities were included; items such as press releases were excluded. During November and December 2020, content published on these organizations’ websites was reviewed and DEI-related policies/position statements and activities were captured. Policy/position statements and activities were grouped by type and purpose (e.g., policies applying to membership, professional development) and counted as a percentage of the number of organizations scanned.

Results
The web searches identified 30 organizations: 4 health IT organizations, 1 non-profit academic research organization, and 25 healthcare professional organizations. Policy/position statements from 5 of these centered on Black, Indigenous and People of Color physicians; 2 served physicians with diverse abilities; and 1 focused on health equity for LGBTQIA+ and sexual and gender marginalized health professionals. Across the organizations, 17% had no policy/position or activity, 47% had 1–5 policies/positions and/or activities, 23% had 6–8 policies/positions and/or Activities, and 13% had at least 10 policies/positions and/or activities. The organizations surveyed in this environmental scan published policies/position statements addressing 8 topical areas (Figure 1). Table 1 presents the most common policy/position statements.

**Figure 2. DEI Activities**

**Limitations**

The authors focused on organizations that were most similar to AMIA to gain a perspective specific to healthcare; this was informed by the DEI Task Force Charge. Future work may include examining examples of DEI efforts outside the healthcare domain that can be adopted for our purposes. Additionally, organizational materials reviewed were only available through the website, which may have resulted in missing some policy/position statements and/or activities.

**Conclusion**

This environmental scan found common DEI activities AMIA could implement to create a culture of inclusion and belonging for members and within the informatics profession. The findings demonstrated that there is no singular activity pursued by organizations, rather, multipronged strategies were the norm across these diverse organization. We also observed commonalities in activities across organizations that need to be explored further by engaging stakeholders from these organizations to learn about their membership outreach strategies for building an inclusive community. The widespread activities across many similar organizations reaffirms the urgency and importance of sustained resource-committed AMIA DEI efforts. As a next step, the DEI Committee is combining these findings with results from the 2021 AMIA DEI listening sessions to inform and prioritize the AMIA Board-approved recommendations. The DEI Committee and subcommittees will also be discussing organizational outreach for additional information and partnership opportunities, and additional policies/positions, and activities to transform AMIA into the professional organization that reflects society and the communities we serve, enabling members and the broader informatics workforce to influence and lead the transformation of healthcare.

**Acknowledgments.** The authors thank the DEI Task Force members and AMIA staff for sharing their insights.

**Learning Objectives**

At completion of this activity, participants will be able to (1) Understand how the AMIA Diversity, Equity, and Inclusion Task Force addressed the DEI Charge given by the AMIA Board to conduct an environmental scan.

To Deep or Not to Deep: Comparison of Traditional and Deep Learning Models in Disease Prediction from Electronic Health Records

Alon Brutzkus, MSc., Guy Amit, PhD.
KI Research Institute, Kfar Malal, Israel

Introduction

Prediction models based on deep neural networks (DNN) have become the state of the art technology for computer vision, natural language processing and speech recognition. Although their applicability for structured data from electronic health records (EHR) have been demonstrated in multiple studies [1], the reported performance gain over traditional linear or tree-based models varies considerably and may depend on specific characteristics of the data or on the study design. Self Attention with Reverse Distillation (SARD), a DNN architecture based on transformers has been recently reported to outperform logistic regression in clinical prediction tasks using claims data [2]. We aimed to evaluate SARD on a disease prediction task and compare its performance to gradient boosted decision trees, which are widely-used traditional models for structured data. For our predicted outcome we selected postpartum depression (PPD), one of the most common complications of childbearing, estimated to affect 10-15% of mothers worldwide [3]. Early identification of women at risk of PPD is clinically important, as timely interventions may improve the health outcomes of both mothers and infants [4]. PPD is associated with a variety of physiological, psychological and socio-demographic risk factors and is therefore an appropriate use case for EHR-based disease prediction.

Methods

Data: We analyzed primary care EHR data from from IQVIA Medical Research Data (IMRD), incorporating data from The Health Improvement Network (THIN, a Cegedim database). This dataset contains primary care records of over 12.5 million patients, covers approximately 5% of the UK population, and is representative of the population in terms of demographics and major condition prevalence [5]. The data includes patient demographics, medical diagnoses, drug prescriptions and lab tests, which were transformed into the OMOP common data model [6].

Population: Our cohort included women who gave live birth between 07/2000 and 03/2018, at age 15 to 50 years, and have been continuously observed at the same clinic for at least one year prior to their pregnancy and one year following giving birth. PPD outcome was defined by having either depression diagnosis or new treatment for depression during the year after childbirth. The group of women without PPD was downsized to obtain a balanced dataset.

Feature extraction: For the traditional models, we extracted, for each patient i, a set Ci of all medication, condition and procedure codes that were recorded in their medical file before the time of delivery. In total we obtained a set C of 25,317 codes. We created a feature vector \( f_i = [f_i(W^{(all)}), f_i(W^{(730)}), f_i(W^{(365)}), f_i(W^{(180)}), f_i(W^{(30)})] \in \{0, 1\}^{5|C|} \) where \( W^{(l)} \) is a time window of l days before the delivery, and \( f_i(W^{(l)}) \) is a one hot vector of dimension \( |C| \) where the element corresponding to \( c \in C \) is 1 if and only if \( c \) appears in a visit in the time window \( W^{(l)} \). Window \( W^{(all)} \) refers to the entire observation period before the delivery. The SARD algorithm learns nonlinear visit representation via embedding of the concepts in each visit, followed by applying a transformer to the sequence of visits (see [2] for details).

Models: We experimented with the following machine learning models: (1) L1-regularized windowed logistic regression (LR) with regularization parameter chosen from [2, 0.2, 0.02] based on the validation set; (2) Extreme gradient boosting (XGBoost [7]) with 140 estimators, maximum depth of 5 and learning rate = 0.1; (3) SARD [2] with minor adjustments to the available implementation. The \( \alpha \) coefficient of the reverse distillation loss was chosen from [0.0, 0.2] based on the validation set.

Experiments: We trained all models and evaluated their performance using 5-fold cross validation, where in each iteration 20% of the data was used as a test set, and a validation of the same size was randomly chosen from the training set. We calculated the mean and 95% confidence intervals (CI) of the area under the receiver operator characteristics [https://github.com/clinicalml/omop-learn](https://github.com/clinicalml/omop-learn)
curve (AUROC) for each model, as well as for an ensemble of the XGBoost and SARD models, using bootstrapping on the pooled prediction scores.

Results
The cohort included 49,911 women with mean age of 30.1±6.1 years, 20,921 of them with PPD outcome and the remaining 28,990 without PPD. SARD and XGBoost achieved similar AUROC of 0.779 [CI 0.775 - 0.783] and 0.782 [0.778 - 0.786], respectively, slightly improving LR (AUROC 0.769 [0.765 - 0.774]). An equally-weighted ensemble of SARD and XGBoost provided an additional small improvement (AUROC 0.786 [0.782 - 0.79]) (Fig 1).

Discussion
Although deep learning algorithms for healthcare data, such as SARD have been reported to achieve state-of-the-art results on some clinical prediction tasks, our experiments indicate that their advantage in the general case is questionable. On our PPD prediction task, gradient boosted trees achieved slightly better performance than SARD, with approximately x100 faster execution time. The improvement achieved by the ensemble model implies that tree-based and deep classifiers may be combined to provide optimal performance. In-depth exploration of the differences between the models and their appropriateness for various types of problems and data is a future extension of this study.

Linguistic Indicators of Behavioral Activation in Text-Based Therapy Sessions Anticipate Changes in Depression Symptomatology

Hannah A. Burkhardt, BS¹, George S. Alexopoulos, MD², Michael D. Pullmann, PhD¹, Thomas D. Hull, PhD³, Patricia A. Areán, PhD¹, Trevor Cohen, MBChB, PhD, FACMI¹
¹University of Washington, Seattle, WA; ²Weill Cornell Medicine, White Plains, NY; ³Talkspace, New York, NY

Introduction
Behavioral Activation (BA) is rooted in the behavioral theory of depression, which states that increased exposure to meaningful, rewarding activities is a critical factor in depression improvement¹. Previous work has shown that depressed and non-depressed individuals may use language differently and that automated tools can detect these differences. The increasing use of online, chat-based mental health counseling presents an unparalleled resource for longitudinal analysis of the language of patients with depression, with the potential to illuminate the role of reward exposure in recovery. Automatic assessment of constructs relevant to BA can facilitate research into these therapies, and guide their application in practice. We investigated how linguistic indicators of planning and participation in enjoyable activities identified in text-based counseling sessions relate to depression symptomatology over time.

Methods
Using messaging therapy logs from previous research² (>10,000 participants, >165 million total words), we developed a lexicon of words collectively capturing the construct of activation as used in BA. Lists of seed terms were constructed for each of the 7 items in the Activation subscale of the BADS questionnaire (examples shown in Table 1), expanded using distributional semantics methods, and iteratively refined with input from author G.A., a clinician with extensive experience in BA approaches. We expanded the seed sets of terms by adding the 30 most related terms as determined by cosine similarity between the terms’ vector representations in a space of 100-dimensional word embeddings trained using the skipgram-with-negative-sampling algorithm³ as implemented in the open source Semantic Vectors software package. This process yielded 7 subconstruct lexicons and one overall BA lexicon.

<table>
<thead>

<tr>
<td>I engaged in a wide and diverse array of activities. (breadth)</td>
<td>activity, active, participate, involved, event, powerlifting, watercoloring, exercise, sport, basketball, restaurant, hobby</td>
</tr>
</tbody>
</table>

Table 1. Seed terms derived by the authors from the individual questions on the “Activation” subscale of the BADS. The name we assigned for each item (for brevity) is shown in parentheses.

Using Linguistic Inquiry and Word Count (LIWC)⁴, we then analyzed the language used in online therapy chat logs with respect to each of the 8 lexicons, as well as the established depression-related markers provided by LIWC, namely first-person singular pronoun (“I”, “me”, etc.) usage, first-person plural pronoun (“we”, “our”, etc.), and emotional tone (the balance between positive and negative affect). LIWC estimates scores for linguistic markers from the frequencies with which related words are used in text. The association of each of these linguistic markers with PHQ scores (depression severity), which were collected in regular intervals for all study participants, as well as the longitudinal development of depression scores over the treatment period (patient trajectory) was assessed. The patient trajectory groups (“improving” (n=3,211) and “non-improving” (n=3,546)) were identified on the basis of latent growth modeling results from previous research². Additionally, we used mixed effects linear regression modeling to determine the relative utility of each marker for predicting PHQ scores and patient trajectories.

Results
The level of activation (average percentage of words belonging to the overall activation construct) across the 10,711 baseline chat logs was 3.66 (SD 0.89) and varied significantly with the depression symptom severity category (Figure 1), as did the LIWC emotional tone measure and the LIWC pronoun measures. Changes in BA with depression severity are consistent with expectations, with activation rising as depression symptoms decrease.

The variance in the overall PHQ score explained (R²) by models fitted to different sets of variables is shown in Figure 2. BA constructs collectively explain more of the variance than the three LIWC variables (“we”, “I”, “tone”) (0.694 vs. 0.629). The combination of the novel and baseline variables explains more variance than either independently (R²...
Tone added more to satisfaction, breadth, accomplishment, and effort than to decisions, long-term planning, and daily structure, suggesting that these variable clusters may capture independent clinical dimensions.

Figure 1. Mean (95% CI) of each LIWC measure by depression symptom severity category at baseline: minimal (PHQ≤4, n=393), mild (PHQ=5-9, n=1,865), moderate (PHQ=10-14, n=4,109), moderately severe (PHQ=15-19, n=3,002), severe (PHQ≥20, n=1,331).

Mixed-effects linear regression confirmed that depression symptoms as measured by PHQ-9 scores improve significantly more for patients in the “improving” group than for patients in the “non-improving” group: a 1-week change was, on average, associated with a 0.37 (95% CI: 0.34-0.40) point improvement in PHQ in the “non-improvement” group vs. 0.71 (95% CI: 0.68, 0.74) in the “improvement” group. Similarly, each of the linguistic indicators showed significantly different amounts of change over time between groups.

Discussion
This work makes several key contributions. First, we devised a computational method to automatically assess theoretical constructs of BA from patient language, mediating measurement of the extent to which chat-based BA therapy is working as intended in large-scale clinical trials. Second, building on prior work demonstrating that activation has a close relationship with depression scores, we demonstrated that this new metric varies with depression symptom severity. Third, we validated established linguistic markers of depression at an unprecedented scale, using a large corpus of naturally occurring language collected as part of psychotherapy sessions. Fourth, we showed that both the well-established LIWC measures as well as the novel BA measures have utility in predicting longitudinal patient trajectories, with implications for the customization of clinical care. Finally, we demonstrated that our metrics of the individual subconstructs of BA capture distinct dimensions of the underlying mechanisms and may lend themselves to unique clinical insights. This work therefore enables further work in automated diagnosis and assessment of depression, as well as refinement of BA psychotherapeutic strategies.

Obesity Classifier Performance Disparities by Demographic Subgroup

Elizabeth A. Campbell, MS, MSPH1,2, Saurav Bose, MS2, Aaron J. Masino, ME, PhD2,3
1Drexel University, Philadelphia, PA; 2Children’s Hospital of Philadelphia, Philadelphia, PA; 3University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

Abstract

Electronic Health Records are important data sources that may be used to develop machine learning models in healthcare research. In this work, classification models are developed to recognize pediatric obesity using temporal condition patterns obtained from patient EHR data. Classifier performance is evaluated by demographic subgroups to identify potential performance disparities. XG Boost and Logistic Regression were the best performing algorithms; algorithms performed similarly across subgroups but tended to be more accurate for minority populations.

Introduction

Childhood obesity is a major public health challenge in the United States that disproportionately impacts racial/ethnic minority groups and socioeconomically disadvantaged households. Electronic Health Records (EHRs) assist childhood obesity diagnosis, treatment, and surveillance at the clinical and population level. While machine learning models trained on EHR data are increasingly used in predictive medicine, there has been limited research on utilizing these methods to predict childhood obesity or potential disparities in classifier performance among vulnerable patient subpopulations. The following study develops a classification model to identify obesity among pediatric patients using clinical diagnostic patterns in their medical history and analyzes model performance by demographic subgroups.

Methods

EHR data was obtained from the Pediatric Big Data (PBD) resource at the Children’s Hospital of Philadelphia (CHOP). Patients in this study were from a retrospective cohort of newly obese patients and matched control patients with a healthy BMI (n = 99,388) identified in a previous study. The sequential pattern mining algorithm SPADE was applied to this cohort in the previous study to identify common temporal condition patterns that surround pediatric obesity incidence. From that study, we retained case-control pairs where patients had BMI measurements at all visits, leading to a population of n = 9,686 for this study. Seventy temporal condition patterns were considered for this study. Each pattern was considered separately as a feature; patients were assigned a binary value of 0 or 1 (indicating that a patient did or did not have a record of a given temporal condition pattern). The Institutional Review Board at the Children’s Hospital of Philadelphia (CHOP) approved this research study and waived the requirement for consent.

We trained four machine learning algorithms (Logistic Regression, Random Forest, XG Boost, and Neural Net) to classify cases and controls as obesity positive or negative, and optimized hyperparameter settings through a bootstrapping methodology. We randomly shuffled the data and split it into training and validation folds in a stratified fashion relative to class balance. We trained each model with all hyperparameter settings on the training fold and evaluated its Area under the Receiver Operating Curve (AUC-ROC) on the validation fold. We repeated the process 200 times to obtain 200 validation AUC-ROCs for each hyperparameter setting for each model, then selected the hyperparameter combination with the highest mean AUC-ROC for a given model class. We implemented all algorithms using the Scikit-learn library in Python 3. We calculated the mean and standard deviation (SD) AUC-ROC values for the total study population and demographic subgroups for each algorithm.

Results

The study population is majority male (55.4%) and majority White (60.1%). African Americans (AA) are the second largest racial/ethnic group (25.3%). Approximately 1/3 of patients (32.1%) were enrolled in Medicaid at the time of their index visit. The case population is majority male (55.4%) and majority White (53.9%), but is comprised of a higher proportion of African Americans (31.7% vs. 25.3%) and Hispanic patients (4.4% vs. 3.5%) patients compared to the study population as a whole. Additionally, a greater proportion of case patients (38.1%) were enrolled in Medicaid (a proxy for low socioeconomic status) compared to the overall study population (32.1%).

Mean AUC-ROC values were consistent across algorithms, ranging from 0.72-0.80. XG Boost and Logistic regression tended to perform the best on the full study population and when evaluated by demographic subgroups. Some evidence of bias was identified, although this was through the models performing better for minority subgroups. The highest mean AUC-ROC were observed among AA patients, patients enrolled in Medicaid, and patients ages 5-11 years.

**Discussion**

In this study, classifiers were trained to identify pediatric patients as obese or not obese using temporal condition patterns previously found to be associated with obesity incidence. Model performance was evaluated for the total population and by demographic classes. Surprisingly, the models tended to perform best on minority groups, including AA patients and patients enrolled in Medicaid, although tests of statistical significance were not performed. Our findings show that bias in complex machine learning models can manifest in varying ways. Prior work has shown that bias in machine learning models has occurred against minorities due to an under-representation in data. However, possible biases need to be examined carefully. We hypothesize that our models performed better on under-represented groups because the features more strongly associated with obesity were more common among minority patients. These findings can be incorporated into future research to develop a thorough analytical approach to identify and mitigate bias that may arise from features and within datasets when developing more equitable machine learning models.

Clinical Decision Support with a Comprehensive in-EHR Patient Tracking System to Improve Inpatient Genetic Testing Follow Up

Ian M. Campbell, MD PhD1,2; Morgan L. McManus, MS2; Fred C. Cusick, BS1; David C. Junod, BS1; Sarah E. Sheppard, MD PhD2; Eli M. Lourie, MD, MBA, FAMIA1,2; Eric D. Shelov MD, FAMIA1; Anthony A. Luberti, MD, FAMIA1

1Department of Biomedical and Health Informatics, Children’s Hospital of Philadelphia, Philadelphia, PA; 2Division of Clinical Genetics, Children’s Hospital of Philadelphia, Philadelphia, PA; 3Department of Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

Introduction

Genetic testing can unlock the promise of precision medicine, potentially informing prognosis, management, surveillance, and recurrence risk. However, to be useful, the testing must be reviewed and interpreted by professionals who can implement care based on the knowledge gained and inform the patient or their family members of its meaning. The inpatient pediatric clinical genetics evaluation workflow involves the primary attending physician requesting consultation of a geneticist (Figure 1). The geneticist evaluates the patient and makes recommendations for genetic testing. It is the responsibility of the primary team to send samples to the hospital or outside reference laboratory for analysis. The laboratory issues a test report which is in turn entered into the patient’s electronic health record (EHR). Because the genetic testing takes weeks or even months to complete, the patient is frequently discharged before the results become available. Ideally, the clinical genetics team would become aware of the results and interpret them based on patient and family history and document their findings in the EHR. In an attempt to facilitate this, the health care team has historically developed ad hoc, sometimes intensely personal systems of Microsoft Office® documents and paper records, a practice not uncommon in other medical contexts1. Because of the complex nature of the workflow, the timescales involved, and sociotechnical issues within the EHR, results may go unnoticed. In an attempt to improve genetic testing result interpretation and follow up documentation, we developed a clinical decision support mechanism using a comprehensive in-EHR tracking system.

Methods

We analyzed the volume, genetic testing performed, result access logs, and follow up documentation of inpatient clinical genetics consultation to determine the scope of the problem and facilitate outcomes evaluation. Data visualization and statistical analyses, including multivariate logistic regression, were performed in R. Informed by the data analysis, we developed a tracking system with two main components. Part 1 is a data capture instrument which is available to clinicians in note templates and from patient lists (Figure 2). The capture form is optimized to reduce double documentation and provides customized suggestions but gives the clinician an opportunity to alter the parameters based on clinical judgement. Part 2 is a management dashboard which gives clinicians an overview of patients with outstanding tasks, provides easy access to information required to make decisions, and facilitates communication with the primary team and the patient’s family (Figure 3).

Results

We analyzed the outcomes of 772 inpatient genetics consultations during the 1-year period prior to implementation of the tracking system. 58% of patients had no subsequent documentation from a provider or staff member of clinical genetics. Of those patients, 78% (or 45% of the total), had genetic testing performed after their consultation but had no follow up documented by the genetics team. It is potentially possible that some of these patients

Figure 1 Clinical genetics inpatient consultation

Figure 2 Data capture instrument for the in-EHR tracking system
had results reviewed and documented by their primary team. We developed a multivariate logistic regression model to predict documentation of follow up based on completion of genetic testing, patient race and ethnicity, preferred language, payor type, and socioeconomic status of their home zip code. Unsurprisingly, we found that performing genetic testing and especially exome sequencing, the most complicated and expensive genetic testing, was strongly positively associated with follow up documentation ($p<0.002$, multivariate logistic regression). Notably, the patient having government insurance was significantly negatively associated with follow up documentation ($p=0.039$, multivariate logistic regression), suggesting a potential socioeconomic influence.

Uptake of the tracking system by the user base has been swift. The system was fully implemented on December 1st, 2020. In the first 6 months, 333 of 373 potentially eligible inpatient consults (89.3%) have been entered into the system. The system facilitated multiple diagnoses that would have otherwise been missed, including a case of 22q11.2 deletion syndrome because genetic testing was inadvertently not sent by the primary management team.

Considering data collected in the 6 months between December 1st, 2020 and June 1st, 2021, 171 of 275 (62.2%) inpatient consults who had genetic testing and were tracked by the system had follow up documentation within 60 days. This is a significantly greater proportion than those not tracked by the system over the previous year, 276 of 530 (52.1%, $p<0.005$, Two-sided Fisher’s Exact Test). Although documentation rates differed among individual attending physicians, use of the tracking system was associated with increased follow up documentation by all providers.

Using EHR access log data, we found that review of genetic results was completed by a clinical genetics provider within one month for a great majority of patients regardless of tracking system utilization (Figure 4). However, the system helped facilitate review of small subset of patients that may otherwise have gone unnoticed ($p<0.001$, Kolmogorov-Smirnov test). Indeed, all results have thus far been reviewed within 3 months (max 73 days) with the tracking system, whereas 8.2% of results remain unaccessed by that time without the system.

**Discussion**

Overall, we have implemented an in-EHR tracking system to serve as a clinical decision support tool that facilitates genetic testing and follow-up. The tool was quickly adopted by the clinical team. Our data suggests that the ability to easily see an overview of outstanding care tasks may expedite review of results and documentation of interpretation and recommendations. We believe the same framework can easily be extended to other medical specialties and patient care problems.

Data-Driven Patterns in Protective Effects of Ibuprofen and Ketorolac on Hospitalized Covid-19 Patients

Rich Caruana, PhD¹, Benjamin J. Lengerich, PhD², Yin Aphinyanaphongs, MD, PhD³
¹Microsoft Research, Redmond, WA; ²Massachusetts Institute of Technology, Cambridge, MA; ³NYU Langone Health, New York, New York

Introduction
The impact of nonsteroidal anti-inflammatory drugs (NSAIDs) on patients with Covid-19 is unclear. Initial guidance was to avoid prescription of NSAIDs to Covid-19 patients [1]. However, more recent meta-analyses have suggested that there is no compelling evidence of a harmful effect of ibuprofen on Covid-19 patients [2, 3]. It is difficult to identify the effect of NSAIDs due to confounding: NSAID usage in Covid-19 patients may be correlated to more severe cases of Covid-19 which manifest with inflammatory symptoms [4]; on the other hand, medical intuition suggests that because NSAIDs are contraindicated for some severe comorbidities, they may be correlated with lower-risk patients. Other analysis has found no association between ibuprofen and clinical outcomes, even without deconfounding [5]. Moreover, a few observational analyses have indicated that a protective effect from outpatient NSAIDs [6] or Ibuprofen¹ is observed after correcting for underlying patient risk factors. Finally, there is some evidence of protective effects of NSAIDs on patients with respiratory illnesses [7], although similar clinical trials have not been completed for Covid-19. In this setting, we seek to use machine learning tools to estimate patient risk at time of admission from patient lab values and then estimate the additive effect of Ibuprofen and Ketorolac.

Methods
Our outcome is in-hospital mortality. We consider only treatments within 24 hours of hospital admission; this captures a total of 97 patients who were treated with either Ibuprofen or Ketorolac. Our control condition is not receiving either NSAID in the first 24 hours. Our analysis includes deidentified records from 3108 patients hospitalized from March to August 2020 for Covid-19, with an average mortality rate of 18.1%. Our dataset for analysis was selected from a larger set of 11080 total hospitalized patients who have lab-confirmed cases of Covid-19. To filter out patients who were hospitalized for reasons other than Covid-19, we excluded patients who have indicators of (1) pregnancy: outpatient prenatal vitamins, in-patient oxytocics, folic acid preparations; or (2) scheduled surgery: urinary tract radiopaque diagnostics, laxatives, general anesthetics, antiemetic/antivertigo agents, or antiparasitics. We also require that the patients have recorded temperature, age, BMI, and Admission Day, and did not die within six hours of admission.

To correct for confounding, we use a two-stage machine learning procedure to estimate the adjusted risk ratio (ARR) [8], which can be interpreted as an odds ratio after correcting for patient mortality risk at admission. First, we take half of the sample and train a generalized additive model (GAM) [9, 10] to predict mortality risk at patient admission. We use tree-based GAMs [10] implemented in InterpretML². Next, in our held-out sample, we compute the excess risk after accounting for the model predictions of patient risk. To compute the effect of treatments, we compare the excess risk in treated patients with the excess risk in the control patients, and summarize these effects with the adjusted risk ratio (ARR) and adjusted risk difference (ARD) [8]. We use bootstrap to compute standard errors and p-values.

Results
The risk model achieves an ROC of 0.912 ± 0.001 and an F1-score of 0.598 ± 0.002 on held-out patients, significantly outperforming logistic regression which achieves an ROC of 0.859 ± 0.001 and F1-score of 0.455 ± 0.002. The most important features to this risk model are: Temperature, Age, Admission Day, Calcium, and Charlson score (Fig. 1). Estimated effects of Ibuprofen and Ketorolac are shown in Table 1. The observed mortality rate of patients treated with Ibuprofen or Ketorolac is lower than would be expected based on patient risk factors (comorbidities, demographics, and lab tests) at admission. For Ketorolac, the evidence is sufficient to reject a null hypothesis of no effect at p=0.05.

**Table 1:** Observed and expected rates of mortality for patients treated with Ibuprofen or Ketorolac.

**Figure 1:** Additive effects of Temperature and Age. Shaded regions are 90% CIs. Yellow ticks indicate 10 patients.

**Discussion**

These results add to the growing body of evidence that NSAIDs, and in particular Ibuprofen or Ketorolac, may not have detrimental effects on patients hospitalized with Covid-19. While these medications were correlated with a younger subset of the hospitalized patients and later treatment dates, the protective effects remain after correcting for confounding. This suggests that further study, including randomized control trials, should be performed to better understand any potential benefits of Ibuprofen and Ketorolac on patients hospitalized with Covid-19.

Abstract

Age-related macular degeneration (AMD) is the leading cause of visual loss in developed countries. Reticular pseudodrusen (RPD) are a critical disease feature of AMD (associated with increased risk of progression to advanced AMD). We propose a deep learning framework to detect RPD automatically. It achieved an Area Under the Curve (AUROC) of ~0.9 and ~0.8 on fundus autofluorescence images and color fundus photographs, respectively. It also achieved an AUROC of ~0.9 on an external dataset.

Introduction

Age-related Macular Degeneration (AMD) is the leading cause of blindness in developed countries. By 2040, 288 million patients are projected to have AMD worldwide (1). Following these developments in retinal imaging, an important macular feature -- reticular pseudodrusen (RPD) -- is now recognized as a key AMD lesion (2, 3). RPD presence is strongly and independently associated with increased risk of progression to late AMD. While it is pressing to identify the presence of RPD, it is very poorly visible to human eyes on clinical examination for color fundus photography (CFP), the most widely used and accessible imaging modality in ophthalmology, even to trained experts at the reading center level (4). In contrast, only more recent retinal imaging techniques such as fundus autofluorescence (FAF) is effective to identify RPD, but it is not widely available in the clinical practice.

In this work, we propose a novel deep learning framework for the detection of RPD detect RPD presence accurately using CFP alone, FAF alone, or both, employing >8000 CFP-FAF image pairs obtained prospectively as part of the Age-Related Eye Disease Study 2 (5). The framework includes multi-modal (detection from single or multiple image modalities), multi-task (training different tasks simultaneously to improve generalizability), and multi attention (improving ensembled feature representation) operation (6). It has been the first study on the detection of RPD using multiple imaging modalities. Importantly, with the multi-task feature, the final models support all three image scenarios (CFP alone, FAF alone, or CFP-FAF pairs) as inputs; therefore, clinicians could use it according to the availability of imaging equipment.

Performance of the models was compared with 13 human retinal specialists; an external validation on patients from different populations (Rotterdam Study, Netherlands) was also performed. The models achieved area under receiver operating characteristic (AUROC) 0.832, 0.931, and 0.933 for CFP alone, FAF alone, and both, respectively. Its performance on CFP was very substantially superior to human retinal specialists (median F1-score 0.644 versus 0.350). The External validation also demonstrated high accuracy of the models; e.g., it had an AUROC of 0.965 for CFP alone. Overall, this work demonstrates the successful development, robust evaluation, and external validation of a novel deep learning framework that enables accessible, accurate, and automated AMD diagnosis and prognosis.

Data and methods

The primary dataset consisted of all AREDS2 images where a CFP-FAF pair was available, i.e., where a CFP and a corresponding FAF image (taken from the same eye at the same study visit) were available. The dataset is described with these CFP-FAF pairs as the imaging unit. The total number of images was 8487 (i.e. 8487 CFP, 8487 FAF images, and 8487 CFP-FAF image pairs). The dataset was split randomly into three sets: 70% for training, 10% for validation, and 20% for testing of the models.
The framework consists of three deep learning models: the CFP model, the FAF model, and the CFP-FAF model. The CFP model takes CFP images as its input and predicts RPD presence/absence as its output; the same idea applies to the FAF and CFP-FAF models. For the CFP model and FAF model, each has a CNN to extract features from the input image, followed by an attention module, followed by fully-connected layers, and an output layer, making the prediction. The CFP-FAF model has the same structure except that, instead of having its own CNN backbone, it receives the image features from both the CFP and the FAF models. The method is summarized in detail in (6).

The following metrics were used to evaluate the performance: F1-score, area under receiver operating characteristic (AUROC), sensitivity, specificity, Cohen’s kappa, accuracy, and precision. The model performance was further compared with the performance of 13 ophthalmologists (from ‘fellow level to ‘attending’ level).

Figure 1. Evaluation results of the models and the ophthalmologists for both CFP and FAF imaging scenarios (6).

Results and discussions

For RPD detection, the model achieved area under receiver operating characteristic (AUROC) 0.832, 0.931, and 0.933 for CFP alone, FAF alone, and both, respectively. As shown in Figure 1, its performance on CFP was very substantially superior to human retinal specialists (median F1-score 0.644 versus 0.350). We further performed an external validation (on Rotterdam Study, Netherlands). It also demonstrated high accuracy on CFP alone (AUROC 0.965). Finally, we evaluated the framework on detecting other AMD disease features: geographic atrophy and pigmentary abnormalities. It achieved an AUROC of 0.909 and 0.912, respectively, demonstrating its generalizability.

Overall, we believe that this framework demonstrates the potential for automated but accurate ascertainment of the full spectrum of AMD features from CFP alone. This is extremely valuable for improved AMD classification and risk prediction. Importantly, operation from CFP alone makes it accessible far beyond the small number of specialist centers in the developed world with access to multi-modal imaging and expert graders. Planned future work consists of additional external validation and prospective assessment in a clinical trial setting. This would take a step towards clinically applicable artificial intelligence systems.

Reproducibility in natural language processing: What we need to know

KB Cohen, PhD1, A Ripple, MLS2, A Ben Abacha, PhD2, O Bodenreider, MD, PhD2, O Hargraves, BA3, K Verspoor, PhD4, P Zweigenbaum, PhD5, D Demner-Fushman, MD, PhD2

1 U. Colorado School of Medicine, Denver, CO, USA; 2 Lister Hill National Center for Biomedical Communications, National Library of Medicine, NIH, USA; 3 U. Colorado, Boulder, CO, USA; 4 RMIT University, Australia; 5 LISN, CNRS, U. Paris-Saclay, France

Introduction

The philosopher of science Hans Radder put it well: in order to know whether or not an experiment has been reproduced, we first need to know what was actually done1. But, case studies have demonstrated that it is not always intuitively obvious what exactly needs to be reported about a natural language processing experiment2. Furthermore, work by Olorisade et al.3 has demonstrated that this is not always clear even for a relatively constrained subfield, such as text mining research. When we begin to think about the fundamental issue of generalizability in reproducibility, the question becomes even more complicated, and the answers probably much more nuanced4.

To address the basic question of what was actually done in this natural language processing experiment?, we take an approach based in the FAIR Principles for managing the products of scientific research5. The FAIR Principles propose that products of research, including publications and data, be Findable, Accessible, Interoperable, and Reusable. For publications, this suggests that a paper should be retrievable and analyzable by the semantics of its contents, and not only by search on the words with which that content is written. Although there are alternatives, it is a good choice because of its wide acceptance in biomedical research (see the reviews in6 and7; at the time of writing, the original paper has been cited over 4500 times).

The goals of retrievability and analyzability suggest an ontology or terminology to which concepts mentioned in papers can be normalized. Consequently, we propose here a two-part schema for representing a natural language processing paper as a collection of metadata. The first part models a paper itself. The approach to this is frame-based and is inspired by previous work in the domains of biomedical research publishing8–10 and of standards for the reporting of experiments11–13. The second part is an ontology of slot-fillers for that frame. Because community consensus is essential to the adoption of any such representation of scientific work5, our overall approach includes a significant amount of solicitation of feedback from a diverse cross-section of the natural language processing community. Additionally, we tested the coverage of the ontology using frequency-based methods applied to the language processing and text mining literature from two relatively distinct communities—biomedical text mining, and the Association for Computational Linguistics family of conferences.

Materials and Methods: The representation of a paper consists of a frame with slots for the following four items:

1. Topic: what is the paper primarily about?
2. Method: what was done?
3. Data: what kind of material was used?
4. Evaluation: how was the work evaluated, question answered, or hypothesis tested?

The slot fillers form an ontology structured by the typical relations, i.e. is-a and has-part, and a few novel ones.

In order to minimize subjectivity, the first draft of the ontology was constructed based on the indexes and tables of contents of popular language processing textbooks. Definitions were taken from open-source materials, including the primary literature and Wikipedia, and reviewed by a lexicographer. The overall model of papers, as well as the ontology of slot-fillers for describing them, was evaluated in two ways: by quantitative comparison to frequency and terminological analyses of the literature, and by solicitation of feedback from researchers in the field.

Quantitative evaluation: We analyzed over 9,000 PubMed-indexed natural language processing and text mining papers. The Sketch Engine terminology extraction tools14 generated a silver standard for evaluation of coverage.

Expert feedback: We did initial annotations of the complete sets of PubMed-indexed publications of several authors. We then met with them individually, and they corrected the metadata that we assigned to their papers.
Table 1: High-level annotations for four typical biomedical natural language processing papers.

</tbody>
</table>

Results: The ontology currently contains 390 unique concepts and several relation types. Table 1 shows the high-level metadata for four typical papers. Meetings with individual authors led to improvements in the granularity of the representation. The initial overlap after manual filtering of terminology extraction errors was 48%. Most missing concepts were very domain-specific, such as electronic health record and biomedical text.

Conclusion: Thanks to the combination of methodologies, this work has resulted in an ontology for the representation of natural language processing papers that is both empirically supported by quantitative data, and vetted by members of the natural language processing community.

Examining the Sociotechnical Process of Clinical Photography to Encourage Photo Diversity in Medical Education

Benjamin Collins, M.D., M.A.¹, Pamela Pierce, M.L.S., M.S.¹, Linda Felver, Ph.D., R.N.¹
¹Oregon Health & Science University, Portland, Oregon

Introduction:

Smartphone technology has allowed clinical photography to play an increasingly significant role in medical education for learning to recognize visible diseases. It should be noted that skin tone alters the appearance of many conditions, making it essential to view conditions on a variety of skin tones. However, representation of different skin tones is lacking for photographs in many medical education resources. This inequity leads to poorer patient care and the perpetuation of health disparities. To facilitate acquiring diverse photographs for medical education, it is necessary to understand the sociotechnical process of clinical photography, including the technology, workflow, policies, and ethics involved. The objective of this study was to gain an understanding of the process for clinical photography at an academic medical center through interviews with faculty. This will serve as a foundation for developing a process to ethically and efficiently obtain clinical photographs of patients with diverse skin tones for medical education.

Methods:

The IRB at Oregon Health & Science University (OHSU) in Portland, Oregon approved this study. Twelve 30-minute video interviews were conducted via the virtual meeting platform, WebEx, with faculty knowledgeable of the clinical photography process. The number of interviews was set by reaching a saturation of new information. Participants were contacted by email for initial consent and scheduling of the interview. Consent was reaffirmed at the time of the interview. Interviewers used two versions of an interview guide depending on whether the interviewee actively took photographs or had knowledge of the process but did not actively take photographs. There was some leeway to deviate from the question guide to pursue further information or clarification. After completion of the interview, video recordings were securely stored in an OHSU approved cloud service then transcribed to a Microsoft Word Document. The interviewee’s identity was redacted from the transcript followed by discarding of the video recording with interviews thereafter identified by a randomly generated three-digit number to ensure confidentiality. Transcripts were analyzed in QDA Miner Lite using deductive themes based on the question guide as a foundation with inductive subthemes revealed when reviewing the transcript text within each theme. These codes were organized in Microsoft Excel for ease of review.

Results:

Twelve interviews were conducted with ten clinicians, one medical photographer, and one clinical administrator from the following clinical departments: Dermatology, Plastic Surgery, Internal Medicine, Emergency Medicine, Pediatrics, Ophthalmology, Vascular Surgery, and Endocrinology. Qualitative assessment of the interviews yielded five main themes based on the interview guide: technology, workflow, benefits, ethics, and diversity. Within these themes, there were 19 inductive codes used to build a chronological and technical workflow of the clinical photography process.

The workflow for clinical photography starts from the decision to take a photograph which is largely dictated by clinical role. Some roles take photographs multiple times a day and others may do so on a less than weekly basis. Also, clinicians who are less comfortable with the process may take photographs less frequently. Taking clinical photographs expressly for educational purposes was not common. They were typically taken to track the appearance of a condition over time. Once a decision is made to take a photo, consent is obtained from the patient. For clinical purposes, verbal consent is considered sufficient, but for other reasons, including education, written consent is deemed necessary. The written consent process was considered a significant burden on time. However, the interviewees recognized the importance of communicating the reason for the photo with the patient and following HIPAA guidelines. They were also aware that institutional policy existed, although sparse on the details. After consent is obtained, the photograph is taken. Most of the interviewees used personal smartphones to take photographs via the Epic Haiku app that bypasses storage in the phone and places the photo directly in the Epic EHR. There were concerns about the lower quality of these images due to limitations of the smartphone camera and data compression from using Haiku. Some interviewees also acknowledged that not all faculty use the Haiku app, leading to photographs stored on their personal smartphone, putting confidentiality at risk. Only the medical photographer spent time setting up for photographs. For clinicians, efficiency was more important than quality. After taking the photograph, viewing it requires entering the patient’s chart. Searching for photographs in the EHR to use for education was considered
problematic because they are stored in the patient’s chart, and being able to recall patients with photos of specific diseases is difficult. Additionally, Haiku does not have editing capability to remove identifiable features from a photo which would be necessary to use it for education, but this can be completed later on a computer. When discussing the diversity of clinical photographs in medical education, many of the interviewees referenced the lack of diversity in the population served by the institution. Interviewees also discussed the need for more diverse photographs in medical education from the perspective of racial diversity without specifically discussing diversity of skin tone.

Discussion:

The interviews revealed a number of important areas to address when aiming to obtain more clinical photographs with diverse skin tones for educational use. While interviewees displayed a clear understanding of the need for more diverse images, there was a lack of proficiency in this understanding. The discussion centered on race, which is a social construct, but skin tone varies significantly within races. Having a photograph of a lupus discoid rash on a white person and a Black person does not achieve the same effect for learning to recognize the rash as having photographs of the condition on multiple skin tones. The history of exploitation of persons of color must also be acknowledged in this pursuit of health justice. Persons of color should not need to be concerned about being exploited for education, and should feel welcome to participate. While the provision of good clinical care remains the priority, an academic medical center should be upfront about its role in medication education. This understanding could be improved by obtaining written consent from each patient so that not every educational photograph needs new written consent at the time of the encounter and can instead be verbally reaffirmed. This would also reduce the burden of time on clinicians. There would be exceptions to this such as photographs of faces, genital regions, physical abuse, or other images that need increased privacy. It would be beneficial to involve people of different backgrounds in a focus group to determine the best way to achieve a balance of encouraging participation in medical education and avoiding mistrust.

An ideal educational database for clinical photographs would be paired with a secure smartphone app, similar to Epic Haiku, that transmits the photograph straight into the database without being stored in the phone. This app would also have the ability to edit out identifiable features at the time of the photograph being taken and the option to add metadata by which the photograph can be organized when stored in the database. Photographs stored in the database would maintain a level of resolution suitable for use in education. To make the most of this database, clinicians should be trained on clinical photography which would increase the number of photographs taken. Overall, the sociotechnical process of clinical photography requires supportive policies, an efficient workflow with a reliable database, and trust from the community to improve the diversity in photographs for medical education. Important limitations of this study include that it was performed at one institution with use of one EHR. There is also selection bias from participants interested in clinical photography, influencing the frequency of photographs and adherence to institutional policies.

A Retrospective Analysis of Machine Learning Driven Antibiotic Selection in the Emergency Department

Conor K. Corbin, MD, Arhana Chattopadhyah, MD, Lillian Sung, MD, PhD, Amy Chang, MD, Stan Deresinski, MD, Jonathan H. Chen, MD, PhD

1Department of Biomedical Informatics Research, Stanford University, Stanford, California; 2Division of Haematology/Oncology, The Hospital for Sick Children, Toronto, Ontario, Canada; 3Medicine and Infectious Diseases, Stanford Medicine, Stanford, California

Introduction
Over 700,000 people die globally due to antibiotic resistant infection, and this figure is expected to reach 10 million by 2050. Over 50% of antibiotic use in the hospital is either unwarranted or sub-optimal, expediting growing resistance. Empiric antibiotic administration is often required because of rapid clinical deterioration in the event of true infection. However, appropriate antibiotic selection is difficult because selection must be made before knowing the result of cultures and antibiograms of isolated organisms. Clinicians must balance broader coverage to ensure activity against life-threatening infection and narrower coverage that adheres to antibiotic stewardship goals. We hypothesized that antibiotic selection could benefit from machine learning based clinical decision support. In this study we conducted the following: 1) trained machine learning models using electronic health record (EHR) data that estimate the probability that twelve distinct antibiotic therapies would cover identified isolates from individual patients, 2) retrospectively benchmarked an optimized allocation of antibiotics that uses the outputs of the machine learning models against both a random allocation of antibiotics and the observed clinician allocation, and 3) estimated the extent to which patient coverage decreases as fewer broad-spectrum antibiotics are used.

Methods
We used the Stanford Research Repository (STARR) clinical data warehouse to extract de-identified EHRs for patients who visited the Stanford or Valley Care emergency departments (EDs). The unit of observation was a patient ED admission. Analysis was restricted to admissions between 2009 and 2019. We included patients 18 years or older who were admitted to the hospital from the ED. We further restricted the analysis to admissions where at least one order for a blood, urine, cerebrospinal fluid (CSF), or fluid microbial culture, and at least one order for intravenous or intramuscular antibiotics were placed in the first 24 hours after presenting to the ED. Patients who had a record of receiving antibiotics in the two weeks leading up until the ED admission were excluded. The analysis was also restricted to patients with at least one positive microbial culture.

Binary machine learning classifiers were trained to predict the probability that a patient would be covered by twelve distinct and commonly administered empiric antibiotic selections using EHR data collected up until the point antibiotics were ordered. Features included patient co-morbidities, procedures, labs, medications, vital signs, and prior microbiology lab results. Features were represented as counts, and our final feature matrix contained 43,220 columns. Labels representing sensitive organisms were derived from the results of microbial cultures. The label was positive if all microbial organisms isolated from a patient were listed as susceptible to at least one of the antibiotics in the antibiotic regimen. Train (2009-2017) validation (2018), and test (2019) splits were made based on the years the admissions took place to best mimic potential distributional shift that occurs because models are trained and deployed on data from different time periods. We conducted a model selection procedure including four model classes (l1 and l2 regularized logistic regressions, random forests, and gradient boosted trees) and associated hyperparameters.

We used the out of sample probability estimates of the final model for each of the twelve prediction tasks as inputs to a linear programming-based optimization procedure that maximized predicted patient coverage over the set of observations in our test set with several constraints. Let $N_{test}$ be the number of ED admissions in our held out test set and $M = 12$ be the total number of antibiotic selections. Let $S \in R^{N_{test} \times M}$ be a matrix of binary variables indicating antibiotic selections, where $s_{ij} = 1$ represents that the $j$th antibiotic selection is allocated to the patient in the $i$th ED admission. Let

$$\text{maximize} \quad \sum_{i=1}^{N_{test}} \sum_{j=1}^{M} \phi_{ij} s_{ij}$$

$$\text{subject to} \quad \sum_{j=1}^{M} s_{ij} = 1 \quad i = 1, ..., N_{test}$$

$$\sum_{i=1}^{N_{test}} s_{ij} = K_j \quad j = 1, ..., M$$
\( \Phi \in R^{N_{\text{test}} \times M} \) be a matrix of probability estimates from our classifiers, specifically \( \phi_{ij} \) represents the predicted probability that the patient in the \( ith \) ED admission would be adequately covered by antibiotic selection \( j \). Finally, let \( K_j \) be the total number of times the \( jth \) antibiotic must be used over the set of our \( N_{\text{test}} \) ED admissions - the budget for antibiotic \( j \). We first chose the \( K_j \) parameters to be the number of times clinicians actually allocated the \( jth \) antibiotic selection. We later perturbed these parameters to estimate the extent at which patient coverage decreases when fewer broad-spectrum antibiotics are allocated. Our problem formulation is shown in Equation 1 and was implemented using the PuLP python package and solved with the CBC solver. Using these data we calculated the miss rate, defined as the fraction of patients who were assigned an antibiotic regimen that did not cover their infection.

**Results**

Our training, validation, and test sets had \( N_{\text{train}} = 5,804 \), \( N_{\text{val}} = 1,218 \), \( N_{\text{test}} = 1,320 \) observations respectively. The model class of the final model, positive class prevalence, average precision, and area under the receiver operating characteristic (AUROC) curve for each of the twelve binary classification tasks are listed in Table 1. 95% confidence intervals were estimated by bootstrapping the test set 1000 times.

The miss rate for a random allocation of antibiotics (preserving clinician budget constraints) was 21.5% (95% CI [18.6, 24.3]). The miss rate for the allocation made by clinicians was 15.7% (95% CI [13.3, 18.3]). The miss rate for the optimized antibiotic allocation (preserving clinician budget constraints) was 14.1% (95% CI [11.6, 16.5]).

By perturbing the budget parameters \( (K) \) in our problem formulation, we found that the optimized allocation yielded a miss rate equivalent to the actual clinician miss rate while reducing the Vancomycin & Piperacillin-Tazobactam budget in favor of a larger Piperacillin-Tazobactam budget by 69.8%. Similarly, an optimized allocation yielded a miss rate equivalent to the clinician miss rate while reducing the Piperacillin-Tazobactam budget in favor of Cefazolin by 40.2%, while reducing the Ceftriaxone budget in favor of Cefazolin by 33.4%, and while reducing the Ceftriaxone budget in favor of Ampicillin by 21.1%.

**Discussion and Conclusions**

Tree based models consistently outperformed both l1 and l2 penalized logistic regressions in our twelve prediction tasks. The optimized antibiotic allocation performed significantly better than a random antibiotic allocation, but not significantly better than the clinician allocation. The optimized allocation yielded an equivalent miss rate to the clinician allocation while using fewer broad-spectrum antibiotics. More work is needed to evaluate how well these models would perform on the full deployment population (not just patients with positive cultures) and on prospective cohorts through use of the Epic Cognitive Compute platform which allows model predictions to display within medical records themselves. However, because of the benefits of reducing broad-spectrum antibiotic administration, this type of machine learning-based allocation may be advantageous compared to relying on clinician judgement.

Development and Validation of a Machine Learning Model to Predict Contact Moments in Post-Myocardial Infarction Home Measurements

Anne A.H. de Hond, MSc1, Esmee Stoop, MSc1, Nicole van Keulen, MSc1, Loes van Winden, MSc1, Ellen Poorter, MSc1, Douwe E. Atsma, MD, PhD1, Ilse Kant1, PhD, Ewout W. Steyerberg, PhD1

1Leiden University Medical Center, Leiden, the Netherlands

Introduction

Telemonitoring a patient after myocardial infarction (MI) could help detect clinical deterioration earlier which is associated with better clinical outcomes and higher patient satisfaction of care1-2. To this end, the Leiden University Medical Center provides its post-MI cardiovascular patients with ‘the Box’ consisting of several digital monitoring devices3. Patients are contacted by a nurse practitioner if their measurements indicate a significant clinical deterioration, referred to as a ‘contact moment’. However, the supervision of this daily incoming home measurements data is a time-consuming and taxing task for nurse practitioners. The resulting information overload can lead to burnout4 and poses a risk to patient safety5.

The aim of this study is threefold: i) develop a machine learning (ML) model that identifies high-risk patients in need of a contact moment, ii) validate the model in silent mode, and iii) identify areas for improvement in model performance and presentation based on the initial user experience of the nurse practitioners.

Methods

The data for this study concerns post-MI cardiovascular patients and was collected through the ‘the Box’ study3 at a tertiary care center in the Netherlands between 2015 and 2020. The contact moments were initiated by the nurse practitioner upon suspicion of a significant clinical deterioration based on the wearables data. Nurse practitioners later checked and adjusted the contact moments in the collected data to improve the quality of the outcome variable. Age, sex, weight, height, activity, blood pressure, heart rate and daily number of measurements were used in the modelling. The ratio of diastolic and systolic blood pressure and the body mass index (BMI) were calculated and added. For the blood pressure, heart rate and BMI, the mean and standard deviation (rolling window of 4 days) and the observations of the previous 6 days were included. A logistic regression, random forest and gradient boosted decision tree (XGBoost) algorithm were trained to predict relevant disease progression leading to unscheduled contact moments between patient and nurse practitioner, using 3-fold cross-validation. Performance was measured with the Area Under the Receiver Operating Characteristic Curve (AUROC) and Area Under the Precision-Recall Curve (AUPRC). Confidence intervals (CI) were calculated via bootstrapping. Shapley Additive exPlanations (SHAP) were added to estimate the importance of individual variables for the model predictions.

Figure 1. Time series for home measurements of patient with contact moment with a) systolic blood pressure, b) diastolic blood pressure, c) heart rate and d) BMI. Red line indicates a contact moment.
Upon completing model development, we will proceed by integrating the model in the IT infrastructure of the hospital and running it in silent mode, meaning that the predictions of the model will not be available to the users. In this pre-production environment, the model is prospectively validated on new incoming home measurements. Next, we will conduct user acceptance tests where nurse practitioners are able to interact with the model and provide feedback on its predictions and associated explanations.

Preliminary results

The data consisted of 373 MI patients telemonitored with ‘The Box’ for an average duration of 126 days. The patients were on average 59 years old and the majority was male (76%). Of these patients, 50 had one or more contact moments (13% of all included patients). Among all daily measurements, there were 88 contact moments (0.2% of total 46959 observations). For an indication of the progression for some of the clinically relevant variables see Figure 1.

The logistic regression model achieved an AUROC of 0.83 (0.73-0.92) and an AUPRC of 0.02 (CI 0.01-0.04, baseline 0.02). The random forest model obtained an AUROC of 0.86 (CI 0.77-0.94) and an AUPRC of 0.03 (CI 0.01-0.07, baseline 0.02). The XGBoost model achieved an AUROC of 0.86 (CI 0.77-0.94) and an AUPRC of 0.03 (CI 0.01-0.12, baseline of 0.02). The random forest and XGBoost models performed similarly and slightly better compared to the logistic regression. The XGBoost was selected to be implemented in clinical practice, because of its ability to easily process missing data and good processing speed. The strongest predictors based on SHAP values were those related to systolic blood pressure and daily number of measurements.

We expect good prognostic validation results, as the intended population is the same for development and validation. The nurse practitioners are likely to have some very valuable input on clinically meaningful thresholds for probability predictions, acceptable levels of false positives and false negatives, and presentation of results and explanations.

Conclusion

We developed a model that can predict the need for unscheduled consultation between ‘The Box’ patients and nurse practitioners to address disease progression. An accurate prediction of contact moments between patient and nurse practitioner aids in prioritizing the incoming home measurements. The nurse practitioners can then immediately direct their attention to the most urgent cases. This has the potential to save time and energy and can address the problems related to information overload on the clinician’s side, like burnout.

Clinician involvement is crucial to promote a successful implementation of new technologies. We therefore closely work with the nurse practitioners during development and validation of the algorithm. Their input will be used to improve the algorithm and its presentation.

Using Genomic Association Replication Rates as an EHR Quality Measure via the Phenotype-Genotype Reference Map (PGRM)

Sarah DeLozier, BS,1 Jing He, MS,1 Josh Peterson, MD, MPH, FACMI,1 Josh C. Denny, MD, MS, FACMI,2 Lisa Bastarache, MS1

Introduction: Genome-wide association studies (GWAS) of large cohorts have greatly enhanced our understanding of the pathophysiology of complex disease. Secondary use of clinical data from the electronic health record data (EHR) would benefit from validated quality control methods to ensure the reliability of results.1 We created a phenotype-genotype reference map (PGRM) consisting of single nucleotide polymorphism (SNP)-trait associations from the GWAS catalog (SNP/phenotype pairs). We mapped phenotypes from the catalog to PheWAS codes (phecodes) and used reported effect sizes and allele frequencies to calculate the number of cases required for replication at 80% power. The PGRM map contains all associations in the GWAS catalog which have an exact matching phecode, a total of 9,770 SNP/phenotype pairs, and is annotated with the genetic ancestry of subjects from the original study. The PGRM can be used prior to GWAS to calculate a replicate rate for EHR cohorts that are linked to genetic data. We propose using the PGRM as an EHR data quality measure for GWAS and as a method of testing the effect of standard GWAS parameters (e.g., minimum code count) on replication.

Methods: Developing the phenotype/genotype reference map reference map (PGRM)

Figure 1 illustrates the workflow of the phenotype/genotype reference map (PGRM). Phenotypes in the map are represented by phecodes, groups of International Classification of Disease-9, 10, and 10-CM billing codes developed to support phenome-wide association studies (PheWAS).3 The GWAS catalog diseases and traits are annotated with the Experimental Factor Ontology (EFO). We mapped EFO terms used in the catalog to phecodes through manual review and annotated those that were exact matches. Inexact matches between EFO/phenocodes were characterized by type of match and those overly broad matches (e.g., phecode 305.2 "Eating disorder" mapped to the EFO "Bulimia nervosa") or narrow matches (e.g., phecode 627.4 "Premenopausal menorrhagia" mapped to EFO "Menorrhagia") were excluded. Continuous traits and associations not reaching genome wide significance (i.e., p-value <5x10^-8) were also excluded. Lastly, we annotated associations by study ancestry, derived from the ‘Initial Sample’ and ‘Replication Sample’ fields in the GWAS catalog. Information missing from the GWAS catalog was ascertained manually from the original manuscript. Power calculations were conducted using the average effect size reported in the catalog and ancestry matched allele frequencies reported in GnomAD.

Calculating replication rate

We attempted to replicate all powered associations in the PGRM in a local DNA biorepository (BioVU) cohort of 65,215 individuals of European ancestry, age >=18, genotyped on the MEGA array. SNPs with minor allele frequency of <1% and those with missingness > 5% were excluded. Cases were defined as having at least two phecodes, the default minimum code count (MCC) threshold used in PheWAS studies.3 Associations were included in the analysis when the number of cases in the BioVU cohort were equal to or exceed the “cases needed” in the PGRM to achieve 80% power. The replication rate for the cohort was calculated by dividing the number of SNP/phenotype pairs with p<0.05 by the total number of SNP/phenotype pairs attempted in replication. In total, we attempted replication on 1,428 SNP/phenotype pairs, and 95 unique phecodes across 12 different disease categories.

Comparing replication rates

We used the PGRM to compare the replication rate of associations using different minimum code counts (MCC) in the BioVU cohort. We tested MCC 1-4 and calculated the replication rate and the number of associations powered in each analysis (Figure 2). Replication rates between MCC were compared using a one-sample test of proportions.

Results: Overall, the PGRM includes 9,770 SNP/phenotype pairs for 173 unique phecodes. By ancestry, the European genetic ancestry map is the largest, with 7,981 unique SNP/phenotype pairs, compared with 295 and 1,686 for the African ancestry and Asian ancestry maps respectively. The density of the PGRM differed by phecode category, with neoplasms having the highest number of associations (1,779), followed by mental disorders (1,343). Congenital anomalies had the fewest associations (24), followed by infectious disease (119).

Using the BioVU cohort, we attempted to replicate 1,482 associations in European ancestry PGRM. Comparing different MCC thresholds, we found a significant improvement in replication rate between MCC=1 and MCC=2.
(59% to 67%, p=8x10^{-6}). There was no significant difference in replication rates above a MCC of 2. Increasing MCC also resulted in a decrease in SNPs that were adequately powered for replication (Table 1).

**Discussion**

Meta-analyses of GWAS findings suggest high external replication rates of SNP/phenotype associations.\(^4\) Researchers using EHR-based cohorts can similarly instill confidence in their results through replication. Low replication rates in a given dataset may help identify incorrect or implausible data not fit for GWAS.\(^1\) The PGRM enables the calculation of replication rates for novel datasets and continued opportunity to validate known GWAS associations, including testing associations across ancestries. Thus, through known associations in the GWAS catalog, the PGRM encourages replication as a part of the QC process.

While the PGRM does include a diverse set of 173 phenotypes, not all diseases are equally represented in the map. For example, as in the GWAS catalog, infectious diseases are not well replicated in the PGRM. Furthermore, the European ancestry map is far more robust than that of Asian and African ancestries, reflecting a well described ancestry-based disparity in genetics research.\(^5\) The PGRM should be used to optimize GWAS models, including but not limited to minimum code count criteria, that are likely phenotype-specific.

**Key Conclusions**

In this study, we modeled common data problems and tested GWAS methods predictive of replicating known associations from the GWAS catalog, finding that adding minimum code counts increased replicating total possible associations replicated while decreasing power. Future work should assess the assimilation of the PGRM in GWAS and its impact on the ability of a novel dataset from the health record to predict known or novel associations.

Can reproducibility be improved in clinical natural language processing?  
A study of 7 clinical NLP suites

William Digan, PhD,1,2, Aurélie Névésol, PhD,3, Antoine Neuraz, MD, PhD,1,4, Maxime Wack, MD,1,2, David Baudoin,1,2, Anita Burgun, MD, PhD,1,2, Bastien Rance, PhD1,2

1INSERM, Centre de Recherche des Cordeliers, UMRS 1138, Université de Paris, Université Sorbonne Paris Cité, Paris, France; 2Department of Medical Informatics, Hôpital Européen Georges Pompidou, Assistance Publique–Hôpitaux de Paris, Paris, France; 3Université Paris Saclay, CNRS, LISN (formerly, LIMSI), Orsay, France; 4Department of Medical Informatics, Necker Children’s Hospital, Assistance Publique–Hôpitaux de Paris, Paris, France

Introduction
The increasing complexity of data streams and computational processes in modern clinical health information systems makes reproducibility challenging. Clinical natural language processing (NLP) pipelines are routinely leveraged for the secondary use of data. However, the practical implementation of state-of-the-art methods that have been validated in NLP research studies proves challenging in a clinical operational environment. Translational research would benefit from facilitating the transition of experimental NLP methods to clinical NLP tools. This is especially true for languages other than English, for which a variety of tools are developed outside of large NLP pipelines. Faced with similar challenges, the field of bioinformatics has developed over the years multiple solutions to help tackle these challenges. In particular, workflow management systems (WMS) have been widely used to handle the reproducibility bottleneck. In a recent study1 we aimed to evaluate whether WMS and other bioinformatics practices could impact the reproducibility of clinical NLP frameworks.

Materials and Methods
Based on the literature across multiple research fields (NLP, bioinformatics and clinical informatics) we selected articles which (1) review reproducibility practices and (2) highlight a set of rules or guidelines to ensure tool or pipeline reproducibility. We aggregate insight from the literature to define reproducibility recommendations. Finally, we assess the compliance of 7 NLP frameworks to the recommendations.

Results
We selected 8 selected articles5,6,7 from 455 articles discussing reproducibility retrieved from Web of Science and PubMed. We identified 5 topics of reproducibility (namely, traceability, versioning, standardization, usability, and shareability) covering 40 recommendations. Frameworks based on WMS match more than 50% of features (26 features for LAPPs Grid,8, 22 features for OpenMinted) compared to 18 features for current clinical NLP framework (cTakes,9, CLAMP10) and 17 features for GATE11, ScispaCy12, and Textflows13. This indicates that the community is well aware of the need for reproducibility and already making valuable efforts towards compliance. While current systems integrate many criteria in spite of structural limitations, there is still room for growth.

Discussion
All recommendations are largely described by NLP and bioinformatics communities. 34 recommendations are endorsed by at least 2 articles from our selection. Overall, 15 features were adopted by every NLP Framework. Nevertheless, frameworks based on WMS had a better compliance with the features. This suggests that the clinical NLP community can benefit from integrating reproducibility guidelines that have been formulated and sometimes implemented in various communities. In particular, WMS combined with modular design and integration of tools (regardless of programming languages and specifications) shows great potential at limited cost. In addition, documenting provenance of components and data can ensure the traceability and usability of analysis. Finally, curated lists of annotated datasets, programming libraries, containerized tools and pipelines could facilitate the re-usability of shareability of research results.
Conclusion
In summary, we identified 40 reproducibility recommendations based on the review of eight articles from heterogeneous research fields (bioinformatics, medical informatics and natural language processing) and our daily experience of deployment and use of NLP processes in a clinical setting. NLP frameworks can take advantage of lessons learned from other fields (and especially bioinformatics) to improve reproducibility for NLP systems in clinical settings. More precisely, specific features could be transferred to clinical NLP such as public repositories of curated workflows, enhanced modularity and shareability with containers or provenance information for traceability of processes and results. We believe that reproducibility is a necessary - although not sufficient - intermediate step towards the reuse of NLP tools, including modern neural methods. Versioning and reproducibility (including distribution of sample open data) are actionable steps that augment FAIR principles to empirically verify the validity of tools used in a new environment.

Alerting Primary Care Teams to Out-of-Network Acute Care Events using Health Information Exchange: Impact on Timely Follow-Up

Brian E. Dixon, MPA, PhD1,2,3; Kimberly M. Judon, MPH4; Ashley L. Schwartzkopf, MSW1; Vivian M. Guerrero, MA4; Nicholas Koufacos, MSW4; Justine May, MSW1; Cathy C. Schubert, MD1; Kenneth S. Boockvar, MD, MS4,5

Peters VA Medical Center, Bronx, NY; 5Icahn School of Medicine at Mount Sinai, New York, NY

Introduction
Providers seek to leverage health information technologies to access information on their patients, regardless of its source. Health information exchange (HIE) is the electronic transfer of clinical, administrative, or other information necessary for the delivery of health care across diverse systems or organizations. Most often HIE takes the form of an information system transaction mediated by technical standards, such as the electronic reporting (or pushing) of a result from a laboratory information management system to an electronic health record (EHR) system using the Health Level Seven (HL7) messaging standard. Other times HIE involves querying (or pulling) information from another system, such as the transmission of a summary of care record using the HL7 Consolidated Document Architecture (CDA) standard outlined in meaningful use criteria for Medicare and Medicaid providers (1).

Event notification is a form of HIE involving the electronic reporting (or pushing) of information pertaining to a clinical event from one provider to another facilitated by a messaging standard. Notification usually pertains to acute care events (e.g., hospitalization, emergency care), and the notifications are typically sent to primary care providers responsible for coordination of care (2). To date there has been just one quantitative study of event notifications sent to ambulatory providers for acute care events over a 3.5 year period using a regional HIE network (3). The study found a statistically significant 2.9% reduction in 30-day readmissions observed during the intervention period.

Our objective was to examine the effectiveness of event notification on health care delivery processes and outcomes for patients with out-of-network events. Given the ability of HIE to facilitate access to patient information, especially after a handoff or transfer of care, we hypothesized that HIE would impact care coordination activities, including timely follow-up and reintegration into primary care following an acute care episode.

Methods
We employed a concurrent cohort study involving two groups: 1) patients whose primary care team received an alert following an acute care event at an out-of-network facility; and 2) patients for whom no alerts were sent (e.g., controls). All patients were older Veterans (age ≥65 years) who received primary care at the following U.S. Veterans Administration (VA) medical centers: 1) James J. Peters VA Medical Center (JJP VAMC) located in the Bronx, New York; and 2) Richard L. Roudebush VA Medical Center (RLR VAMC) located in Indianapolis, Indiana.

This study is part of a larger, cluster randomized controlled trial at the two VA medical Centers. The protocol for the larger study is published on ClinicalTrials.org (NCT02689076) and available online (4). The study was reviewed and approved by the Institutional Review Board (IRB) of Indiana University as well as the VA Research & Development Committee at both the Indianapolis VA Medical Center and the Bronx VA Medical Center.

Upon utilization of non-VA acute care, an HL7 admission-discharge-transfer (ADT) message was electronically sent from the non-VA acute care facility to an HIE network connected to the two participating VA sites. Each HIE network responded to the ADT message by notifying (or alerting) the VA that an enrolled patient visited a non-VA care facility. Following notification, study coordinators at the two VA sites sent an internal electronic note within the VA’s EHR system to the Veteran’s primary care medical home team, referred within the VA as a Patient-Aligned Care Team (PACT). This note, which becomes part of the Veteran’s medical record, identifies the non-VA care facility and provides information on the reason for the visit or chief complaint. Each note required acknowledgement of receipt by a PACT team member. Alerts were sent between March 2016 to December 2019.
This analysis examined each eligible non-VA encounter during the study period. We examined the notes entered by PACT team members to ascertain whether the Veteran was contacted within 7 days following the non-VA discharge and/or whether the Veteran had a follow-up appointment within 30 days following non-VA discharge.

Baseline characteristics of patients were assessed using descriptive statistics. Comparisons in baseline characteristics between the two arms were examined using \( \chi^2 \) test or Fisher exact test for categorical variables and t-test for continuous variables. Since the units of randomization were primary care teams rather than Veterans, there was potential for imbalance between groups in terms of baseline covariates due to clustering. Group comparisons were analyzed using PROC GLIMMIX for outcomes assuming a random intercept and binary distribution while accounting for clustering within primary care teams. P-values and odds ratios were calculated for comparisons between groups, adjusting for baseline group differences in age, race/ethnicity, and Medicaid status.

**Results**

Overall the mean age of participants was 74.8 years, and the cohort was almost exclusively male (98.0%) which is typical in VA-based studies. Enrollment site and the type of non-VA acute care received during the study period was balanced, with no differences between arms. Age did vary by arm, with the usual care group mean age younger (72.5 years) than the notification group (76.9 years, \( p<0.01 \)). More non-Hispanic black Veterans were in the usual care group (30.4%) compared to the notification group (17.1%, \( p<0.05 \)).

Compared to usual care, Veterans whose primary care team received notification of their non-VA acute care encounter were 4-times more likely to have phone contact within 7 days (AOR=4.10, \( p<0.001 \)) and 2-times more likely to have an in-person visit within 30 days (AOR=1.98, \( p=0.007 \)) with a primary care provider (PCP, medical doctor or nurse practitioner) after discharge. When follow-up was expanded to include registered nurses on the primary care team, Veterans whose team received acute care notifications were almost 3-times more likely to have phone contact or in-person visit (AOR=2.65, \( p<0.001 \)) within 30 days of the acute care event.

**Discussion**

There exists a strong theoretical case for HIE to impact care coordination activities, such as reintegration into primary care following an acute care episode. We found that when primary care teams are notified of out-of-network acute care episodes, they respond by initiating contact with the patient via phone or by scheduling an in-person visit. In pre-implementation conversations with primary teams, clinicians said they often learn about non-VA encounters weeks or months after the acute care encounter, if they learn about them at all. Our findings provide evidence that care teams will use event notifications to coordinate follow-up care. Yet, more research is necessary to examine the impact of event notification on patient and population outcomes. Moreover, additional informatics research will be necessary to optimize integration of event notifications into workflow across the VA and outside the VA health system. Not all providers acted upon the alerts, even if receipt was acknowledged. Healthcare workers beyond providers might play critical roles in the process. There may be other technologies that could facilitate the process, including patient portals and decision support that could prioritize patients for follow-up care based on encounter diagnostic codes. While some non-VA events may have been missed by the system, each regional HIE network covered >90% of the geographic areas and populations served by the two VA medical centers minimizing potential for missed events.

Abstract

In April 2020, researchers at Columbia University deployed COVIDWATCHER, a citizen-science platform to understand the impacts of the novel coronavirus pandemic. This mixed-methods study examined the self-reported symptoms from COVIDWATCHER to compare the symptom experiences of users who identify as female compared to male, and further, for users who identify as Hispanic compared to non-Hispanic. Our results show a difference between reported symptoms that are likely attributed to social and environmental factors.

Introduction

In response to the surge in the novel Coronavirus disease (COVID-19), a collaborative team at Columbia University built COVIDWATCHER, an application to help inform the response to COVID-19 and better understand the personal, social, and health implications of the pandemic. COVIDWATCHER is driven by the approach of citizen science, or the public actively participating in scientific research.

Medical providers during the pandemic have often needed to make a COVID-19 diagnosis based only on symptoms. Major health organizations have already established the differential impact of the COVID-19 pandemic on women and girls [1] and, further, on women of color, including Hispanic women [2] and African American women [3]. Hispanic women across their life course have already been noted to be a demographic group at high risk for testing positive for COVID-19.

Even before the COVID-19 pandemic, women have been reported to share the same medical diagnosis differently than men [4]. The most famous example of this is the somatic symptoms during a heart attack. Though both men and women experience severe chest pain, women tend to present to emergency rooms with nausea, increasing fatigue, and shortness of breath compared to men who predominantly focus on the chest discomfort [5]. The core concern is that much of the research underlying the known biology has historically been conducted in men has contributed to gender bias in research [6].

This mixed-methods study utilized the data from 551 (49.6%) users who report their gender as female. Across the entire COVIDWATCHER user sample who answered the symptoms attestation, 10.4% of the sample registered their ethnicity as Hispanic.

We hypothesized that there were symptom phenotypes based on health status, environmental factors, and access to healthcare that impact a participant’s health trajectory throughout the pandemic and that these phenotypes are different for users who identify as female compared to

| Number of users who answered the symptoms survey | 1,109 |
| Number of user encounters | 15,455 |
| Gender | N (%) |
| Male | 529 (47.8%) |
| Female | 551 (49.6%) |
| Nonbinary | 13 (1.2%) |
| Transgender | 1 (<0.1%) |
| Other* | 15 (1.3%) |
| Hispanic heritage | N (%) |
| Yes | 115 (10.4%) |
| No | 972 (87.6%) |

Table 1. Participant characteristics in COVIDWATCHER.
those who identify as male users. Further, we hypothesized that there would be different symptom phenotypes between Hispanic and non-Hispanic women.

**Combined Qualitative and Quantitative Analysis of Reported Symptoms**

Our team completed a clustering analysis of reported symptoms from participants in COVIDWATCHER. As shown in Figure 1, there was a visual difference in the reported clustering of participants from users who identify as female and Hispanic/Latina (n=64) compared to non-Hispanic females (n=481) and users who identify as male of all ethnicities (n=529).

Labeling of the clusters based on the rich qualitative interviews found that clusters represented diagnosis variation (i.e., healthy, COVID-19, vaccine side effects, allergies, or stress). Clusters that represented COVID-19 symptomology were further characterized to show highly predictive symptoms such as fever, loss of taste, and loss of smell as driving symptoms in that cluster. Themes in the qualitative interviews expanded on both social and environmental stressors, particularly for women of color, that contributed to symptom development.

**Conclusion**

The mixed-methods results from this study highlight a discordance between when a participant uses COVIDWATCHER and when they experienced COVID or COVID-like symptoms. Clustering using COVIDWATCHER data may not be able to discern between healthy or seasonal allergies diagnoses but may be able to identify COVID for a smaller group of participants. Limitations of self-reported symptoms and a lack of training data with confirmed COVID symptoms make it difficult to answer our original hypothesis. More rigorous confirmed symptomology would be needed to fully test the hypothesis that women experience COVID disease differently than men. However, use of citizen science platforms during the pandemic can yield important insight into both health and social impacts of this unique time period.

1University of Rochester School of Medicine, Rochester, NY; 2University of Minnesota Masonic Children’s Hospital, Minneapolis, MN; 3Medical College of Wisconsin, Milwaukee, WI; 4Children’s Hospital of Philadelphia, Philadelphia, PA; 5Northwestern University Feinberg School of Medicine, Chicago, IL; 6St. Jude Children’s Research Hospital, Memphis, TN

Introduction: Widespread adoption of electronic health records (EHRs) has led to significant growth in the volume of information available to clinicians in real time. The pediatric intensive care unit (PICU) is a data-intense environment, with hundreds of thousands of data points generated daily, including laboratory results, streaming vital signs, and ventilator parameters. Clinical decision support (CDS) systems are primed to leverage these rich data, however, most of the CDS in use are rule-based alerts, order sets, and order entry systems. While many studies have focused on the development of novel predictive models, real-world implementations using CDS have lagged. Broad consensus around the goals and challenges of CDS in the PICU is lacking. In reviewing CDS in the PICU over a decade ago, Mack et al. concluded that while effectiveness was variable, factors such as incorporating into workflows, enhancing usability and considering human factors were essential to achieving success.1 This remains true today. However, to fully realize the potential for CDS in the PICU, we need to address critical gaps including understanding CDS usage, utility, and usability.

Objective: Describe the current state of PICU CDS, perceived goals and challenges, and evaluation approaches.

Methods: This IRB-approved multi-institution survey followed a published seven step development process.2 Following a literature review, semi-structured interviews were completed and coded by 3 authors to identify relevant themes. From these, survey themes were developed, and subsequent items were iteratively developed and grouped into themes. Surveys were implemented in REDCap; evaluation and guided exploration were performed at multiple sites. Finally, surveys were piloted at author institutions and updated before distribution.

1Remaining indicated a mixture of other EHRs in use. 2Remaining indicated mixed units.

Free text responses were coded independently and discrepancies were resolved by discussion. Descriptive statistics are presented as n (%) or median (IQR) unless noted. Data analysis was performed in R Studio.

Results: Survey was organized into themes identified from 10 semi-structured interviews included current CDS usage, perceived limitations of CDS use, goals and perceived concerns of CDS use, and CDS evaluation. A total of 109 surveys were completed from 45 institutions. Demographics and counts per respondent group can be found in Table
1. Groups were similar in unit type and bed numbers; medical directors were further from last training and attendings were less likely to use Epic Systems EHR compared to Cerner.

**Current CDS Usage:** CDS were divided into EHR and non-EHR tools. In all groups, most-used EHR tools included passive CDS (“Lab result highlighting”, “Abnormal vital signs”) as well as active CDS (“order sets”). Least used were “Predictive tools” and “Non-order-based alerts.” Most-used non-EHR tools included “Bedside monitors” and “People-based resources”, while least-used included “Dashboards”, “Medical calculators” and “Predictive algorithms.” Custom EHR predictive tools (38%) included sepsis alerts (N=25, 61%), acuity scores (N=14, 35%), COVID-related (N=1, 2%) and other (N=11, 27%). Some responses included multiple categories and thus percentages do not add to 100%.

**Perceived Limitations:** All groups agreed that “use of order sets saves time” and “abnormal lab highlighting is useful”; most respondents were neutral or disagreed that EHR and non-EHR “predictive algorithms provide useful information” (Figure 1). **Goals and Concerns:** CDS goals common to all respondent groups include “evidence-based” CDS, “well-placed and delivered at the right time”, with a “proven impact on patient safety”. Common concerns include “unknown decision support accuracy”, and practitioners “losing the ability to think independently”. **CDS Evaluation:** Among all groups, feedback on CDS use and burden is rarely or never provided, workflow observations are not traditionally part of CDS development, and systems to understand alert burden are non-existent.

**Discussion:** In this multi-institution survey, we identify current practice patterns and perceptions of CDS use across multiple provider roles in the PICU. Interestingly, we identified both in survey development and in the survey results that clinicians’ description of CDS broadly includes resources not traditionally considered “CDS” by informaticians, such as people-based resources (pharmacists, dieticians). Passive CDS was generally considered more useful than active CDS. Perhaps because of the slow integration of predictive algorithms with clinical systems, perception of predictive algorithms was poor across all groups. These usage patterns and perceptions identify areas of focus for targeting CDS to particular groups, as well as future exploration of under-developed CDS space such as translating evidence-based predictive models into clinical care.

The identified goals and concerns of this broad group of practitioners can be used to establish a framework to evaluate CDS in the PICU. Following development, evaluation of CDS use and performance is critically under-developed across all respondents. While most felt that feedback on CDS was well-received, use and alert burden was rarely tracked and provided to users. This space provides ample opportunity for research and operational support.

Overall, practitioners have shared goals and concerns regarding CDS and its implementation. It should be a priority for institutions and the larger ICU informatics community to support thoughtful development and implementation supporting these priorities.

Development and Global Use of a Platform-Independent Mobile App to Enable Citizen-Scientist Data Collection on Mask-Wearing

Peter J. Embi, MD, MS1, Marcelo A. Lopetegui, MD, MS2, Joshua R. Vest, PhD1
1Regenstrief Institute and Indiana University, Indianapolis, Indiana, USA; 2ICIM-Universidad del Desarrollo, Santiago, Chile.

Introduction: Wearing face masks in public is one of the easiest and least expensive strategies to control the COVID-19 pandemic. When properly worn, masks can effectively filter out respiratory droplets that may contain SARS-CoV-2. Policies mandating mask wearing have been associated with reduced risk of community-wide transmission of COVID-19. Despite this, mask wearing has been inconsistently adopted by the public, and self-reported mask behavior has varied over time, geography, and demographic groups. Further, data on proper masking wearing and from direct observational studies of mask wearing are limited.

Approaches that enable public data collection and aggregation via mobile apps have proven successful for crowd-sourcing activities such as monitoring traffic patterns. Mobile apps have also been used to enable scientific data collection by the public in fields ranging from ornithology and entomology to biomedicine. During the COVID-19 pandemic data on mask-wearing behavior was scant, but sorely needed. Potential benefits to direct observational data collection included correlating mask-wearing data with other public health data on COVID-19 disease activity, assessing the impacts of public health policies and mandates, and providing real-world data on mask usage to inform public health policies and educational campaigns.

To enable crowd-sourced data collection of directly observed public mask-wearing behavior, whether by the general public (citizen scientists) or even by trained public health workers and field researchers, we developed a Web-based mobile app. Importantly, we designed the app to be used discretely and to ensure anonymity of those being observed, while still enabling the easy and accurate capture of observed mask-wearing by the user.

Methods: Given the time-sensitive nature of the pandemic and the need to quickly create and maintain a cross-platform mobile app that could work across the globe in a low-cost manner, we elected to use Web-based technologies for the rapid development of our mobile app. User centered design was used, incorporating early adopters’ feedback on every sprint. Iteratively, the user interface design team created an extremely simple means for capturing mask wearing observations.

The app was built on a serverless architecture-based technology, Google Firebase, chosen for its flexibility, low costs, and given the world-wide scalability required. Internationalization of the user interface was achieved by using automated, artificial intelligence-based translation of text from the original English to 15 total languages at the time of release. Several languages considered the most likely to be used were manually validated by native speakers, including German, Italian, Portuguese and Spanish. Upon account creation, users were informed that the application would collect location data only while the app was in use, that their information would remain confidential, and they were asked to accept a user agreement that included an informed consent to use their deidentified data for secondary analyses. Each observation was represented by a dot on a map on the users’ screen that reflected their precise location. If needed to improve data accuracy, users could correct data (e.g. move the location of an observation, change the type of observation, increase or decrease the count observed, or delete the observation). This project and the use of the tool and data for research was reviewed and approved by the Indiana University Institutional Review Board.

Results: In under 3 weeks, a beta-version of the software was deployed for initial testing. Feedback from testers informed each development sprint, leading to the first stable version and release on September 12, 2020, just 5 weeks after conceptualization of the app. Based on user feedback, several enhancements were made during the Beta-testing and early release periods. Given the need for discrete data capture, often while the user was moving through a public space, we evolved the interface from a simple button-based data collection approach for noting “mask” “partial mask” or “no mask” to one that also included the well-known swipe gesture, commonly used for dating apps (Figure 1). They achieved this by swiping to the left, down, or right, respectively. Beta users and early adopters reported this was easy to use the app ‘on the move,’ while maintaining attention on their surroundings and not making it obvious they were collecting data. Over time, users requested, and we built-in, more registration and login options, including multiple social media authentication services, email and password, and even password-less login via SMS or email links. To encourage repeated use of the app, gamification techniques were also enhanced over time, such as the earning of

1356
badges with increasing levels of ‘prestige’ the more sessions a user completed. Registered users could also view more detailed, aggregate data on mask-behavior around the vicinity of the user could also be viewed on the app itself upon registration for an account (Figure 1).

At the time of public release, we also created a Website (www.maskcount.com) to provide easy access to the app, detailed information about the app, including its purpose, and frequently asked questions. To encourage adoption and demonstrate public value, a separate dashboard was subsequently added to the Website where anyone could visualize aggregate data generated by Maskcount users in real-time (Figure 2).

From release through July 27, 2021, 1321 individuals across 13 countries registered accounts. Among those, 511 actively used the app to collect 93,892 observations collected across 3339 sessions. In addition to use by the public, public health practitioners, researchers and educators reported use of the app and have started to publish findings based on its use.

Discussion: The rapid creation and deployment of a Web-based app designed to enable anonymous data collection by ‘citizen-scientist’ resulted in substantial adoption and use by interested individuals across the globe, and it provided new data that was used by some to gain new public health insights.

Despite the global pandemic, even greater widespread ‘viral’ adoption was not observed. Targeted use of such apps by public health, academic and research professionals was notable and could have implications for similar approaches. Further details about the platform and the data generated, a live demo, and additional lessons learned will be discussed during the presentation.

Advancing National HIE Measurement by Using Shared Patients Volume

Jordan Everson, PhD\textsuperscript{1} and Julia Adler-Milstein, PhD\textsuperscript{2}
\textsuperscript{1}Office of the National Coordinator for Health IT at HHS; \textsuperscript{2}University of California, San Francisco, California, USA

Introduction
Advancing health information exchange (HIE) has been a top policy priority for more than a decade. National measures of HIE adoption have been reported as the percent of hospitals and physicians that respond on surveys that they engage in HIE; specifically, survey questions ask if they electronically find/query, send, receive, and integrate data from outside sources (e.g., from other hospitals, health systems).\textsuperscript{1} However, these measures fail to capture heterogeneity in HIE connectivity – a given provider may be able to exchange with some providers but not others based on the HIE network(s) in which they participate. Importantly, these measures also do not capture the extent to which information is shared between organizations that commonly share in the treatment of patients. Providers may not be able to share information with other organizations that participate in HIE because HIE networks have developed unevenly across the country, with hundreds of different networks that offer varied approaches to connectivity – some focus on a given region, others focus on customers of a given EHR vendor, and still others focus on a care setting (e.g., emergency departments). As a result, provider organizations face a complex array of options and must decide in which network(s) to participate.\textsuperscript{2}

These networks are not necessarily optimally distributed, such that hospitals are able to engage in HIE with the other hospitals that treat the same patient population. For example, Epic Systems has created a network that allows hospitals on Epic to engage in HIE with other hospitals on Epic (vendor-centric HIE networks) but many care transitions occur between Epic and non-Epic provider organizations. Hospitals also choose to join HIE networks that are vendor-agnostic and have been established in some (but not all) regions. However, these HIE networks often serve a defined geographic area that may not match where patients travel for their healthcare. In addition, most states have multiple vendor-agnostic networks in overlapping geographic regions and, in recent national data, only 47% of eligible hospitals (i.e., those in the targeted region) decided to join any network.\textsuperscript{3} We therefore sought to create improved, patient-centered measures of national HIE connectivity based on the proportion of shared patients for which treating hospitals are able to exchange information because they connect to the same network.

Methods
We combined three datasets to generate measures for 2018. The first was a publicly-available dataset containing pairs of hospitals and the annual volume of shared fee-for-service Medicare patients (defined by both providing treatment to the same patients within the calendar year).\textsuperscript{4} We combined this pair-level data with information from Definitive Healthcare (formerly HIMSS) and from the American Hospital Association IT Supplement Survey on the specific HIE networks (including both health information organizations (HIOs) and electronic health record (EHR) vendor networks) that hospitals participated in each year. Using these data, we measured the proportion of patients shared between pairs of hospitals that were connected by HIE in 2018. Finally, we created multivariable regression models examining characteristics of the hospital pairs associated with participation in the same HIE network. Our analyses include all non-federal, acute-care hospitals in the United States included in all three datasets (1,721), comprising 16,433 hospital pairs that had a total of 6,492,232 shared patients in 2018. Analyses used sampling weights to adjust for differences in characteristics between hospitals in our analytic sample and all US non-federal, acute-care hospitals.

Results
As shown in Figure 1, in 2018, 65% of shared patients received care from hospital pairs connected to the same HIE network. Of these, 30% were connected via HIOs only, 18% were connected via vendor networks only, and 17% were connected by both types of networks. For 13% of shared patients, the two hospitals in the pair were connected to different networks (i.e., not able to electronically share patient data with each other). For 20% of shared patients, only one hospital in the pair participated in a network and for 2% neither hospital participated in a network.

Shared patients were more likely to be treated by hospitals on the same network when the pair shared a higher number of patients. Shared patients were less likely to be treated by hospitals on the same network when: 1) one member of the pair had a small number of other hospital partners while the other had a high number; 2) ownership
of one or both hospitals was for-profit, or both were government owned; and 3) both hospitals in the pair were located in moderately or highly competitive markets.

![Figure 1. Percent of Patients Shared by Two Hospitals, by Connectivity Status of the Two Hospitals (2018)](image)

**Discussion**

While national measures suggest that approximately 80% of hospitals participate in a HIE network\(^1\), only 65% of shared patients are treated by hospitals on the same HIE network. Targeted efforts to encourage lagging hospitals to join HIE networks could lead to exponential increases in connectivity for the 20% of shared patients in which only one hospital participates in any HIE network. More broadly, the federal Trusted Exchange Framework and Common Agreement, a voluntary national exchange framework that is still being finalized\(^2\), offers a logical policy vehicle to close the gaps we identify by explicitly considering how to prioritize participation based on shared patient volume. For example, the Recognized Coordinating Entity could identify hospitals and networks that, if connected, would most substantially increase connectivity based on shared patient volume. They could then share this list with the Qualified Health Information Networks (the networks that will be connected under TEFCA) to guide their recruitment and onboarding efforts. Our measures indicate that this explicit focus is necessary in order for ongoing public and private efforts aimed at connecting disparate HIE approaches to result in large gains in connectivity.

The Relationship between Multiple Methods used to Obtain Health Information and Use of Outside Information by Hospitals

Jordan Everson, PhD, MPP\textsuperscript{1} and Vaishali Patel, PhD\textsuperscript{1}

\textsuperscript{1}Office of the National Coordinator for Health IT at HHS

Introduction

Interoperable Health information exchange (HIE) technologies have developed such that healthcare providers can choose among several methods to obtain electronic patient health information from providers outside of their organization.\textsuperscript{1} However, in general each method does not facilitate exchange with providers using other methods or meet all use cases. In consequence, providers have adopted multiple methods to obtain and share information from outside providers, with the median hospital having adopted four methods in 2017.\textsuperscript{2}

Despite the prevalence of multiple methods of HIE, little is known about how these methods inter-relate and are associated with information availability and use by providers.\textsuperscript{3} Better characterizing how these methods are adopted, used, and relate to overall information availability could help guide health system strategy related to selecting strategies to engage in HIE and policy initiatives such as the 21\textsuperscript{st} Century Cures Act: The Trusted Exchange Framework and Cooperative Agreement, which is aimed at creating a 'single on-ramp' for information exchange by linking networks together such that participation in one network implies participation in all.\textsuperscript{4} We therefore sought to characterize how commonly each method of obtaining health information was used, how each method related to each other and how adoption of each method related to the likelihood that health information was routinely available to providers and often used.

Methods

We performed cross-sectional analysis of the 2019 American Hospital Association Information Technology Supplement to assess relationships between seven different electronic methods hospitals used to receive or find information from outside providers. Four methods involve different types of intermediaries or networks that facilitate exchange with many other hospital and providers. The other 3 methods enable one-to-one connections between organizations. In multivariable analysis controlling for hospital characteristics, we measured the relationship between adoption of each method and the likelihood that other methods were adopted and used, that providers had access to outside information and that providers used that information routinely. We report relative risk ratios rather than odds ratios for ease of interpretation.

Results

Single EHR vendor networks and national networks were the most commonly used method by those that had adopted each, with 63.8\% (95\% CI: 61.4\%-66.2\%) and 55.8\% (95\% CI: 53.4\%-58.2\%) of adopters reporting often using the method, respectively. Though most frequently adopted, provider portals were only reported as often used by 34.6\% (95\% CI: 32.5\%-36.7\%) of respondents.

In multivariate analysis, hospitals with regional HIEs were much more likely to also obtain information through Direct Messaging via a health information service provider (HISP) (RR=2.24; 95\% CI: 1.98-2.52; Figure 2); hospitals participating in national networks were modestly more likely to use Direct (RR=1.31; 95\% CI: 1.15-1.50) and hospitals with single vendor networks were only slightly more likely to use Direct (RR=1.13; 95\% CI: 1.05-1.21). Similarly, hospitals that obtained information through Direct Messaging via a HISP were much more likely to also obtain information through a regional HIE (RR=1.68; 95\% CI: 1.55-1.82), and hospitals in national networks were also more likely to use an HIE (RR=1.45; 95\% CI: 1.35-1.56). Hospitals with single vendor networks were again only slightly more likely to use an HIE (RR=1.07; 95\% CI: 1.00-1.14). Associations between the three methods without an intermediary and either Direct Messaging or HIE use were small.

Finally, hospitals that participated in Direct Messaging via a HISP, regional HIEs, and single vendor networks were more likely to participate in a national network (RR=1.48; 95\% CI: 1.34-1.64; RR=2.18; 95\% CI: 1.87-2.54; RR=1.64; 95\% CI: 1.50-1.80). Associations between the three methods without an intermediary and use of national networks were small.

All four methods of obtaining information with intermediaries were associated with greater likelihood of
Relative risk for Direct messaging via HISPs was 1.39 (95% CI: 1.25-1.54); for HIOs the relative risk was 1.19 (95% CI: 1.07-1.32); for single vendor networks the relative risk was 1.37 (95% CI: 1.25-1.49); and for national networks was 1.28 (95% CI: 1.17-1.40). These risk ratios are not statistically distinguishable (p>0.05 in all comparisons). However, only the single vendor networks and national networks were associated with greater risk of information being used by providers. The association between single vendor networks and use of information (Odds Ratio= 4.28; 95% CI=3.53-5.18) were substantial and larger than the association between national networks and use of information (Odds Ratio=1.87; 95% CI=1.59-2.20).

**Figure 2. Relationship between Methods of Obtaining Information**

Discussion
Specific methods of information exchange were highly related, indicating that these methods may be complementary or facilitate exchange by each other. As technology continues to evolve, and the Trusted Exchange Framework and Common Agreement facilitates exchange across networks, it will be important to assess whether these methods become more closely tied together or if the number of methods used decrease. Our findings also highlight important differences between available technologies. While all four HIE methods involving intermediaries were associated with greater availability of information, adoption of a regional HIE was not associated with more frequent use of that information. This reinforces concerns about the usability of data provided via these methods.5

Collecting and Sharing ECG Data with Privacy Protection

Liyue Fan PhD1, Zeyun Wu2, Luca Bonomi PhD3
1Department of Computer Science, University of North Carolina at Charlotte, NC
2UCSD Department of Electrical and Computer Engineering, La Jolla, CA
3UCSD Health Department of Biomedical Informatics, La Jolla, CA

Introduction. Advances in mobile sensor technology (e.g., wearable devices, smartphones) are revolutionizing the way in which electrocardiography (ECG) data are collected, enabling high-quality and fine-grained data to be gathered directly from the individual’s personal device1. Integrating these data into the clinical decision process has the potential for developing better interventions for cardiovascular disease and improving patient care2. However, there are significant privacy concerns in collecting and sharing ECG data. Data collected by sensing devices may contain patterns that could reveal sensitive information about individuals (e.g., heart rate and mobility patterns may be used to infer an individual’s activity). As a result, privacy methods are needed to protect data at the time of data collection. Furthermore, several studies have demonstrated that ECG data could be used as biometric to identify individuals3,4. As an example, Biel et al.4 have shown that carefully selected features from ECG could be used to achieve 100% re-identification rate on a dataset with 20 patients. As a result, simple de-identification methods that rely on removing personal health information (e.g., SSN), do not provide adequate privacy protection. To mitigate these privacy risks, current solutions for ECG data rely on encryption-based methods5. While these methods have shown promising results, their end-to-end encryption paradigm allows only a small number authorized health professionals to access the raw data. Additionally, encryption solutions may still be vulnerable in the presence of an informed adversary (e.g., in genomic data sharing applications6). Therefore, to facilitate the collection and sharing of ECG data, it is imperative to develop novel privacy technologies that address individual’s privacy concerns while enabling a broad access to the collected data.

In this on-going work, we examine how recent formal privacy models can benefit ECG data-driven applications. Specifically, we consider: metric privacy7 and local differential privacy8, which are extensions of the popular differential privacy model. These privacy models have shown to provide provable privacy protection for individual-level data and have been recently deployed by IT companies (e.g., Google, Apple) to provide privacy in IoT settings. Building on these rigorous privacy models, we develop privacy-protecting solutions for individual-level ECG data sanitization that can be deployed on each individual’s wearable device, protecting data as they are collected. We conduct empirical evaluations to understand the tradeoff between usability and privacy protection for clinical predictive tasks. Additionally, we also assess the privacy protection provided by these models when the collected individual data are first aggregated and then shared for secondary use (e.g., ECG data published for targeted cardiovascular studies). In such a setting, we consider an informed adversary who may use external information to infer the presence of a target individual in the study (i.e., membership inference).

Our preliminary evaluations on a real-world ECG data show that rigorous privacy models (e.g., metric privacy) for individual-level data can be adapted to provide privacy at the point of data collection, thus addressing individual’s privacy concerns and facilitating data participation. Additionally, these privacy models are successful in reducing the membership inference risk when the aggregate-level data are shared for secondary use.

Method. In this on-going work, we study the applicability of two recent privacy models (i.e., metric privacy and local differential privacy) in the ECG data collection and sharing setting. Specifically, we focus on: (1) privacy-utility trade-off in collecting individual-level ECG data for clinical predictive tasks, and (2) practical privacy risks when these data are aggregated and shared for secondary use.

Individual-level ECG data sanitization. In our work, we consider the ECG being collected as time-series data. To protect privacy during data collection, we design data sanitization methods that obfuscate the original ECG data as they leave the individual’s wearable devices, enabling individual to share a sanitized version of their ECG data with a central (not necessarily trusted) authority without revealing sensitive information. For example, our metric privacy method achieves privacy by first representing the time-series using the Discrete Cosine Transform (DCT), and then by carefully sampling the DCT domain a new set of coefficients are used to generate a sanitized time-series. Intuitively, under this privacy model, an individual can generate a sanitized time-series $\hat{s}$ that resembles the original ECG data $s$, for which the amount of information revealed by $\hat{s}$ about $s$ is controlled by the privacy parameter $\epsilon$. Each individual can increase the privacy protection by setting smaller values of $\epsilon$. Using this privacy paradigm, we study the impact of the user’s privacy preferences (e.g., values of the privacy parameter $\epsilon$) on the quality of the collected data for predictive analytics.

Privacy risk evaluation. To quantify the privacy protection provided by these privacy models when data are aggregated and shared for secondary use, we conduct empirical privacy risk evaluations to assess the membership inference risk. In this preliminary study, we consider an adversary who may have access to partial information of a target individual (e.g., few readings from the target). This assumption is motivated by the fact that individuals may inadvertently reveal part of the recorded data (e.g., by sharing the data on web portal provided by apps on their mobile devices) or their devices may be compromised. The goal of the adversary is to determine whether the target is in the sanitized ECG dataset, potentially learning sensitive information about the target (e.g., diagnosed with left ventricular dysfunction). We simulate such an attack, in which we control the number of readings from the original target ECG time-series data
known to the adversary and are used to re-identify the target in the shared data. For re-identification, we perform a similarity match between readings and the time-series using the Dynamic Time Warping distance (DTW). This similarity measure allows a temporal stretch in matching time-series. Furthermore, the attack is successful if the target’s time-series is identified in the top-5 nearest series to the target’s known readings (i.e., TPR@top5). Higher values of TPR indicate higher privacy risk.

**Results.** Our preliminary evaluations are conducted on the ECG200 dataset with 200 ECG time series\(^\text{10}\). Each series contains 96 samples and has been normalized to zero mean and unit variance. The dataset is labeled, where patients belong to two classes: normal heartbeat and Myocardial Infarction.

To evaluate the usability of the sanitized data, we considered a classification task, where a SVM classifier is used to classify patients as either normal or with myocardial infarction. The overall data is divided into 80% training and 20% testing. The training set is sanitized using metric privacy. We then train the SVM classifier on the sanitized data and measured the accuracy on the test set. The accuracy results are reported in Table 1. We observe that the usability increases as the value of the privacy parameter increases (i.e., weaker privacy), and the results obtained on sanitized data are comparable to those obtained on the original data (0.87 accuracy for non-private approach) when \(\varepsilon \geq 5.0\).

Figure 1 reports the empirical privacy risk in terms of true positive rate (TPR) for both the original ECG data and sanitized data with metric privacy. Our preliminary evaluations show that in the non-private data, an adversary who has access to roughly 40% of the readings achieves 0.6 TPR (i.e., more than 60% of the times a target is included in the top-5 nearest time-series). By sanitizing the ECG data using metric privacy with \(\varepsilon = 2.0\), the TPR reduces to around 0.32, thus providing significant privacy protection against this type of membership inference attack while preserving data usability.

**Discussion.** In this work, we presented our preliminary investigation on the applicability of recent formal privacy models to provide privacy protection for individual-level ECG data. Evaluations using the metric privacy model have shown that the obfuscated ECG data collected from each individual can be used to build predictive models for cardiovascular diseases, and the aggregated data can be broadly shared for secondary use. For the time of the conference, we will include our results using local differential privacy and will test our methods on larger datasets (e.g., MIMIC-III). Overall, our privacy study provides important insights on the development of privacy-protecting pipelines for collecting individual-level data and making them available for secondary use, which could facilitate emerging health applications (e.g., telemedicine and personalized medicine).

Radiology Dictation Errors with COVID-19 Protective Equipment: Does Wearing a Surgical Mask Increase the Error Rate When Using Speech-Recognition?

Abiola Femi-Abodunde, MD 1, Kristen Olinger, MD 1, Lauren MB Burke, MD 1, Thad Benefield, MS 1, Ellie R. Lee, MD 1, Katrina McGinty, MD 1, Benjamin M. Mervak, MD 1,2

1 - Department of Radiology, University of North Carolina School of Medicine, Chapel Hill, NC
2 - Corresponding Author

Introduction: COVID-19 has resulted in numerous changes to the daily practice of medicine, including the use of face masks. One study demonstrated a negative impact of personal protective equipment (PPE) on interpersonal healthcare communication in a clinical setting. Radiologists widely use speech-recognition dictation software to generate radiology reports, although transcription is imperfect even in optimal situations. Masks have a yet-unknown effect on accuracy of speech recognition. The purpose of this study is to determine the effect of surgical masks on the number and type of dictation errors in unedited radiology reports.

Methods: IRB review was waived for this prospective matched-pairs study without patient data. A power analysis was conducted. Model radiology reports (n=40) simulated those typical for an academic medical center, divided evenly between Magnetic Resonance (MR), Computed Tomography (CT), Ultrasound (US), and X-ray (XR). Six radiologists used speech-recognition software to dictate from model reports with and without a surgical mask. Models and dictations were manually compared, and errors classified by type and severity. A statistical model compared error rates using a t-test. A sensitivity analysis was performed excluding a trainee with an exceptionally large number of errors.

Results: Error rates (per 1000 words) were 21.7 ± 4.9 when unmasked and 27.1 ± 2.2 when masked (25% increase, adjusted p<0.0001). A sensitivity analysis in a group with fewer errors revealed error rates of 16.9 ± 1.9 when unmasked and 20.1 ± 2.2 when masked (19% increase, adjusted p=0.054). Single incorrect word errors were the most common (64-66%), and most errors were minor (56-58%). MR and XR reports had higher error rates than CT reports. For some participants, MR reports had significantly more errors than US reports.

Discussion: Wearing a mask was found to result in more overall errors and particularly affected some radiologists. However, most errors were minor single incorrect words and, while a nuisance, are unlikely to affect clinical care.

Introduction

Communication between patients and healthcare providers can impact patient-provider relationships, yet capturing and analyzing these interactions is time-consuming and costly, relying on video- or audio-recordings and laboriously coding them. We sought to determine whether a machine learning algorithm could be developed to more efficiently identify important communication behaviors within asynchronous secure messages (SM) written by healthcare team members. We adapted the Roter Interaction Analysis System¹ (RIAS) method to identify Communication Behavior Indicators (CBIs) in provider messages within SM threads exchanged between patients and clinical team members.

Methods

Secure messaging is a part of the Veteran’s Health Administration’s (VA’s) My HealtheVet patient portal. Secure messages stored as progress notes within the Electronic Health Record are available as Text Integration Units (TIUs) in the VA Corporate Data Warehouse (CDW). To identify CBIs in SM threads, we first created a human annotated reference set of threads to develop and evaluate a Natural Language Processing (NLP) system. To ensure the richest possible messages, we chose the thread with the highest number of messages for each patient. Based on the facility usage of SM, patient’s threads were proportionally sampled and stratified based on gender and number of patients. Since the Veteran population is predominantly male, we oversampled females to ensure adequate representation. We adapted a limited set of RIAS codes appropriate for SMs and created a coding manual for use by the team. Each message thread was annotated by two clinicians and adjudicated by a third expert. Agreement was evaluated for each of the in 36 sets of 250 threads so agreement could be checked as annotations progressed. Agreement varied but remained above .7 on average for the entire corpus. Targeted CBIs are show below in Table 1.

</tr>
</tbody>
</table>
After annotation was complete, we performed data cleaning and transformation on the threads to produce a dataset ready for analysis. The author of each message in the thread was assigned based on the “to” and “from” fields, and the datasets was created for analysis. Each sentence, phrase, or line of the body of the message was assigned a value encoding the corresponding annotations. Every line was assigned a value representing a targeted CBI. To improve incidence CBIs, we combined them into groups of related CBIs based on RIAS CBI categories still meaningful to the study. The resulting grouped CBIs and the component CBIs are listed below in Table 2. We removed lines that were not written in English, as well as blank lines and those containing only numbers.

</tbody>
</table>

The 9000 threads resulted in a total of 138,294 lines of text from the bodies of the team messages. We held out the lines of 2000 of the threads as a validation set, leaving 7000 for development. During model development the remaining data were split for into 80/20 training and test sets. We considered two multi-class models: logistic regression using the sklearn package and a feed-forward neural network, namely a multilayer perceptron (MLP). We preprocessed the text by tokenizing and removing punctuation; we then padded instances such that they uniformly comprise 100 tokens. Models were developed in Python using the Keras package with Tensorflow as a backend.

We performed hyperparameter search over the number of epochs, size of vocabulary, activation types, and other hyperparameters. We considered several methods to counteract “class imbalance” in the data, including class weighting and balanced batches. We also considered using multiple MLP models in tandem, combining the prediction probabilities of eleven separate models and deriving a new decision point to determine class membership.

Results

The results of the final best models are presented below. The logistic regression fared as well as the MLP. The overall results were better than our initial models on the individual CBIs. Ten of the original CBIs were represented in the data at under 3% of the lines of text and produced f-scores of under .5. For the combined CBIs performance on Counsel and Connection were acceptable, performance on Empathy and Build were weak. Precision for the weak performers were both over 0.7 which is desirable since for this study, since we are more concerned that the instances identified as positive be a true positive.

</tr>
</tbody>
</table>

Conclusion

To our knowledge, this study represents the first attempt to automatically extract CBIs from secure messages. The targeted CBIs were abstract, and some of the CBIs were rare (occurring in ~3% of the lines of text). Combining CBIs into related groups as new CBIs provided better targets in the PACT’s message data and we were able to achieve high F-scores for two of the four CBIs and acceptable precision on the other two. Future work includes examining associations between CBIs and patient reported satisfaction scores at the patient and facility level.

High-throughput sequencing of SARS-CoV-2 in wastewater provides insights into circulating variants

Introduction

Wastewater-based epidemiology (WBE) and genomic epidemiology represent non traditional forms of public health surveillance that have been leveraged during the SARS-CoV-2 pandemic. The former is possible since SARS-CoV-2 is shed through bodily excretions while the latter uses high-throughput sequencing (HTS) of SARS-CoV-2 genomes to highlight transmission events and the diversity of circulating variants. Since both symptomatic and asymptomatic individuals contribute to wastewater, we hypothesized that pooled samples of population-wide excreta can provide a more comprehensive picture of SARS-CoV-2 genomic diversity in a community than clinical sequencing alone.

Methods

We collected 24-hr composite samples of untreated wastewater using automated samplers from locations in 11 states from 7th April to 16th June 2020. We filtered aliquots of 150 ml of each composite sample via a 0.45 µm polyethersulfone (PES) filter and then subsequently through a 0.2 µm PES filter. For each sample, we used a 200 µl aliquot to extract total RNA. To determine the presence of SARS-CoV-2 in wastewater samples, we used the extracted RNA in a reverse transcription-quantitative PCR (RT-qPCR) assay targeting the E gene, as designed and validated by Corman et al.¹. We generated cDNA from the total RNA from each sample and used 10 µl for Illumina sequencing libraries with the Swift Nomalase® Amplicon SARS CoV-2 Panel. The samples were subsequently normalized, pooled and sequenced at Psomagen on an Illumina HiSeq 2500 sequencer (2×100 paired-end option on 1 lane in rapid mode).

Figure 1: Novel SARS-CoV-2 SNVs (not yet detected in clinical-derived samples as of 17th June 2020) in the 52 wastewater samples. y-axis: number of samples with the SNV, x-axis: position of SNV in the SARS-CoV-2 genome.
Results

We collected 60 of our 91 samples (66%) in Arizona (9 locations located in Maricopa County, AZ), 12 (13%) were from 9 locations in Louisville, KY, and 19 (21%) from other states. The tiling PCR amplification enrichment process for the SARS-CoV-2 genome generated 341 amplicons covering ~99% of the genome. We detected 7,973 single nucleotide variants (SNVs) in the 52 samples. For these, we identified 548 novel SNVs, of which 469 were non-synonymous (not including nonsense mutations) and 79 were synonymous substitutions (Figure 1). Since we evaluated all variants regardless of frequency, some locations (as expected) had more than one possible variant (Figure 1). These 548 SNVs are distributed along the SARS-CoV-2 genome with three located in non-coding regions.

In Figure 2, we show our principal coordinate analysis (PCoA) results using nucleotide frequencies to evaluate the viral population diversity within and between samples. Overall, sequences from the 10 states were highly diverse, and those from the same state clustered closer together. An exception to this are the AZ sequences which are broadly distributed. Conversely, the samples from Louisville, KY are more tightly clustered despite sampling from several city locations over a two-month period. One factor to the differences in viral diversity could be that Tempe (where most of the AZ samples originated) includes one of the largest universities in the USA and is near a busy international airport.

Conclusion

This study highlights the use of WBE and HTS for analyzing the genomics of ongoing outbreaks of infectious diseases, such as SARS-CoV-2. This approach can provide novel information on SNVs which, when coupled with data derived from clinical cases, can help identify new emerging variants of importance within a population. These approaches can be used within a public health setting as an early warning tool to inform infectious disease mitigation measures.

Can ICD-11 Replace ICD-10-CM for Morbidity Coding in the U.S.?

Kin Wah Fung¹, MD, MS, MA; Julia Xu¹, MD, PhD; Shannon McConnell-Lamptey², MS, RHIA; Donna Pickett², MPH, RHIA; Olivier Bodenreider¹, MD, PhD

¹National Library of Medicine, National Institutes of Health, USA; ²National Center for Health Statistics, Centers for Disease Control and Prevention, USA

Introduction

The International Classification of Diseases (ICD) has been in use for collection of global health trends and statistics for over a century. ¹ Its latest version, ICD-11, was adopted in May 2019 and will be implemented in member countries of the World Health Organization (WHO) from January 2022. ² Due to specific requirements in some countries, over two dozen national extensions of ICD have been developed for past versions of ICD. In the U.S., the first version of the national extension known as Clinical Modification (CM) was ICD-9-CM released in 1979. According to the official documentation of ICD-9-CM, “the term "clinical" is used to emphasize the modification's intent: to serve as a useful tool in the area of classification of morbidity data for indexing of medical records, medical care review, and ambulatory and other medical care programs, as well as for basic health statistics. To describe the clinical picture of the patient, the codes must be more precise than those needed only for statistical groupings and trend analysis.” ³ The same practice of modifying the international ICD core for clinical purpose continued in ICD-10-CM, which replaced ICD-9-CM in 2015.

The main advantage of developing a U.S. national extension is the ability to add necessary detail under the framework of the international core to serve clinical and administrative (e.g., reimbursement) needs. Another advantage is that updates to the national extension can happen more frequently, as ICD-10-CM is updated yearly compared to the three-year cycle for ICD-10. However, there are potential drawbacks. Firstly, significant effort is involved in maintaining an extension. Secondly, there is usually a delay between the release of the international version and the national extension. Moreover, there can be incongruence between the national extension and the international core. In principle, everything in the Clinical Modification should be totally compatible with the parent system. However, some significant differences can be observed between ICD-10-CM and ICD-10. For example, the ICD-10 category E14 Unspecified diabetes mellitus is not present in ICD-10-CM, because diabetes mellitus of unspecified type is coded under E11 Type 2 diabetes mellitus by default. Another example is the addition to ICD-10-CM of a new category K68 Disorders of retroperitoneum that is not present in ICD-10.

ICD-11 has some new features not available in previous versions. Apart from the introduction of the foundation component, the most noticeable novel feature in ICD-11 is postcoordination. ⁴ Postcoordination is the combination of codes to represent new meaning - a powerful and efficient way to expand the coverage, expressivity and granularity of a terminology. Towards this end, ICD-11 offers 14,500 extension codes for postcoordination. This new capability, together with the considerable increase in the number of codes - 4,015 (37.9%) more codes than ICD-10, may lead one to question whether it is still necessary to develop a Clinical Modification for ICD-11. The recommendations from the National Committee on Vital and Health Statistics (NCVHS) to the Secretary of the Department of Health and Human Services include research to determine whether ICD-11 can fully support morbidity classification in the U.S. without development of a U.S. clinical modification. ⁵

In a previous study, we examined a limited sample of ICD-10-CM codes to see how well they could be represented in ICD-11. ⁴ The objective of the present investigation is to do a comprehensive assessment of the feasibility of replacing ICD-10-CM with ICD-11 for morbidity coding, without creating a CM extension.

Methods

We used two sources of data to identify the most commonly used ICD-10-CM codes. First source was a full year of Medicare claims data in 2017. Since the Medicare population did not cover obstetric and pediatric codes, we supplemented it with data from three hospitals in Nebraska. In both sources, we identified the most commonly used ICD-10-CM codes that accounted for at least 60% of usage in each chapter. For each ICD-10-CM code, we identified the best matching ICD-11 code by using WHO’s online ICD-11 browser. ⁶ If the ICD-10-CM code’s meaning was not fully represented by the ICD-11 code, we would attempt postcoordination, as guided by the browser, to achieve full representation. Each ICD-11 recoding was done independently by two terminologists who are very knowledgeable in ICD-10-CM and ICD-11. All discrepancies were recorded and discussed until consensus was reached. Failure analysis was then performed for all codes that only achieved partial representation to determine the reason for failure and the type of missing information. Further review was carried out on the accompanying coding guidance - inclusion terms, exclusion terms and index entries - for potential conflicts between
the ICD-10-CM and ICD-11 codes e.g., the ICD-10-CM code had an inclusion which was an exclusion of the matching ICD-11 code.

Results

Based on both data sources, we identified altogether 962 unique ICD-10-CM codes required to cover 60% of patients, of which 943 codes were still active in 2021. Overall, of the 943 codes, 221 (23.4%) could be fully represented without postcoordination and 81 codes (8.6%) could be fully represented with postcoordination (Table). Concerning coding variability, agreement on the ICD-11 main codes was observed in 716 (75.9%) cases before discussion. Among these 716 cases, postcoordination was used by both terminologists in 253 cases, and they used the same postcoordination codes in 199 cases (78.7% agreement). Failure analysis showed that many of the partially represented codes were missing information related to episode of care, laterality, mode of drug exposure and trimester of pregnancy. With the addition of only nine extension codes in ICD-11 (three episodes of care, three trimesters of pregnancy and three modes of exposure), the proportion of codes that could be fully-postcoordinated will increase to 35.2%. Coding guidance review showed potential conflicts in 10% of the codes. For example, the ICD-10-CM code A41.9 Sepsis, unspecified organism was recoded as the ICD-11 code J140 Sepsis without septic shock. “Septicemia” was an inclusion for A41.9 but an exclusion for J140. In ICD-11, “septicemia” pointed to MA15 Microbiological findings in blood, blood-forming organs, or the immune system. Therefore, the ICD-11 code A41.9 was correct in the broader context of sepsis. However, in the special case of septicemia one should use MA15.

Table. Recoding commonly used ICD-10-CM codes in ICD-11

<table>

</tbody>
</table>

Discussion

Without postcoordination, only 23.4% of ICD-10-CM codes are fully represented in ICD-11. However, this can be increased to 58.6% with postcoordination and some minor enhancements. Considering that only 24.3% of ICD-9-CM codes have exact matches to ICD-10-CM codes (based on the 2016 General Equivalence Maps), migrating from ICD-10-CM to ICD-11 appears to be less disruptive than the ICD-9-CM to ICD-10-CM transition. However, postcoordination increases coding complexity and will impact tooling, coder education and coding variability. Replacing ICD-10-CM directly with ICD-11 will avoid the cost of maintaining a national extension and the potential divergence of meaning from the international core. Before embarking on the development of ICD-11-CM, serious consideration should be given to using ICD-11 for morbidity coding.

Introduction

Many patients continue to experience symptoms long after the acute phase of infection with the SARS-CoV-2 (COVID-19) virus,\textsuperscript{1} and currently, the persistence of symptoms 28 days after the diagnosis of COVID-19 infection is referred to as ‘post-acute COVID syndrome’, ‘long-haul COVID-19’ or ‘long-COVID’. A growing body of research is exploring long-COVID and the constellation of symptoms that patients experience following the acute phase of COVID-19 infection. However, there are still many unknowns associated with long-COVID, including the full spectrum of symptoms that patients experience, their progression, and their long-term manifestation. One potential source of information regarding long-COVID syndrome is social media, as many people, including healthcare professionals who had been infected with COVID-19, are reporting their experiences through this medium.\textsuperscript{2} In this study, we attempted to mine publicly available data from Reddit to discover and analyze the spectrum of symptoms self-reported by sufferers of long-COVID. Our objectives for this study were to extend a COVID-19 symptom lexicon built using Twitter data, deploy the extended lexicon to identify self-reported long-COVID symptoms from a specific forum on Reddit, analyze the distribution of symptoms and compare them with symptoms reported in recent studies.

Methods

We collected data for study from the subreddit /r/covidlonghaulers, which has emerged as the go-to forum for the discussion of long-COVID-related topics, and it is an information-rich source for obtaining self-reported long-COVID symptoms. As of 6\textsuperscript{th} June, 2021, the subreddit had over 14,000 subscribers and over 1200 threads, most of which focus on long-COVID experiences self-reported by users, their symptoms, and often the timelines of their symptoms. We first manually annotated a symptom lexicon from Reddit, grouping similar symptoms and mapping each symptom expression to a standard identifier in the unified medical language system (UMLS) using the National Center for Biomedical Ontology BioPortal.

To detect symptoms from free text, we applied an inexact matching method. Exact matching on social media free texts typically results in low recall due to the presence of nonstandard expressions and misspellings. To overcome this issue, in line with our past work, we searched through term sequence windows in the texts and computed the similarity of each text window with all entries in the meta-lexicon. Text windows that obtained similarities above a specific threshold with any entry in the lexicon were extracted and considered to be candidates for long-COVID symptoms. For an expression of $n$ terms, the term sequence windows were of the range $[n-1:n+2]$. A negation detection algorithm is then applied to search for the occurrence of negations in the same post as the candidate symptom and estimating if the symptom appears within the scope of the negation. The negation detection algorithm labels any term appearing within a 3 token window or before an end-of-sentence marker following the negation term (eg., a period) as negated. We grouped the symptoms per user and generated their frequency distributions for comparison.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1.png}
\caption{Number of users reporting each of the top 20 symptoms and their percentages.}
\end{figure}
We evaluated the performance of the algorithm using the precision, recall and F1-score metrics. To estimate precision and recall, we selected a random sample of posts, including posts from which at least one symptom was automatically detected and posts from which our algorithm did not detect any.

Results

We collected 42,995 posts from 1220 threads and 4249 users. We reviewed posts associated with a total of 450 symptom expressions (i.e., the same post could be reviewed multiple times in association with different detected symptoms) along with 25 posts without any detected symptoms to estimate the performance of our approach (recall = 0.93, precision = 0.95, F1-score = 0.94). 1744 users expressed at least 1 non-negated symptom (2576 users without accounting for negations).

Table 1. Comparison of long-COVID symptom distributions (in percentage) identified in this study with those reported in recent literature for frequently-reported symptoms. Estimated values are marked with †.

Figure 1 presents the raw counts for the top 20 symptoms reported by the users and their relative frequencies as a percentage of the total number of users who reported at least 1 non-negated symptom. The most commonly reported long-COVID symptoms are anxiety/stress and related mental health symptoms. The next 4 most commonly reported symptoms are fatigue, general & body ache & pain, confusion/disorientation and dyspnea. Pyrexia, which was the most commonly reported symptom among users who self-reported to have tested positive for COVID-19 on Twitter,5 is reported much less frequently for long-COVID (6th). Table 1 presents the relative frequency distributions of 10 commonly-reported long-COVID symptoms from this study and 3 recently-published papers on long-COVID. Fatigue is consistently reported with high frequency across studies, but considerable variations can be observed in the symptom distributions.

Discussion and Conclusion

With limited scientific data available about long-COVID and with medical care globally primarily focusing on treating acute COVID-19 cases, many long-COVID sufferers are turning to social media to discuss their persistent symptoms, finding other sufferers with similar symptoms, and identifying potential solutions to their debilitating symptoms and improving quality of life. The spectrum of symptoms identified from Reddit may provide early insights about long-COVID. Social media data, including from Reddit and Twitter, may help the medical community to better understand long-COVID from the perspective of patients and thus enable them to improve the care they provide. Considering the large volume of data that is generated in social media about this topic, it is necessary to develop automated methods involving NLP for long-term surveillance.

1Kaiser Permanente NW Center for Health Research, Portland, OR; 2OCHIN, Inc., Portland, OR; 3HealthPartners Institute, Bloomington, MN; 4Oregon Health and Science University, Portland, OR

Introduction: Modifiable cardiovascular disease (CVD) risks can be effectively managed, but CVD risk control remains suboptimal in socioeconomically vulnerable populations.1 Primary care providers must consider multiple factors impacting a patient’s CVD risk, and assess which to address for optimal impact, within a brief encounter.2 Electronic health record (EHR)-based clinical decision support systems (CDSS) have been shown to support this process and improve CVD risk management.3–5 However, little relevant evidence on the adoption and impact of such informatics tools comes from health care settings serving low-income patients, such as community health centers (CHCs). Such settings primarily serve patients regardless of insurance coverage. They are rarely resourced to develop their own CDSS. Thus, implementing CDSS proven effective in other settings might efficiently enhance CVD risk management in CHCs. To test this approach, we conducted a randomized trial in CHCs of a non-proprietary, web-based CDSS developed at an integrated care system,6 called CV Wizard©. It processes EHR data through algorithms that reflect evidence-based CVD care and are updated as guidelines evolve. This is one of the first trials evaluating the impact of an effective CDSS developed in an integrated care setting, when implemented in primary care CHCs.

Methods: Design: Cluster-randomized trial; randomization was by CHC organization. As adoption rates necessarily drive the CDSS’ impact, we assessed a) population-level impact in an intent-to-treat analysis (ITT), and b) impact when the CDSS was used, in an effect-of-treatment-on-the-treated (ETOT, or ‘per protocol’) analysis. Setting: 67 clinics, managed by 15 CHC organizations, that share an EHR as members of OCHIN, Inc. The CDSS was activated in the intervention CHCs in September 2018. The presentation will include further details about the intervention’s design and content. Patients: Adults aged 40-75 with high modifiable CVD risk (either diabetes or heart disease and ≥1 uncontrolled CVD risk factor, or an absolute 10% reversible 10-year CVD risk). The CDSS was used at 35% of eligible patients (7.4% of all eligible encounters), and just viewed at 3%; 61% of eligible patients were exposed to the tool at least once. In ITT analyses of clinic patients (n=10,984 intervention and n=7,247 control), there was no significant overall effect on CVD risk. However, intervention clinic patients’ modifiable CVD risk improved 8.4%, significantly more than among control clinic patients (7.4%), among those in the highest risk quartile at baseline (p=.046; baseline reversible risk quartile parameters were as follows: Q1 ≥10–<12, Q2 >12–<15, Q3 >15–<20, Q4 >20). In ETOT analyses, intervention
clinic patients were categorized by how often CV Wizard was used in their index and follow-up encounters (never, once, or more than once) and matched to control clinic patients on demographic and clinical characteristics. Among those for whom the tool was used more than once, intervention patients’ CVD risk decreased significantly more (by an absolute 1.68%) than control patients, whose risk declined by just 0.13% ($p<.001$). Among those in the highest quartile of baseline CVD risk, intervention clinic patients’ CVD risk improved by 4.6%, significantly more than among control patients (2.5%; $p<.001$). Those for whom the tool was used more than once had a statistically, but likely not clinically, significant improvement in diastolic BP (annual change of -3.2 mmHg) versus their matched controls (-2.5 mmHg; $p=.013$) but no change in systolic BP. No other outcomes differed significantly between comparison groups. The presentation will include details about tool adoption rates and user perceptions of the tool’s utility and lessons learned from this study.

**Discussion:** This cluster-randomized trial of a CDSS designed to reduce modifiable CVD risk found few improvements in the main outcome measure when comparing all eligible patients in intervention versus control clinics, after accounting for baseline covariates. However, significant impact was seen among those in the highest quartile of baseline CVD risk in both ITT and ETOT analyses. Adoption of the tool was far lower than that seen in its integrated healthcare setting, where its use was part of standardized workflows; such standardization is not pragmatic across diverse CHCs. Analyses are ongoing to better understand these adoption rates and implementation barriers. More research is also needed to assess the benefits of preferentially targeting higher CVD risk patients who are most likely to benefit. These results may inform future efforts to improve CVD care in CHCs by implementing CDSS and may provide a positive template for implementation of cutting-edge informatics tools in CHCs. The relatively low adoption rates of the CDSS in the CHC setting suggest that obstacles to routine use of such technologies must be addressed for this strategy to improve clinical care outcomes for millions of socioeconomically vulnerable high-CVD risk patients nationwide. In conclusion, informatics tools such as CDSS can improve CVD risk among socioeconomically vulnerable patients; further research is needed to understand which patients benefit most and how to improve tool adoption in the CHC setting.

Patient Perspectives on an Interactive mHealth Intervention to Improve Symptom Management and Medication Adherence in Early-Stage Breast Cancer: Evidence from the THRIVE Study

Ilana Graetz PhD¹, Rebecca Krukowski PhD², Janeane N Anderson PhD², Mehmet Kocak PhD², Teresa Waters PhD³, Edward Stepanski PhD⁴, Andrea N Curry PhD⁵, Andrew Robles MA¹, Gregory A. Vidal MD PhD²,³, Lee Schwartzberg MD⁵

¹Emory Rollins School of Public Health, Atlanta, GA, USA; ²The University of Tennessee Health Science Center, Memphis, TN; ³University of Kentucky College of Public Health, Lexington, KY; ⁴ConcertAI, Boston, MA; ⁵The West Cancer Center, Memphis, TN

Abstract
The THRIVE study is an ongoing randomized controlled trial of an interactive mHealth intervention with tailored messaging to improve symptom management and medication adherence for women with early-stage breast cancer. Initial evidence from patients demonstrates high level of satisfaction with the interactive app-based intervention and response from oncology team. Tailored text messages provided through the intervention was endorsed as helpful by almost all participants.

Introduction
Despite the efficacy of oral adjuvant endocrine therapy (AET) for improving survival among women with hormone receptor-positive, early-stage breast cancer, adherence rates remain low.¹ AET-related adverse symptoms have been identified as a key reason for non-adherence.¹⁻⁴ The THRIVE study is an ongoing randomized controlled trial of an interactive mHealth intervention with tailored messaging to improve symptom management and medication adherence for women with early-stage breast cancer.⁵⁻⁶ The THRIVE trial is among the first to test the efficacy of an interactive and tailored app-based intervention on AET adherence. We used early evidence from THRIVE intervention participants who completed the 6-month intervention to describe user satisfaction with the app-based intervention.

Methods
We are recruiting and randomizing 300 patients initiating AET to one of three arms: 1) an “App” group (N=100) that receives weekly reminder text messages to use the study app with clinical follow-up for concerning symptoms or non-adherence; 2) an “App+Feedback” group (N=100) that receives weekly reminders to use the app and additional tailored text messages based on their use of the app and reported preferences; or 3) a “Usual Care” group (N=100) that receives usual care only. This analysis presents preliminary results on user satisfaction with the app-based intervention. Intervention participants reported preferences on frequency of text messages, perceived impact of app use on their relationship with their oncology team, and overall satisfaction with the app. App+Feedback participants reported feedback on the tailored text messages, including rating each type of message (medication reminders, symptom management, healthy lifestyle, patient-provider communication, and positive affirmations) from most to least helpful.

Results
Overall, 106 App and App+Feeback participants completed the 6-month intervention by January 2021; 51.9% of patients were ages 60 or older (range 34-82 years), 32.1% were Black, 23.6% had incomes below 200% of the federal poverty level and 52.8% had a 4-year college degree or higher education. Most (80.6%) expressed satisfaction with the app-based intervention. Among 59 participants (55.7%) who reported a symptom or non-adherence event that triggered a follow-up phone call from their oncology team during, 69.5% reported that the response met their expectations and 28.8% that it exceeded their expectations. Most participants (79.3%) reported wanting to receive text messages once per week, 16.0% every two weeks or monthly, and 3.8% daily. Among the 53
participants (50%) randomized to ‘App+Feedback’ who received additional tailored text messages, 66% reported that the messages were “helpful” and 30.2% “somewhat helpful.” Over half (52.9%) rated messages with medication reminders as “very” or “most helpful” 32.1% (Figure 1).

Evaluation of Token Collections and Matching Models to Support Privacy-Preserving Record Linkage (PPRL)

Shaun J. Grannis, MD, MS\textsuperscript{1,2}, Abel Kho MD, MS, FACMI\textsuperscript{3}, Jasmin Phua\textsuperscript{4}, PhD, Suranga N. Kasthuriratne, PhD\textsuperscript{1,2}

\textsuperscript{1}Regenstrief Institute, Indianapolis, IN, USA; \textsuperscript{2}Indiana University, Indianapolis, IN, USA; \textsuperscript{3}Northwestern University, IL, USA, \textsuperscript{4}Datavant Inc.

**Introduction.** Patient information is fragmented across the US health care system in numerous independent clinical and claims repositories with no single unique identifier. Fragmented information hinders public health reporting, and reduces the utility of electronic patient information for clinical research, among other use cases requiring integrated data. Data collaborators increasingly seek to integrate data in a privacy preserving fashion for various reasons, including a lack of a business associate relationship, which limits sharing protected health information. Further, local legislation, business processes, and sociopolitical expectations also limit the exchange of identified health data. Consequently, there has been a steady growth in the use of privacy-preserving record linkage (PPRL) methods, and evidence-based approaches for optimizing PPRL accuracy are needed. One such PPRL use case involves the National COVID Cohort Collaborative (N3C) initiative\textsuperscript{[1]}, which seeks to integrate observational clinical data, including medications, lab results, and procedure data for a COVID-19 cohort from sites across the US.

PPRL methods typically use several token definitions (or simply tokens), which represent combinations of demographic and identifier fields that define a match between two records. For example, one token may be defined as agreement on \{last name\}_\{first initial of first name\}_\{gender\}_\{birth date\}, while another may be defined as agreement on \{Social Security number\}_\{first name\}. Tokens can serve as inputs to a variety of matching models. While the body of PPRL literature is growing, there remains a paucity of evidence-based, best-practice guidelines comparing the performance of various matching models using real-world data. This study seeks to evaluate match performance for three different matching models and for two collections of pre-selected PPRL tokens under consideration for the N3C initiative.

**Materials and methods.** **Token Collections.** Our team has over two decades combined experience matching billions of clinical and claims records across a wide variety of use cases and datasets. Using that experience, authors SG, AK, and JP identified an initial collection of 35 PPRL tokens from which we further prioritized 18 tokens for evaluation (N3C tokens, see Appendix A). We sought to evaluate both the 18-token subset collection and the complete 35-token collection. **Evaluation Dataset.** We previously developed a manually reviewed 30,000-record gold-standard matching dataset randomly sampled from the Indiana Health Information Exchange, which contains > 47 million patient registration records across more than 100 clinical data sources. The HIE represents a unique in-vivo laboratory to evaluate real-world patient matching methods, and the demographics of the HIE catchment area closely mirror the demographics of the US overall, supporting generalizability of findings. A list of the HIE demographic fields can be found in Appendix B. **Matching Models.** We selected 3 matching models: First, a baseline deterministic model wherein a record-pair is declared a match if one or more of the token definitions is satisfied. Additionally, we selected eXtreme Gradient Boosting (XGBoost) classification\textsuperscript{[2]} and Least Absolute Shrinkage and Selection Operator (LASSO) regression\textsuperscript{[3]} methods for evaluation. For all three models, we treated each token as an independent feature. For the two advanced models, we randomly split the dataset into 80% training and 20% test partitions; we optimized model parameters via hyperparameter optimization and applied to the holdout datasets. **Evaluation Metrics.** We compared the performance of the three models across both token collections using sensitivity (recall), specificity, precision (positive predictive value), and F-scores with 95% confidence intervals.

**Results.** The gold standard dataset contained 7,840 (52.3\%) true matches and 7,160 (47.7\%) non matches. **Precision and Specificity.** (Figure 1) Both XGBoost and LASSO models exhibited superior precision and specificity compared with the deterministic model. The 35-token collection exhibited significantly lower precision and specificity than the N3C token collection using the deterministic model. While not statistically significant, a similar trend favoring the N3C token collection was noted for both the XGBoost and LASSO methods. **Recall.** For both token collections, the XGBoost and deterministic methods showed statistically similar recall performance, and both were superior to the LASSO method for both token collections. **F-Score.** The N3C token collection provided the highest F-scores for the XGBoost and deterministic methods. LASSO-based methods outperformed only the deterministic method using all 35 tokens.

**Discussion.** While simple in approach, the deterministic model combined with the N3C token collection performed well, with all performance metrics exceeding 97\%. Our results suggest this method and token combination is a low complexity, technically feasible PPRL approach. Because the XGBoost model outperformed LASSO for both recall and the related F-Score metrics while showing similar precision and specificity, our results suggest that XGBoost may provide a modest improvement in match precision, at the cost of greater complexity. Future work will validate these findings among other datasets and use cases. We will also explore automated token selection methods.
Conclusion. Applying a deterministic patient matching decision model to a large, heterogeneous clinical data source using 18 PPRL tokens produces performance metrics (precision, recall, specificity, and F-Score) above 97%. Additional performance gains may be achieved by applying a more complex XGBoost classification model.

Precision VISSTA Study: mHealth Physical Activity Patterns and Patient-Reported Outcomes in Patients with Inflammatory Bowel Diseases

Ashley C. Griffin, PhD, MSPH1,2, Lucas Mentch, PhD3,
Feng-Chang Lin, PhD1, Arlene E. Chung, MD, MHA, MMCi, FAMIA1,2
1University of North Carolina at Chapel Hill, Chapel Hill, NC; 2Carolina Health Informatics Program, Chapel Hill, NC; 3University of Pittsburgh, Pittsburgh, PA

Introduction

Inflammatory bowel diseases (IBDs), which are comprised of Crohn’s Disease and ulcerative colitis, are chronic intestinal disorders of the gastrointestinal tract. IBDs are characterized by cycles of active and dormant states of inflammatory immune response with symptoms such as abdominal pain. Physical symptoms are frequently accompanied by anxiety, depression, or diminished quality of life and may be worsened by IBD therapies. Physical activity may improve physical and psychosocial symptoms, although there may be variations in inflammation related to dimensions of activity such as duration, frequency, or intensity. Much of this research is based on self-reported data which are typically over-reported. Wearable devices provide objective mobile health (mHealth) data on physical activity (i.e., steps, distance, duration), and provide richer data on various dimensions of activity. Little is known about whether there are activity phenotypes, which are observable behavioral physical activity characteristics, and how these may differ relative to patient-reported outcomes. A more nuanced understanding of activity phenotypes could be meaningful in tailoring lifestyle recommendations to improve outcomes.

Objectives

The objectives of this Precision VISSTA study were to identify clusters of physical activity patterns to generate phenotypes and to evaluate the associations between physical activity and various patient-reported outcomes (disease activity and psychosocial domains) in patients with IBDs.

Methods

Precision VISSTA uses data from the Crohn’s and Colitis Foundation of America (CCFA) Partners study, a U.S. Internet-based cohort of adults (18+) with self-reported IBDs where participants have access to a portal to sync physical activity tracking smartphone applications or wearables through a bring-your-own-device model. Participants also complete biannual questionnaires including Patient-Reported Outcomes Measurement Information System (PROMIS) short forms in the domains of depression, anxiety, pain interference, sleep disturbance, social relationships, and fatigue, and complete disease activity questionnaires specific to type of IBD (short Crohn’s Disease Activity Index-SCDAI or Simple Clinical Colitis Activity Index-SCCAI). PROMIS questionnaires are scored using standardized T-scores with a population mean of 50 (SD=10) where higher scores indicate worse symptoms. SCDAI scores range from 0 to 600, and SCCAI scores range from 0 to 19 with higher scores indicating more severe disease.

Participants were included in this analysis if they were enrolled in the CCFA Partners study between 2011 to 2020 and had at least 50% of non-consecutive or consecutive days of wearable activity data within the 6 weeks prior to completing at least one questionnaire. Participants could be included in multiple time periods if they completed more than one questionnaire (~20% of participants (113/543) who completed a questionnaire but did not have sufficient activity data were excluded). Features included in the analysis were daily average for each day that activity was recorded by a participant: number of steps, duration of moderate-to-vigorous activity (minutes), and distance of activity (miles). Features were then averaged during the 6 weeks prior each questionnaire timepoint per participant.

K-means cluster analysis, which is a simple and widely used algorithm that organizes data into non-hierarchical groups, was used to generate the physical activity groupings. K-means uses an iterative approach to assign each data point to the closest mean (i.e., centroid) within each cluster by minimizing the average sum of squared Euclidean distance. The number of clusters (K) was determined by calculating the sum of squared errors (SSE) for different values of K. The value of K was selected where the change in SSE decreased and was becoming plateau, indicating additional clusters produced little value (“elbow point”). The quality of clustering was evaluated using silhouette coefficients to measure the amount of cohesion and separation within and among the clusters. Ranging from -1 to 1, higher coefficients indicate better clustering. Based on these clusters, we conducted a cross-sectional analysis to assess sociodemographic differences between the clusters and to compare means of disease activity and PROMIS scores.
across clusters using one-way analysis of variance (ANOVA). All analyses were conducted in Python 3.7, and K-means was conducted using the k-means Scikit-learn package.

**Results**

The final analytic sample included 430 participants with 285 (66.3%) having Crohn’s Disease and 145 (33.7%) having ulcerative or indeterminate colitis. Participants were primarily female (74.0%), white (95.2%), and attained at least a college degree (77.9%). On average, age was 42 years, BMI was 26, and duration of disease was 15 years. The majority used a Fitbit device (86.3%). Daily on average, participants took 7,893 steps, performed moderate-to-vigorous activity for 41 minutes, traveled 3.5 miles, and burned 520 calories during exercise activities.

K-means cluster analysis identified three clusters. Data within each cluster were assessed to determine a label that represented each cluster’s activity attributes. We labeled the clusters in a way that is interpretable: low, moderate, and high physical activity phenotypes (Table 1). Participants could be in multiple clusters if they completed ≥1 questionnaire and had sufficient activity data. For the 430 participants, there were 1,255 total 6-week periods, of which 423 (33.7%) were classified as low activity, 577 (46.0%) as moderate activity, and 255 (20.3%) as high. Overall, clusters were moderately defined with an average silhouette coefficient = 0.54. Across all patient-reported outcomes (PROs), patients in the low activity cluster had the worst scores and those in the high activity cluster had the best scores. Scores varied significantly across clusters for depression, pain, fatigue, sleep disturbance, social relationships, and short Crohn’s Disease Activity Index (p<0.01). Sociodemographic characteristics varied across clusters with those with low activity being older, having higher BMIs, and longer disease duration compared to the other clusters (p<0.05).

* p<0.05, ** p<0.01

The sample was limited to participants in the CCFA Partners cohort who synced their smartphone application or wearable device, which may not be representative of all patients with IBDs. Most consumer-grade wearable devices do not make the details of their algorithms or firmware updates available, so there may be differences in hardware or sensors across brands and devices over the ten-year study period. The clustering approach was limited by the lack of gradient or differentiation between individuals once clusters were established, so it is possible that individuals with similar activity patterns could be in different clusters. The sparse nature of the 6-month longitudinal survey timepoints also precludes causal inferences.

**Conclusion**

Recognition of patterns and changes in lifestyle behaviors by leveraging real-world mHealth data supports opportunities to inform interventions. Patients in the low activity cluster generally reported worse psychosocial and disease activity than those in moderate and high activity clusters. Additional support for physical and psychosocial symptoms and exercise may be valuable for those in low activity subgroups. Future research should examine these findings among more diverse cohorts with more frequent PROs measurements and validate reproducibility.

Effect of Abbreviation and Acronym Expansion on Patients' Comprehension of their Health Records: A Randomized Trial

Lisa Grossman Liu1*, Meghan Reading Turchioe2*, David Russell3, Annie Myers2, David K. Vawdrey4,1, Ruth M. Masterson Creber2

Introduction
Taking effect in April 2021, U.S. federal policy implementing the 21st Century Cures Act will require that all electronic health record information, including clinical notes, be made accessible free of charge to patients.1 An estimated 100 million Americans accessed their own health records online in 2019, compared with 65 million in 2017.2 This transparency has prevented medical errors, increased shared decision-making, and improved health outcomes. Given the positive effects of transparency on health and healthcare, as well as the protections proffered by the 21st Century Cures Act, patient access to records will likely continue to increase.

Unfortunately, medical abbreviations and acronyms hinder patients' comprehension, interpretation, and use of their own health information, especially clinical notes, which may cause miscommunication and diminish the potential value of transparency.3 Abbreviations constitute 30 50% of words in clinical notes, compared to <1% in general text such as news media, which demonstrates the inaccessibility of health records for most U.S. patients. Entire sentences may be composed of abbreviations, for example "50 yo F w/hx BSO pw/ LLQP," translated as "50 year old female with a history of bilateral salpingo-oophorectomy presents with left lower quadrant pain." It is therefore unsurprising that abbreviations cause confusion and other unintended negative consequences, and practical solutions are needed.

The Joint Commission prohibits abbreviations in discharge summaries and other patient-only documents. Unlike patient-only documents, however, clinicians contribute to and use health records such as notes, and prohibiting abbreviations is unrealistic. To address this challenge, the field has focused on post-hoc or automated expansion of abbreviations that are already present, which is a more pragmatic solution. It is undoubtedly important to expand most of these abbreviations before patients will understand them. However, the magnitude of the effect on comprehension has not been quantified. This quantification will be essential to guide policy efforts around expansion. In this two-arm, parallel, individually randomized trial at three urban hospitals, we estimate the effect of expansion on patients' comprehension of abbreviations. To isolate the main effect, we control for patients' prior exposure to the healthcare system, the clinical and written context, and the potential difficulty of comprehension.

Methods
We recruited a purposive sample representative of the U.S. population from 3 medical centers in the New York City area. To control for prior health system exposure and clinical context, only English-speaking adult patients with advanced heart failure (NYHA Class III or IV) currently or recently hospitalized (<1 month ago) were recruited.

Participants received either abbreviations (e.g., "MI") or expansions (e.g., "myocardial infarction"). Six clinicians rated 20 abbreviations and expansions commonly found in advanced heart failure notes as easy, moderate, or difficult for their patients to comprehend. We then chose 10 abbreviations of varied difficulty and their corresponding expansions for inclusion in the trial (Figure 1): [easy] "hrs" (hours), "MD" (medical doctor), "BP" (blood pressure), "ED" (emergency department), [moderate] "yo" (year old), "pt" (patient), "HF" (heart failure), [difficult] "hx" (history), "HTN" (hypertension), "MI" (myocardial infarction).

A coordinator interviewed participants by phone or in-person at the outpatient clinic or inpatient unit. Participants completed a baseline questionnaire to assess demographic and socioeconomic characteristics and were screened for inadequate health literacy. Then, participants were assigned groups (1:1 ratio) using a computer-generated block randomization algorithm (size=4) that concealed allocation sequence. We presented abbreviations and expansions in
a short paragraph to contextualize them, similar to the HPI (history of present illness) section of doctors' notes. Data were recorded in REDCap, a HIPAA-compliant research application.

Based on clinicians' predictions, we expected 89% (8.9/10) overall comprehension in the intervention group and 56% (5.6/10) in the control group. We used a two-sided unequal variances t-test at P<0.05 to analyze differences in overall comprehension (primary outcome), defined as the summary (count) score of the total number of abbreviated or expanded terms comprehended. Fisher’s exact tests at P<0.05 were used to examine differences between abbreviated and expanded versions of each individual term. We conducted bivariate analyses to assess whether baseline characteristics differed by group. Nominal variables were compared using Fisher’s exact tests, while ordinal and numerical variables were compared using Wilcoxon rank-sum tests. In a subgroup analysis of control participants, correlation (numerical variables) and t-test or ANOVA (categorical variables) were used to determine relationships between individual baseline characteristics and overall comprehension (summary score).

Results

Of 41 patients approached between February and November 2020, 29 agreed to participate. We randomized 17 to receive abbreviations (control group) and 12 to receive expansions (intervention group). Overall comprehension scores were significantly greater among patients in the intervention group who received expansions (score 9.3/10 [95% CI, 8.9 to 9.7]) than among patients in the control group who received abbreviations (score 6.7/10 [95% CI, 5.5 to 7.9], P<.001). Participants with an older age, lower educational attainment, and inadequate health literacy comprehended fewer abbreviations.

Discussion

Today, millions more patients access their own health records online than even 5 years ago, and U.S. federal policy will require access beginning April 2021. Unfortunately, abbreviations and acronyms hinder patients' comprehension of their own information, which may cause unintended negative consequences. In this randomized trial, patient comprehension of common abbreviations in health records was poor-to-moderate (67%). However, expanding abbreviations led to an impressive increase in comprehension (93%, P<.001). The findings suggest that post-hoc or automated expansion would substantially improve patient understanding of their own health information. As such, expansion should be encouraged as part of federal policy.

Acknowledgements

We gratefully acknowledge the support and contributions of the patients and healthcare providers who participated in the study. Thank you to George Hripcsak, Suzanne Bakken, and Jessica Ancker for your support.

Introduction

International Classification of Diseases (ICD) coding system have codes for the recording of social needs; however, documentation of non-clinical issues in electronic health records (EHRs) is infrequent compared to medical conditions. ICD codes in EHRs for social needs identification, therefore, may under-report patients with such needs and risks, which makes it difficult for healthcare systems to target “high risk” patients for interventions addressing social needs. Social needs may be discussed with healthcare providers during visits and, therefore, recorded in EHR unstructured data or free-text providers’ notes. These notes might provide a more accurate accounting of social needs; however, traditional approaches for review and abstraction of patient information from the notes are laborious, expensive, and slow. Recent developments in text mining and natural language processing (NLP) of digitized text allow for reliable, low-cost, and rapid extraction of information from EHRs. In this pilot project, we evaluated whether an NLP algorithm could extract valid measures of social needs from Epic-based EHRs in three healthcare systems: Johns Hopkins Health System (JHHS), Kaiser Permanente Mid-Atlantic States (KPMAS), and KP Southern California (KPSCal). The focus of our study was residential instability (i.e., homelessness and housing insecurity).

Methods

The study was conducted independently, in a parallel and coordinated framework across sites. The study population included beneficiaries ≥18 years of age during 2016 through 2019 who received care at JHHS, KPMAS, KPSCal and had at least one provider note in the EHR. To develop hand-crafted linguistic patterns a team of experts at JHHS reviewed ICD-10, CPT, LOINC codes, SNOMED terminologies to identify phrases related to residential instability, and the description of residential instability in public health surveys and instruments (e.g., U.S. Census, American Community Survey). Our team also reviewed phrases derived from a literature review of other studies and the results of a manual annotation process from a past study. To craft the linguistic patterns, the expert team developed a comprehensive list of available codes, specific content areas, and phrases for residential instability, matched them across different coding systems, and developed several phrases and synonyms to describe each content area. Using these phrases each study site included lemma variants of the terms to address variation in describing the residential instability in the providers' notes at their site. Each study site performed pre-processing on the extracted providers' notes, which included (1) cleaning developments and non-word or digital characters, (2) spelling check and correction for mistyped, misspelled, or concatenated words detected during the NLP development process in previous studies, (3) sentence separation, and (4) tokenization (i.e., segmenting text into linguistic units such as words and punctuation). The validation assessment and NLP algorithm logic were identical across sites; however, the “gold standard” for assessment of algorithm validity differed according to data availability: while JHHS and KPMAS used the positive/negative responses to specific residential instability questions in the EHR-based questionnaires, KPSCal used relevant ICD-10 codes and manual annotation of a limited number of patients to develop the gold standard (Table 1).

We applied spaCy’s open-source natural language processor to process and interpret unstructured provider notes. Using the EntityRuler module of the spaCy 2.3 Python toolkit, we created a rule-based NLP system made up of 61 expert-developed patterns that, if present, would represent residential instability. Our patterns included word 'lemmas' and base forms to account for morphological variations (e.g., singular and plural forms) as well as substitutions of different prepositions (e.g., about and for), and synonym words (e.g., house and apartment). We utilized SpaCy’s
PhraseMatcher function to efficiently identify phrases indicating residential instability using the developed patterns. The process included searching each sentence for patterns addressing residential instability and patterns associated with a historical term or a historic date of residential instability. We considered the identification of negated patterns and patterns describing residential instability for someone else or the actual situation (false positive) as the absence of residential instability for the patient. We revised and optimized the patterns through an iterative application of the natural language processor within the training dataset. We completed pattern revision and optimization before model implementation on the validation dataset. Therefore, the validation dataset pattern results did not influence the pattern generation and revision. We calibrated and then validated the algorithm using a split-sample approach. The sample size for the training and validation datasets was selected proportional to the number of available responses to the EHR questionnaires (JHHS and KPMAS) and documented ICD-10 codes and resources available for manual annotation (KPSCal) (Table 1). Validity was assessed at each site by measures of sensitivity and specificity.

1 Randomly selected from the pool of patients with +/− responses to the residential instability questions in the EHR questionnaires. Randomly selected 50% of the sample to develop the training dataset and reserved the remaining subset for the validation dataset. Total number of available +/− responses to the residential instability questions in the EHR questionnaires. Randomly selected 80% of the total sample to develop the training dataset and 20% for the validation dataset. 2 Randomly selected from patients with documented ICD-10 codes related to residential instability. Randomly split the total sample into 5 subsets (each containing 30 + and 30 - patients for residential instability). Used 4 subsets to develop the training dataset and reserved the remaining subset for the validation dataset.

Conclusion
The consistent performance of this NLP algorithm to identify residential instability in three different healthcare systems suggests the algorithm is generalizable. The consistent and relatively high sensitivity and specificity demonstrate the algorithm’s validity. The variation in the performances among different health systems could be due to different approaches for development of the “gold standard” for assessment of algorithm validity. The development of generalizable NLP algorithms with promising performance will enhance the value of EHRs to identify at-risk patients across different health systems, improve patient care and outcomes, and mitigate socioeconomic disparities across individuals and communities. The NLP algorithm could be further developed to address other social needs and expand internationally.

Abstract

Systematic Reviews (SRs) and meta-analyses (MAs) are tools to synthesize evidence for important clinical topics. They are frequently used by decision makers as they provide precise estimates of effect for clinically important benefits and harms outcomes with associated certainty of evidence. However, when the field is rapidly evolving, laborious process of systematic reviews cannot keep pace with new evidence and SRMAs are quickly outdated. Thus, it is important to keep the systematic reviews “living”. For truly living systematic reviews (LSRs), the most laborious step of screening thousands of citations to identify few relevant studies must be automated. Thus, we propose a hybrid approach that integrates interactive web-based user interface and multiple natural language processing and machine learning based techniques to screen publication to maintain LSRs.

Introduction and Background

Systematic review is a synthesis technology that is widely used by researchers across many specialties 1. Developing an SR generally requires screening of thousands of citations to identify a small number of studies which meet the inclusion criteria. To maintain an LSR, this becomes a long-term iterative process where new studies must be screened at a regular interval to identify new citations. Several machine learning (ML) and natural language processing (NLP) based methods have been proposed to help with the screening process 2. Those methods could provide effective support and reduce the workload in one screening instance.

However, keeping a SR living requires repetitive screening, for example on a weekly basis, and thus applying these models necessitate users to learn not only the computer programming languages to use the packages, but also the modules and workflow to processing the massive data. Thus, maintaining LSRs continues to be an intensely laborious manual process. To semi-automate the screening process, we present a hybrid approach that integrates interactive web-based user interface and multiple NLP and ML based techniques to iteratively screen incoming citations and thus making the screening process efficient for LSRs.

Method

Studies or citations included in LSR are first identified using a conventional search strategy followed by an automated search strategy. Conventional search strategy is executed in multiple databases (e.g., PubMed, EMBASE, etc.) with customized keywords to retrieve the most recent literatures for a specific clinical question. At the first stage, our platform allows users to either complete the initial screening process utilizing the user-friendly interface or the results from the projects where screening has been completed can be simply uploaded (Fig.1 (B)). The main output of the first stage is the decisions for every record (i.e., included or excluded), which could be used as the input for the next stage. Since our team has conducted systematic reviews on several clinical research projects and accumulated relevant datasets, we could proceed directly to the next stage based on these datasets for each project. At the second stage, the search strategy developed in the first stage is re-used periodically based on the speed of influx for new evidence (e.g., weekly, bi-weekly, or monthly) to retrieve new records and expand the project dataset continuously.

In each small batch update, the pipeline works on the new emerging studies based on several different techniques in three steps (Fig.1(A)). We developed two modes to get new records, namely pull mode and push mode. In the pull mode, our system actively retrieves new records for each project by sending the pre-defined query requests to data sources based on the same search strategy designed in the first stage to make sure all the new coming studies meet the same criteria. The pull mode could be performed automatically at regular intervals or manually per user request. Once

* Those authors have contributed equally as co-first authors
the new studies are pulled from the data source, our system will remove the duplicates. Then, all of the new studies are saved in the project database and set to an unscreened status. In contrast to the pull mode, the push mode passively receives new records from the data sources by using the email subscription services provided by the data sources (e.g., Ovid AutoAlert). Our system checks the email inbox regularly and generates a new study list by parsing new emails’ attachments. Then, similar to the pull mode, each study will be further processed, and the new studies will be saved.

In the second NLP and ML based labeling step, various models based on NLP and ML methods are used to add labels to new studies for further screening. For example, the randomized controlled trial detect model based on support vector machine and convolutional neural network is integrated to detect whether a study is an RCT or not; the national clinical trial (NCT) number detect model based on regular expression extracts the NCT number from study abstract; publication type model detects whether a study is original or follow-up. Those automatically generated labels will be stored in the project database as part of the meta-data and indexed by integrated search engine.

In the third interactive screening step, we present the labeled new studies through an interactive web-based user interface to assist users screening (Fig. 1(B)). In this web-based user interface, all studies and their meta-data are listed by the study status (e.g., unscreened, excluded, included, etc.). At this stage, we facilitate the screening process by an interactive design to reduce workload and improve screening efficiency. For example, the labels generated in the second step for study type (RCT or not) are displayed intuitively with each study to help users identify the study type. Furthermore, the search engine allows for filtering studies by text and the color-encoded inclusion/exclusion keywords highlighting eases the screening process. After the third step, the screened new studies have been saved in the project database with the decisions. The meta-data from already screened citations will be used to train and fine-tune the NLP model which will automate the screening process for LSR in future.

Discussion

We iteratively designed and developed this screening system while maintaining living systematic review projects for first line treatment of metastatic kidney cancer, cancer associated thrombosis, and toxicity of immune checkpoint inhibitors. Qualitative feedback from experienced systematic reviewers suggests that our approach decreases the workload and increases efficiency for creating LSRs. The next steps include ongoing enhancements to the visual interface, implementing fine-tuned NLP models for each LSR based on labeled meta-data generated by initial screening of each project, and formal user testing.

Investigating the Narratives of Anti-Asian Hate Speech on Twitter During the COVID-19 Pandemic

Lu He¹, Ya Cheng², Tianyang Zhou², Yongxu Xian²
¹Department of Informatics, University of California, Irvine, Irvine, CA, USA,
²Department of Computer Science, University of California, Irvine, Irvine, CA, USA

Introduction
The COVID-19 pandemic has caused significant fatalities, economic loss, and emotional disturbances around the world. The pandemic is characterized by great uncertainties and controversies in its origin, severity, transmission mechanisms, and coping strategies. Facing great uncertainty and emotional stress, people turned to social media such as Twitter to gather information and express their opinions. Among social media discussions related to COVID-19, hate speeches targeting specific racial groups also arose and increased discrimination against certain racial groups. While recent studies investigated the detection, dissemination patterns, network structures, and associations with demographic features of anti-Asian hate speeches on Twitter,¹ ² ³ few studies have investigated the narratives of hate speech during the pandemic to understand how their creators narrated their arguments to attack and discriminate people of specific racial groups. Understanding the narratives and discourses of hate speech during the pandemic could provide implications into design public health communication strategies to reduce hate speech and associated racism.

In this preliminary, exploratory study, we investigated the topics commonly discussed in hate speech targeting Asian and Chinese populations during the COVID-19 pandemic on Twitter. We found that anti-Asian hate speech on Twitter during the COVID-19 pandemic has two major categories: 1. Attributing the virus origin to a specific country by drawing on conspiracy theories; 2. Calling for political actions to punish the proposed origin country.

Methods
Data collection and preprocessing. We collected Twitter data by choosing keyword queries from Hashtagify.me, a hashtag search engine that allows users to find relevant and commonly used hashtags. We started with a few seed hashtags (#ChinaVirus and #WuhanVirus) and used Hashtagify to identify other hashtags that were commonly used together. We also manually looked through tweets that used those hashtags to make sure that they represented content related to hate speech targeting Asian and Chinese populations. In the end, we used the following hashtags to retrieve tweets: ChinaVirus, WuhanVirus, ChinaLiedAndPeopleDied, ChinaLiedPeopleDie, ChinaMustPay, MakeChinaPay, ChineseBioterrorism, ChineseVirus19, ChineseVirusCorona, ChineseWuhanVirus, XiVirus. Data were collected from January 20th, 2020 to April 12th, 2020. After retrieving tweets containing the identified hashtags, we preprocessed the data to remove image and video links. We further excluded non-English tweets and then removed all common English stop words. Then, we tokenized each tweet’s text and prepared the data for analysis.

Data analysis. To extract the commonly discussed topics, we applied Latent Dirichlet Allocation (LDA), which is an unsupervised probabilistic text mining technique widely used in previous studies.⁴ ⁵ We tested different numbers of topics until the resulting topics were distinguishable and comprehensible. We manually read tweets that contained the topical words returned by LDA to derive the topic names and descriptions. We also calculated the Term Frequency-Inverse Document Frequency (TF-IDF) and identified the most important bigrams and trigrams to enhance the readability of the topics when the topical unigrams were not informative enough to derive the topics.

Results
Descriptive statistics. Overall, 151,315 tweets from 45,529 users were collected from the three-month period. Similar to previous studies, we observed a sharp increase in the tweet volume after President Trump tweeted using the phrase “China Virus” on March 16th, 2020.²

Commonly discussed topics. The three commonly discussed topics are presented in Table 1 below. All example tweets were paraphrased to protect the privacy of the original posters.

<table>
<thead>
<tr>
<th>Topic</th>
<th>High-frequency words and phrases</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Discussion and Conclusion

Through exploratory and unsupervised topic modeling on a large Twitter dataset, we identified two major categories of anti-Asian hate speech during the initial stage of the pandemic. The first category (Topic 1) attributed the origin of the virus to a certain country and attacked Asian and Chinese populations based on this virus origin. Tweets within this category also drew on conspiracy theories (e.g., the country of the proposed virus origin intentionally hid the outbreak) to support their arguments. The second category (Topic 2-3) called for political actions, such as voting to support political leaders/parties that will punish the proposed origin country and boycotting products and businesses in the proposed origin country.

Our preliminary study provides initial insights into how creators of hate speech narrated their posts to attack people of certain racial groups during the pandemic. Public health communication should target these hate speech narratives to clarify virus origins and debunk conspiracy theories used to support their arguments. In addition, we note that hate speech in a public health crisis is not only about the disease itself (i.e., virus origin) but also highly politicized by tying political actions such as voting for specific political leaders/parties and calling for sanctions to the disease.

Our study has several limitations. First, we adopted an unsupervised text mining technique that may have degraded performance on informal and short texts such as tweets. In future work, we plan to develop more advanced machine learning models based on qualitative analysis results to obtain more accurate and in-depth categories of hate speech. Second, our analysis only included data from the initial stage of the pandemic and did not provide insights into how anti-Asian hate speech evolved over time in the later stage of the pandemic. In future work, we will include more tweets to date to analyze the temporal changes of anti-Asian hate speech and how they correspond to different events.

Apps for Covid-19 in Germany: Assessment Using the Mobile Application Rating Scale

Felix Holl, M.Sc.¹,²,³, Fabian Flemisch¹, Walter J. Swoboda, M.D.¹, Johannes Schobel, Ph.D.¹
¹DigiHealth Institute, Neu-Ulm University of Applied Sciences, Neu-Ulm, GERMANY; ²IBE, Ludwig Maximilian University of Munich, Munich, GERMANY; ³Institute for Global Health Sciences, University of California, San Francisco, San Francisco, CA

Introduction

Fueled by the wide availability of cellular networks and mobile phones, mobile health (mHealth) applications have become widely used to expand access to care and are being used to monitor communicable diseases.¹² The Covid-19 pandemic, which started in 2019, has put healthcare and public health systems around the globe under immense pressure. mHealth applications have been identified as an essential mechanism to control the spread of Covid-19, and a multitude of apps have been developed.³⁴ This study aims to give an overview of apps for Covid-19 in Germany and assess these apps using the German Mobile Application Rating Scale (MARS-G)⁵.

Methods

Both the Apple App Store and the Google Play Store were systematically searched to identify apps for Covid-19 using the regional setting Germany and the following search terms: “Corona, Corona Warn App deutsch, Corona App, Robert Koch-Institut, Kontaktdaten, Kontaktverfolgen, Covid-19 App, Covid-19 App deutsch, Covid-19”. Only apps available for both operating systems (OS) were included in the analysis to reduce potential bias because of the price differences of smartphones running the different OS. Apps included had to be available in Germany and the German language. In addition, apps meeting the following criteria were excluded: 1) city or county-specific, 2) apps in a pilot stage, and 3) scheduling apps for vaccinations and Covid testing.

The MARS-G, a translated and validated version of the Mobile Application Rating Scale, was used to assess the applications included in the analysis.⁵⁶ Two trained raters independently evaluated the quality of the included apps, each rater using both a device with Android OS and iOS. Rating differences of 2 and greater were resolved.

Results

The search was performed on June 6, 2021, and yielded 64 (Google Play Store) and 157 (Apple App Store) results. Fifty apps were available in both app stores, and six apps were extracted for analysis based on the inclusion and exclusion criteria. Table 1 shows the apps included in the study and their characteristics. All apps are free of charge and do not offer in-app purchases.

Discussion

The target audience for all but one app is private citizens. The overall quality of the apps is rated high, despite the short development time of the apps. The fact that all but one applications were developed by federal institutions or a public academic institution could explain the high Information quality rating. The low scores in the engagement section show that there is still room for improvement to increase the uptake of Covid-19 apps in Germany. This study is limited by the fact that apps were searched and downloaded on June 6, 2021. Given the dynamic of the Covid-19 situation, apps get updated often. In addition, the Luca app received a high rating but has been heavily criticized for its security vulnerability, which is not reflected in the rating.

Conclusion

To our knowledge, this is the first study that identified and assessed Covid-19 apps available in app stores in Germany. The study has shown that despite the good quality in aspects such as information and functionality, there is still room for improvement in the engagement section.

Assessing the Impact of COVID-19 on Clinician Electronic Health Record Use

A Jay Holmgren, PhD MHI1, N Lance Downing, MD,2 Mitchell Tang, BA,3 Christopher Sharp, MD,2 Christopher Longhurst, MD,4 Robert S Huckman, PhD3

1University of California, San Francisco, San Francisco CA; 2Department of Medicine, Stanford University, Stanford, CA; 3Harvard Business School, Boston, MA 4Department of Biomedical Informatics, University of California, San Diego, San Diego, CA

Introduction

The COVID-19 pandemic issued in a sudden and dramatic change to many aspects of the health care delivery system, including clinician workflows and relationship with the electronic health record (EHR). In a matter of weeks, health care organizations shifted ambulatory care delivery to include phone- and video-based telemedicine encounters.(1) Clinicians still delivering face-to-face care were forced to re-structure many aspects of their practice in order ensure the health and safety of their patients and staff. The format, structure, management and delivery of care have been considerably altered in response to the pandemic. For example, during virtual encounters clinicians can no longer collect vitals or conduct the physical exams that inform clinical assessment, reasoning, and decision making. In addition, communication nuances may be lost, and communication with patients and across clinical teams may be more difficult. Taken together, these factors result in greater reliance on the electronic health record (EHR) to access historical data, complete documentation, and engage in communication with patients and other clinicians.

These changes in clinical work may exacerbate existing issues of burnout and cynicism amongst clinicians. Further, if the increased EHR burden is driven by activities such as reviewing patient history or secure messaging with patients, these new demands on clinician time will be largely concentrated in tasks that are currently non-reimbursable in our current billing system. In order to inform policymakers and health systems leaders interested in addressing clinician burnout, working to ensure EHRs support clinicians in times of crises, and developing sustainable payment policy for telemedicine and virtual care, it is critical to examine the short and long-term impacts of COVID-19 on clinician EHR use. To address this pressing need, we used a novel dataset of national, longitudinal EHR metadata to examine the impact of the COVID-19 pandemic on a variety of dimensions of clinician work.

Methods

We aggregated EHR active use metadata from 366 health systems, comprising nearly the entire US customer base of the largest electronic health record vendor, Epic Systems, to measure clinician EHR work. This granular data describes the amount of time a clinician spends actively using the EHR per day, broken down by four functions (Clinical Review, InBasket messaging, Orders, and Notes), as well as the amount of time spent after-hours (“pajama time”) based on clinician schedules. This metadata measures only “active use” time spent working in the EHR, including clicks, mouse movement, and keystrokes, and stops counting if no inputs are detected for five seconds, consistent with previous studies using Epic Systems metadata.(2) We limited our metadata to clinical care EHR use, and excluded time spent in the EHR for other purposes such as research or customization. Our sample included all clinicians with scheduled appointments, including physicians and advance practice practitioners such as physician assistants and nurse practitioners.

We also measured daily volume by number of patient encounters per clinician, as well as number of messages received per day by clinicians, categorized by message source: results, patient, team, prescription, system-generated, and other. All data was then aggregated to the organization-week level to create a longitudinal dataset from December 29, 2019 through December 27, 2020.
We used an ordinary least squares regression with an event study framework to estimate the impact of the pandemic over time on total EHR time per day and after-hours time per day, using the imposition of the California shelter-in-place (SIP) order as our date for the onset of the pandemic, with the two weeks prior as the baseline week. Both models control for daily volume and organization-level fixed effects to address time-invariant omitted variable bias. Next, we calculated descriptive statistics for EHR time per day, broken down by each of the four primary functions, as well as the amount of InBasket messages received per day by source, relative to pre-pandemic baseline levels from 12/29/19 – 3/14/2020. Finally, to estimate the impact of each additional message received on clinician total EHR time per day, we created an ordinary least squares regression model with each message type as the independent variables of interest, with organization and calendar week fixed effects. All models use robust standard errors clustered at the organization-level.

Results

Total EHR time per day and after-hours “pajama time” in the EHR per day decreased significantly in the first 10 weeks of the COVID pandemic compared to the pre-pandemic baseline. From July through December of 2020, however, we found clinicians spent significantly more time in the EHR per day and more time working outside of their scheduled clinic hours (Figure 1). This increase appears to be driven by Clinical Review and InBasket messaging time (Figure 2), while Notes and Orders returned to their pre-pandemic baselines. From April through December 2020, on average clinicians received 52.0% more messages from patients per day compared to pre-pandemic levels. Messages from other care team members also increased by an average of 4.8% from 7/2020–12/2020. In our fixed effects regression, we found each patient message increased total EHR time per day by 2.32 minutes (p<0.01).

Discussion

After a sharp decrease during the onset of the pandemic, US clinicians have spent significantly more time in the EHR each day, as well as increased “pajama time” outside of scheduled clinic hours during the COVID-19 pandemic. Outside of holidays, this increase remained relatively constant through 12/2020, despite fluctuations in COVID case counts, suggesting that changes to workflow to incorporate telemedicine is a more likely driver of the effect than COVID levels. This effect was driven by increases in time spent in functions outside of the traditional patient encounter—Clinical Review and InBasket. Additional time spent on Clinical Review may reflect greater reliance on patient history and documentation from the EHR in the absence of physical exams during telemedicine encounters for organizations providing care virtually. The increase in InBasket time is almost entirely explained by a large increase in messages received from patients, which are by far the most time-consuming message clinicians receive. It may be that the COVID pandemic encouraged substitution from in-person visits to asynchronous communication such as secure messaging. Federal payment policy should take this new demand on clinician time into account when designing sustainable reimbursement policy for the post-COVID era.

Introduction: With the advent of Coronavirus Disease 2019 (COVID-19), millions of non-urgent and non-COVID-19 medical encounters were postponed or cancelled by patients and health systems to reduce the risk of COVID-19 infection during in-person visits and prevent the virus spread [1, 2]. For continued healthcare access, most clinic visits have transitioned to online platforms for healthcare access including COVID-19 diagnosis and treatment [3]. Patient portals and other digital platforms hold promise as sustainable and scalable health system intervention strategies to improve access to healthcare for COVID-19 diagnosis and treatment and other healthcare issues [4]. Through the patient portals, patients can receive educational information on COVID-19 preventive care measures, use online triage forms (self-checker and E-visit) for COVID-19 symptom assessment, and send and receive portal messages related to their COVID-19 diagnostic tests and results. If the positively tested patients are at risk, patients can communicate with their providers about COVID-19 care plan. In this study, we propose to characterize patients and their use of asynchronous virtual care for COVID-19 via a retrospective analysis of patient portal messages. The findings can provide insights into the frequency of portal messaging utilization by patients for addressing COVID-19 crisis and impact on patients with respect to COVID-19 related concerns.

Methods: We collected over 2 million portal messages generated by patients between February 1 and September 20, 2020 at Mayo Clinic, a large multi-specialty academic health system. We filtered the patient-generated messages (PGMs) associated with COVID-19 using relevant keywords (e.g., COVID-19, Pandemic, Coronavirus, SARS-CoV-2, and 2019-nCoV) and their synonyms and morphological variations. We then analyzed the distribution of different patient populations by stratifying the unique patients with respect to their personal and social conditions including age, gender, marriage, ethnicity, race, language, and residence and calculated the daily numbers of total PGMs on COVID-19. We summarized reasons for patient utilization of portal messages for accessing COVID-19 related care such as diagnosis, testing, and treatment and seeking supports for various issues including appointment postponement and mental health problems due to COVID-19. We analyzed the PGMs used for assessing COVID-19 symptoms and discussing COVID-19 diagnostic tests and results and care plan to understand the message use for COVID-19 diagnosis and treatment. In addition, we examined other healthcare issues caused by COVID-19 reported in the portal messages to understand COVID-19 impacts on health services and patients.

Results: The majority of PGMs on COVID-19 pertained to COVID-19 symptom self-assessment (42.53%) and COVID-19 tests and results (32.44%) (See Table 1). As shown in Figure 1. The PGMs on COVID-19 symptom self-assessment and COVID-19 tests and results had dynamic patterns (two peaks and three surges) similar to the newly confirmed cases in the US and Minnesota. The trend of PGMs on COVID-19 care plan is in good agreement with that of newly hospitalized cases and deaths. After an initial increase in March, the PGMs on issues such as cancellations and anxiety regarding COVID-19 had a declining trend (See Figure 2). Patients who were 30-64 years old, married, female, white, or urban residents were more likely to send portal messages. The messaging disparity was exacerbated among patients who sent portal messages on COVID-19.

Conclusion: During the COVID-19 pandemic, patients increased portal messaging utilization to address healthcare issues about COVID-19 (particularly, symptom self-assessment and tests and results). The portal messages on COVID-19 could reflect the overall development of COVID-19 and its impact on patients over time. The use disparity of patient populations indicates an opportunity to increase patient engagement in patient portals for minority and rural populations for addressing COVID-19 crisis.

Deep Significance Clustering (DICE) a Heterogeneous Population

Introduction

Deep significance clustering (DICE) is an end-to-end machine learning framework to assist with developing risk stratified interventions for a heterogenous population. DICE applies in scenarios where groups of patients may have similar risk level of an outcome but require different interventions due to differing root causes of the risk. In a heterogeneous population, while classification algorithms can produce a predicted risk, the same risk level can be obtained from patients with very different feature manifestations. Thus, predicted risk alone do not provide enough information about how to choose reasonable clinical treatment as the next step. Similarly, regular clustering algorithms are only unsupervised without a focus on the outcome, thus potentially generating clusters that are not clinically meaningful. In these contexts, clearly partitioned patient groups, or precisely predicted individualized risks, without a bridge to the next clinical steps, bring limited translational value. (1) Yet, few existing clustering and classification algorithms jointly achieve outcome-driven risk stratification in an integrated fashion customized to health data. (2) DICE addresses the practical needs in medicine by generating outcome-driven clusters whose members have both similar risk levels and root causes for the outcome, thus supporting risk-level specific intervention development.

Methods

DICE has 3 main components: long short-term memory (LSTM) autoencoder for representation learning, k-means for clustering, and logistic regression for classification (Figure 1). DICE uses a combined objective function and a constraint that requires statistically significant association between the outcome and cluster memberships. The statistical significance is determined using p-values in testing a statistical hypothesis of equal outcome distribution across clusters. The combined objective function and constraint serve to force DICE to learn representations that lead to clusters that are discriminative to the outcome of interest. Furthermore, a neural architecture search (NAS) is designed with an alternative grid search for the number of clusters and hyper-parameters in the representation learning. DICE back-propagates through the cluster membership classification component, to use cluster membership probabilities as input to predict the outcome to ensure that patients in the same cluster have similar risk levels.

Figure 1. The framework of the proposed deep significance clustering (DICE).
We evaluated DICE using 2 datasets with different structure and outcome rates extracted from electronic health records at 2 urban hospitals. Outcomes and patient cohorts evaluated include discharge disposition to home among heart failure (HF) patients and acute kidney injury (AKI) among COVID-19 patients. HF data included adult patients (n=1,585) from years 2014 to 2018 who were treated in the inpatient Medicine service in the hospital; 36.8% of the patients were discharged to home from the hospital. COVID-19 data included adult patients (n=1,002) who were admitted to the hospital in 2020 from the ED; 30.4% of the patients developed AKI subsequently during hospitalization. We compared DICE with baseline methods including (1) PCA for representation learning followed by k-means clustering (PCA (k-means)), (2) AE for representation learning followed by k-means clustering (AE (k-means)), and (3) AE for representation learning with classification followed by k-means clustering (AE w/ class. (k-means)). The number of clusters experimented were set to 2 through 5. The sizes of the representation dimension searched were 20 through 100 for HF and 10 to 20 for COVID-19. Experiments were conducted in PyTorch.

Discussion

DICE was motivated to join concepts of machine learning and statistics as a customized machine learning algorithm specifically for applications in medicine. The trained outcome-driven cluster memberships by DICE can be used to assign new patients into risk-stratified subgroups for specific interventions in a predictive fashion. These features of DICE were demonstrated in the evaluation across data size, variable types, outcome rates, clinical areas, and clinical settings. Beyond HF and COVID-19, DICE may have the potential to be used in other clinical areas to facilitate subtype-specific care and clinical pathways for clinical decision support.

Leveraging the MedDRA Biomedical Terminology and Weak Labeling for Mental Health Symptom Surveillance from patient Notes

Marie Humbert-Droz, PhD\(^1\), Suzanne Tamang, PhD\(^2\), Olivier Gevaert, PhD\(^1\)

\(^1\)Stanford Center for Biomedical Informatics Research, Stanford, CA; \(^2\)Stanford University Department of Biomedical Data Science, Stanford, CA

**Introduction**

Syndrome surveillance tools allow for the monitoring and identification of public health indicators of an upcoming outbreak. It uses clinical features before an initial diagnosis is made, allowing for real-time disease surveillance.\(^1\) Although clinical syndrome surveillance systems are well developed to monitor somatic symptoms from patient records, they lack greatly the ability to monitor mental health indicators. While some tools monitoring the general population’s mental health are available, such as national surveys, they are significantly lagged and require substantial time and resources. Both are weaknesses when it comes to syndrome surveillance. Indeed, a syndrome surveillance system needs to be timely, i.e. the data has to become available shortly after collection.\(^1\) Such a system should also require little resources in order to be implemented as easily in developed economies as well as in developing countries. This last point being especially important in the context of monitoring a worldwide pandemic.

Electronic Health Records (EHR) contain myriads of individual level information, and are available shortly after the patient encounter, making it an ideal source of information to build a syndrome surveillance system. Unfortunately, the coded part of EHRs, containing readily available diagnosis information does not necessarily reflect the patient’s mental state or symptomatology. However, such information is contained in free-text form, buried in the encounter notes. Natural Language Processing (NLP) and Information Extraction (IE) methods are great tools for extracting such information from clinical narratives. It is well established that the COVID-19 pandemic and associated social restrictions, involving several levels of lockdown, have had a significant impact on the population’s mental health. Such information as anxiety and depressive state is poorly documented in EHRs as it is not always associated with a definitive diagnosis. However, this information is abundantly present in clinical notes. In this work, we present a year-long analysis of clinical notes from Stanford Healthcare (SHC) during the 2020 pandemic, showing a correlation between the evolution of the pandemic and the rise of anxiety and depressive symptoms, demonstrating that an NLP approach can improve the account for mental health in syndrome surveillance systems.

**Methods**

The data source that was used to conduct our study is the STARR-OMOP dataset. STARR-OMOP is Stanford Electronic Health Record data from its two Hospitals in a Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM), with linked de-identified free-text patient notes. To extract as much clinical information as possible from patient notes, we have designed a hybrid tool, taking advantage of existing NLP libraries of industrial quality.
and medical ontologies to annotate all clinical concepts within MedDRA\textsuperscript{5}. Assertion status (polarity, experiencer and temporality) is determined through a weak labeling approach\textsuperscript{4}.

\textit{Pipeline description}

The MedDRA tagger pipeline is composed of 3 modules: the annotation module, the weak supervision labeling module and the hierarchy mapping module (Figure 1a). To annotate all clinical concepts efficiently, we are taking advantage of the fast implementation of core NLP functions of spacy using a scispacy language model\textsuperscript{3}, as well as building a custom rule-based string matching tool. We use the MedDRA terminology and match the string to the lower case attribute of the text tokens. Each term matched by the tool is assigned its medDRA ID number as label for further analysis. Each concept is extracted with a context window of $n$ tokens before and after the concept to help determine the assertion status. A set of rule-based functions is written and applied to each extracted term and its context window using the efficiency of the Snorkel package\textsuperscript{4}. Each term is labeled for polarity (PRESENT/ABSENT), experiencer (PATIENT/FAMILY) and temporality (PRESENT/HISTORY). Finally, each term is mapped to each level of the MedDRA hierarchy using the hierarchy mapping module to ease further analysis. The MedDRA tagger is then used to extract all clinical terms from the patient notes, for the year 2020 – as well as three years prior to establish a baseline. The 2020 data contains 575,199 patients and 4,550,255 notes. The baseline contains an average of 600,209 patients and 4,125,779 notes. The performance of the MedDRA pipeline will be assessed at the mention level against manual annotations of 100 notes with 10 symptoms concepts (5 somatic and 5 psychiatric). The notes are currently in the annotation phase and the resulting precision, recall and F1 scores will be computed.

\textit{Results}

The processing of all the patient notes for the year 2020 has shown a significant increase in psychiatric disorder mentions starting in March 2020, reaching a peak in April 2020 and reducing to a baseline in June 2020. Psychiatric disorders mentions are higher for the year 2020 than the averaged three years prior (Figure 1b.). Next, Figure 1c shows the breakdown of the psychiatric disorders mentions at the MedDRA preferred term level, shown as the difference between the 2020 mentions count and the baseline, and highlighting anxiety symptoms as the driving source of the increase in psychiatric disorders mentions. Finally, Figure 1d shows the top seven psychiatric mentions from the notes and top seven psychiatric diagnosis codes from the coded part of EHR, highlighting a tenfold signal difference, reinforcing the initial hypothesis that mental health information is better documented in the notes than the coded part of EHR.

\textit{Discussion}

Our hybrid clinical concept extraction tool demonstrated promising performance to extract patient information at scale, with emphasis on mental health disorders. A notable increase in anxiety and depression symptoms at the beginning of the shelter-in-place order in the San Francisco Bay Area in early 2020 can be visually observed, when compared to the period three years prior. Such a procedure to automatically extract mental health data from deidentified patient notes could easily be pooled across disparate institutions and implemented to provide real-time information, thus addressing the gap in the detection of mental health indicators in modern syndrome surveillance systems.

Opportunities to Improve Social Determinants of Health Screening Implementation Through Training and Support for Providers: Implications for Health Information Technology

Bradley E. Iott, MPH, MS1, Jessica Pater, PhD, MS2, Shauna Wagner, BSN, RN2, Tammy Toscos, PhD, MS2, Tiffany Veinot, PhD, MLS1

1University of Michigan, Ann Arbor, Michigan; 2Parkview Research Center, Fort Wayne, Indiana

Introduction

Screening for patients’ individual social needs, also known as the social determinants of health (SDOH) at a larger scale, is becoming increasingly common as American healthcare transitions towards value-based payment models.1 SDOH screening creates opportunities for providers to identify patients’ needs and to improve health outcomes by intervening via tailored care and referrals to social service agencies to address social needs.2 While there is much interest in implementing SDOH screening in healthcare settings, there has been little academic study of screening implementation, including identifying best practices and the impact of screening work on providers, staff, and clinical workflows3,4. Here, we describe barriers and opportunities for providers related to training and support needed for expanded SDOH screening implementation and discuss opportunities for health information technology (HIT) to facilitate social referrals.

Methods

Parkview Health is a non-profit health system featuring nine hospitals in northeast Indiana and northwest Ohio. To identify clinical areas with formal or informal SDOH screening and initial interview respondents, we held two stakeholder meetings in November 2019 with 31 healthcare providers. Using purposeful sampling, we then conducted semi-structured qualitative telephone interviews with 36 providers, staff, and administrators at Parkview. Interviews were recorded, professionally transcribed, and, using an iterative process, two coders applied structural, in vivo, and open codes (Cohen’s Kappa = 0.637). Second-round coding resulted in the creation of themes based on initial coding.

Results

Many providers (n = 15, 41.7%) requested additional training and support related to SDOH screening and response due to limited coverage in their formal training. Moreover, interviewees indicated that SDOH work has been impacting a greater number of provider and staff roles than the traditional focus primarily on social workers, which may not have formal training, indicating the need for accessible training and support during SDOH screening implementation for a wide range of provider and staff roles (Table 1). As part of this, it is important for there to be clear communication as to each provider’s roles and responsibilities concerning SDOH screening, disclosure, and follow-up in the health system. Furthermore, providers described the need for support in using SDOH data stored in the EHR, which may be difficult to access, as one administrator explained, “it is for [others ’] access and nobody else is seeing it... the way we’re all using it is so personal... that... people aren’t looking for it or knowing what to look for.”

Providers suggested the potential need for multi-modal education about the workflow of SDOH screening, including emails, huddles, education sessions, and the opportunity for staff to provide feedback and suggestions. One administrator running a program that provides medications to patients at a reduced cost described how an email notification of changes to a referral process had been ineffective in the past and advocated individual and phone training instead (Table 1). Similarly, an administrator from a cardiology group described the need for SDOH education sessions for staff and soliciting staff input on SDOH screening workflow.

Providers described a need to know what next steps to take following a patient’s disclosure of a social need (Table 1). Multiple providers expressed concern with not knowing how to help a patient with their social needs, as an administrator from the Women’s and Children’s service line describes, “if somebody tells me they’re homeless, what am I supposed to do with that information without having really a lot of support... it’s a lot easier to get people to screen if they know that they’re not going to be up at night, like ‘oh my gosh, somebody’s homeless and I don’t know what to do with them.’” Knowing who to hand patients off to was perceived as an important facilitator of referrals.

Discussion

Given the potential for referrals by providers to social care services to reduce social needs and improve patient health outcomes, there is growing interest in standardizing and expanding SDOH screening in healthcare settings. We show that healthcare teams will likely require training and ongoing support to successfully screen and refer patients to relevant resources. Given the importance of facilitating referrals both within the healthcare system and to outside organizations, community resource referral platforms, a form of HIT featuring social services agency directory databases, electronic referrals, outcome tracking, and electronic health record integration, may assist with screening and referrals by offering providers timely information and electronic referrals of patients to community organizations. Assessing patients and connecting them to relevant services is a sociotechnical process, which requires continued investment in both the social and technical components for optimal outcomes, and even when equipped with HIT, providers require training, support, and clear roles to successfully identify and respond to the social needs of patients.

Conclusion

To facilitate expansion of SDOH screening in healthcare settings, there is a need to address providers’ lack of formal training, including clarifying of roles and responsibilities required and improving handoffs within and outside of the health system.

A Data-Driven Algorithm to Recommend Initial Clinical Workup for Outpatient Specialty Referral

Wui Ip, MD, Priya Prahalad, MD, PhD, Jonathan P. Palma, MD, Jonathan H. Chen, MD, PhD
Stanford University School of Medicine, Palo Alto, CA

Introduction

There is a fundamental and growing gap between the supply and demand of medical expertise, as reflected in the projected shortage of 100,000 physicians by 2030.¹ The problem is particularly acute for specialty care, for which over 25 million people in the US have deficient access.² Wait times for in-person specialty visits commonly extend weeks to months after referrals are made. Adding to this problem, essential initial workup is often not completed,³ resulting in ineffective visits when the specialists do not have sufficient information to make a definitive diagnosis and treatment recommendations by the time of their first in-person visit. Such inefficiency could lead to care delay, missed opportunity to provide access to more patients, as well as dissatisfaction of patients and families.

While existing tools including electronic consults⁴ allow referring providers to solicit specialists’ opinions on the types of pre-workup needed, this remains limited in availability as it still requires a human consultant to review and respond to each request.

Our goal is to develop a different paradigm for specialty consultations with a tier of automated guides that proactively enable initial workup that would otherwise be delayed awaiting an in-person visit. Taking advantage of electronic health records (EHR) that contain thousands of specialist referral visits, we propose a data-driven algorithm inspired by Amazon’s “customers who bought A also bought B” to anticipate initial clinical workup based on how specialists cared for similar patients in the past.

Methods

Using pediatric endocrinology as an example, we extracted de-identified EHR data from a cohort of 3424 patents with new outpatient endocrinology referral at Stanford Children’s Health including > 1,150,000 instances of 8263 distinct clinical items (diagnosis codes, lab results, procedures and medications). Data were split into a training set (referral made from 2015 to 2019) and a test set (referral made in 2020). Using the training set, we calculated co-occurrence statistics of pairs of clinical items to build an item association matrix (Figure 1).

![Diagram](Image)

**Figure 1: Recommendation algorithm**

In the test set, using query clinical items (A₁, … ,Aₖ) at the time of specialty referral, the algorithm retrieves scores that resemble post-test probability from the co-occurrence matrix for all possible target items (laboratory and imaging workup orders). For each query item (A), target items (B) are ranked by estimated post-test probability P(B|A), defined as the number of patients who have query item A followed by target item B (Nₐb) divided by the number of patients with query item A (Nₐ). If a patient has q query items, q separate ranked-lists are generated. To aggregate these results, we estimate total pseudo-counts using the following equation that sums across every i-th query item: \[ \frac{1}{\sum_{i=1}^{q} N_{A_i}} \sum_{i=1}^{q} N_{A_i B} \]

Comparing to the workup items actually ordered by endocrinologists, we calculated the mean AUROC for the patients in the test set as well as the precision and recall for top 4 recommendations for these patients (4 is the average number of orders by endocrinologists). In addition, we surveyed practicing endocrinologists (n = 12) to assess the clinical appropriateness of the predicted workup orders in three common referral conditions, where we input a single query item (referral condition) to the algorithm. We also reviewed literature as external validation for these predicted orders in each referral condition.

**Results**

The algorithm achieved high discriminatory accuracy AUC > 0.9 (95% CI 0.95 - 0.96). Compared to a reference benchmark of using the overall most common orders, precision improved from 37% to 48% (p < 10⁻¹⁸) and recall improved from 27% to 39% (p < 10⁻¹⁸) for top 4 workup order recommendations when using the item-
associated recommender algorithm. In three common referral conditions (abnormal thyroid labs with high thyrotropin, obesity, and amenorrhea), the majority of the specialists considered the top recommended workup orders by the algorithm clinically appropriate (Table 1a, 1b, 1c).

**Discussion**

Using pediatric endocrinology as an example, we developed and evaluated a recommender algorithm to anticipate initial workup needs at the time of specialty referral. Such a data-driven approach could boost the capacity of the health system by at least ensuring first specialty clinic visits are more effective while sparing specialists’ time to communicate initial workup needs. While the current algorithm is not suitable for full automation given the level of precision and recall, such an algorithm could serve as a clinical decision support tool by displaying relevant clinical orders for referring providers to make the referral process more effective. Advantages of an algorithmic decision support tool compared to building consensus guidelines among specialists include (1) scalability to answer unlimited queries on-demand, (2) maintainability through automated statistical learning, (3) adaptability to respond to evolving clinical practices, and (4) personalizability of individual suggestions.

**Conclusion**

An item-association based recommender algorithm can predict a specialist’s workup orders with high discriminatory accuracy (AUC > 0.9). Specialists indicate the top recommended orders are clinically appropriate in three common referral reasons.

Tuberculosis treatment support tools: Iterative refinement based on a mixed-method randomized controlled pilot study and usability testing

Sarah Iribarren, PhD,1 Kyle Goodwin,1 Alex Stabile,1 Alfie Vidrio,1 Rebecca Schnall, PhD,2 George Demiris, PhD3
1University of Washington, Seattle, WA; 2Columbia University, New York, NY; 3University of Pennsylvania, Philadelphia, PA

Introduction

Tuberculosis (TB) is a leading cause of death globally, surpassing HIV/AIDS and malaria, despite most forms being preventable and curable. There are ~10 million active TB cases and ~1.5 million deaths each year.1 Effective cure of TB requires a patient to take multiple antibiotics without interruption following a strict schedule for at least 6 months. Unfortunately, many fail to complete their full course successfully which leads to reduced cure rates, prolonged infectiousness, more severe disease and death, and the emergence of multi-drug resistant TB strains. If current trends continue, multidrug-resistant TB could kill as many as 2.5 million people per year and cost the global economy up to US$16.7 trillion by 2050. Innovative interventions, such as digital adherence monitoring, have the potential to enhance patient-centric quality care and help TB programs overcome some of their biggest challenges. Our team has developed digital adherence tools to empower patients and TB teams to improve patient outcomes for this long and challenging treatment. The TB Treatment Support Tools (TB-TSTs) links a patient-centered mobile application, an engineered home-based drug metabolite urine test and interactive communication with a treatment supporter. The objectives of this research were to identify issues during pilot testing and further iteratively refine the TB-TSTs using multiple evaluation methods.

Methods

We report the iterative development and evaluation of the TB-TSTs. First, we refined the tools base on pilot study findings then conducted further usability testing with a new participant population to further refine. The mixed-methods pilot study was conducted within a public respiratory-specialized reference hospital in the Province of Buenos Aires, Argentina. Patients newly diagnosed with TB who were 18 or older, and had mobile phone access were randomized to usual care (𝑛 = 21) or the intervention (𝑛 = 21). Intervention group participants were asked to report self-administering their medication daily, if they were experiencing any potential medication side effects, and submit a photo of the urine drug metabolite test 3-5 times per week using the patient app. A nurse served as the treatment supporter to the intervention cohort and responded to questions, issues, or queried participants who missed a report to ask if assistance was needed. Primary outcomes were feasibility and acceptability; secondary outcomes explored initial efficacy. Feasibility and acceptability were assessed by app usage, issues identified, and experiences using the system reported in exit interviews and survey and during the pilot study. Findings were used to iteratively refine the app and test strip. We then conducted 3 cycles of usability testing using think-out-loud protocol of the patient facing app and assess usability scores using the mHealth Usability Questionnaire (MAUQ) and the HealthIT Usability Evaluation Scale (ITUES) surveys.2,3 Further design refinement efforts were conducted through targeted directed research groups with teams of human-centered design and engineering and multidisciplinary students.

Results

For those randomized to the intervention, interactions between participants and treatment supporter focused on promoting adherence through missed report inquiries and check-ins. Although there was a decrease in interactions over time, adherence support remained needed throughout. App related support was largely due to login issues. Over half reported side effects and requested assistance. Thirty-three themes within the main categories of what worked, issues experienced, and

Fig 1. Example of home screen refinement
recommendations were identified in the analysis of the exit interviews. Early efficacy results were that higher rates of treatment success were seen in the intervention group (n=20) compared to the control group (n=17). Although not all intervention participants reported daily, none abandoned treatment. Only participants in the intervention group had follow-up sputum tests to be classified as cured. Iterative design improvements based on findings included, for example, offline app accessibility, improved and simplified reporting flow, walkthrough app orientation and videos, confirmation of

</tbody>
</table>

successfully submitted reports (Fig 1). Improvements were also made to the treatment supporter interface. During the next refinement and evaluation phase, 26 participants in all three testing cycles rated the TB-TSTs application as having high usability with a mean usability score of 5.96 out of seven on the MAUQ and 4.27 out of five on the ITUES.

Discussion

Interactive communication was considered an essential intervention component. The efforts of the treatment supporter resulted in timely and effective handling of participant needs and created a sense of partnership. The iterative approaches of participant feedback from pilot testing and further usability cycle evaluations resulted in several refinements and additions to the patient facing app (Fig 2). As a next phase, the refined TB-TSTs will be evaluated in a randomized controlled trial with planned recruitment of 400 participants at four public hospitals in Argentina.

TeamTat: A Collaborative Text Annotation Tool for Creating Gold-Standard Corpora

Rezarta Islamaj¹, PhD, Dongseop Kwon², PhD, Sun Kim¹, PhD, Zhiyong Lu¹, PhD
¹National Library of Medicine, National Institutes of Health, Bethesda, MD 20894, USA
²School of Software Convergence, Myongji University, Seoul 03674, South Korea

Introduction

Biomedical research heavily depends on expert-curated data, which typically involves human annotators perusing journal articles and marking up the written facts for knowledge extraction. Such labelled datasets are incredibly valuable both for population of knowledge repositories, and for the development of AI-powered machine-learning algorithms. Human curation is a costly and time-consuming process and, given the rapid growth of biomedical literature, it is paramount to provide annotators with intuitive tools capable of speeding up the process and maintain expert subject-matter quality.

TeamTat¹ is a freely accessible annotation system that fulfills the desiderata to support multi-user projects, offer project management features, and provide an easy-to-use interface². TeamTat was developed to help database curators, and scientists needing manually curated documents, by providing an engaging annotation interface interoperable with a variety of data formats, independent workspace for annotators, collaborative workspace to resolve annotation differences, quality assessment via inter-annotator agreement, etc. Taken together, TeamTat is an all-in-one system with a set of features that cannot be found in existing tools. For example, our previous tool, ezTag³, does not support team annotation and project management. Similarly, other tools (brat⁴, PDFanno⁵, etc.) surveyed in Neves and Seva² are limited in their support of local installation, web capabilities, PubMed/PMC integration, full-text annotation, figure display, collaborative annotation, document format, etc.

Tool Description

TeamTat combines a minimalist user-interface that increases annotator’s focus and efficiency during annotation tasks. TeamTat is a multi-role system with project managers setting up an annotation team and an annotation project. An annotation project uses as input a set of documents and returns those documents with in-line text annotations, downloadable at any time. The project manager sets up the annotation schema supporting both entities, and relations, and organizes the annotation in rounds, reflecting the iterative nature of production life cycle. An annotation round allows annotators to work independently or collaboratively, and inter-annotator agreement statistics allow the evaluation of corpus quality, as shown in Figure 1.
TeamTat annotation interface is designed for ease of integration with PubMed/PMC, ease of use with full text articles and supports figure display for the annotators’ convenience. Annotators can work on the same document independently and anonymously in their workspaces, or collaboratively, with live discussions to resolve disagreements. The important features of the annotation interface in TeamTat include: (1) collaboration between annotators, (2) documents of any length, including full text journal articles, (3) optimized annotation interface for user-friendly browsing, (4) documents can be annotated for triage, for entities and for relations, (5) review interface to facilitate agreement/disagreement between annotation partners, etc.

TeamTat project management interface allows: (1) annotation projects to be organized in multiple rounds, (2) project managers to track task development and completion, (3) the assessment of annotation quality via inter-annotator agreement statistics, and (4) the creation of corpus report statistics. Project managers can define annotation and normalization options for both entities and relations, can select and distribute documents anonymously to prevent bias. Multiple users can work on a document independently and TeamTat offers visual clues to notify the manager for task completion.

TeamTat project administrators can set up TeamTat locally to accommodate data privacy concerns. Documents can be in BioC, plain text or PDF format, and Unicode support allows for documents in different languages. TeamTat interface can display all figures of PubMed Central full text articles, and it is integrated with PubMed/PMC BioC APIs\(^6,7\) to easily retrieve documents or uploaded from local repositories. Since images frequently contain crucial information or experimental evidence, TeamTat is equipped to display images for annotators’ convenience.

Usage
TeamTat offers support for annotation efficiency, consistency, scale; provides an intuitive interface; and mimics a project development workflow with clear procedures that allow the development of a gold standard corpus. TeamTat does not collect any personal information data from its users. TeamTat has been used to build several gold standard annotation corpora such as NLM-Chem\(^8\), NLM-Gene\(^9\), etc.

Availability
TeamTat is available at [https://www.teamtat.org] and in GitHub [https://github.com/ncbi-nlp/TeamTat].

Introduction

Chemical and drug names are one of the entity types most frequently searched in PubMed\(^1\). Chemicals appear throughout the biomedical research literature and encompass studies beyond chemistry, such as medicine, biology, and pharmacology. Identifying chemical names is challenging because they have numerous typographical variants and synonyms, and authors frequently do not follow standard nomenclatures. Moreover, chemical names are often ambiguous, especially when abbreviated, and could refer to known compounds, a mixture of compounds, or novel, previously unknown compounds. These difficulties are compounded in articles’ full text, causing substantial performance reduction in automated chemical named entity recognition (NER) systems trained using only data annotated for titles and abstracts. The creation and maintenance of chemical terminologies and chemical corpora are significant concerns in the biomedical community. Recent efforts have developed several valuable chemical\(^2,3\) corpora for text mining, which have served as valuable resources for the text mining community in recent years. However, a corpus of annotated full-text articles focusing on chemicals does not currently exist.

</table>

The NLM Chemical (NLM-Chem) corpus\(^4\) is currently the largest corpus of PubMed full-text articles annotated with chemical entities at a high degree of granularity (Table 1). The NLM-Chem corpus brings a significant enrichment compared to previously annotated corpora (a 135% increase in MeSH identifiers and a 170% increase in chemical mentions). Full-text annotation provides significantly greater language diversity than was present in titles and abstracts alone.

The development of the NLM-Chem corpus followed a systematic approach. We selected articles where manual curation would be useful for tool improvement and automated tools do not produce accurate results. Ten NLM indexers, with an average work experience of over 20 years in biomedical data curation, annotated 150 full-text articles, doubly annotating each article. The annotation load was evenly distributed, and indexers were randomly paired per article to control for annotation bias. There were three rounds of annotation: 1) Annotators working independently using pre-annotations, 2) Independent review comparing annotations between anonymous partners, 3) Collaborative discussion between partners and revision to produce 100% agreement. Inter-annotator agreement was measured after round 1 and was determined to be approximately 80%. We developed a customized annotation tool, TeamTat\(^5\), to help the indexers in this endeavor.
Results
Improved chemical automatic identification performance

Table 2 summarizes four evaluations of automated chemical recognition tools. The first evaluation shows the performance of our previous state-of-the-art tool, TaggerOne\(^6\), when trained using the existing resource (the BC5CDR corpus\(^3\)) and evaluated on the NLM-Chem test dataset. This model was trained on data from abstracts only; the data shows it is not able to recognize the greater diversity of chemical mentions found in the full text. The second evaluation shows TaggerOne trained on the BC5CDR corpus and the NLM-Chem train dataset, evaluated on the NLM-Chem test dataset. This evaluation clearly shows a sharp increase in performance obtained when trained using a combination of PubMed abstracts and full-text documents. The next two evaluations show the results of the new chemical tagger we developed based on a deep learning model and an approach we termed Multiple Terminology Candidate Resolution. The two evaluations contrast between using a title and abstract corpus versus the full-text annotations, so we can separate the improvement achieved due to the ability of the deep learning architecture to better generalize from context and the availability of full-text annotations. We can clearly see the large improvement in the precision and recall of chemical mentions, and additionally an increase in the accuracy of correctly identifying the MeSH identifiers. Note that these results are not far from the human inter-annotator agreement values.

Table 2 Text mining evaluation, showing performance results on the NLM-Chem test set, when the training is performed on the listed combinations of training sets, and controlled on the development set.

Conclusion
The NLM-Chem corpus contains 150 full-text journal articles selected both to be rich in chemical mentions and for articles where human annotation was expected to be most valuable. We built a new end-to-end chemical NER system and demonstrated improved performance in full-text articles. Finally, our new resource is publicly available at [https://www.ncbi.nlm.nih.gov/research/bionlp/Data](https://www.ncbi.nlm.nih.gov/research/bionlp/Data) and the chemical entity recognition results are available via API [https://www.ncbi.nlm.nih.gov/research/bionlp/APIs/](https://www.ncbi.nlm.nih.gov/research/bionlp/APIs/) and/or Pubtator: [https://www.ncbi.nlm.nih.gov/research/pubtator/](https://www.ncbi.nlm.nih.gov/research/pubtator/).

Introduction

Despite setbacks and challenges, recent advances in healthcare digital technologies and artificial intelligence (AI) demonstrated that AI in the assistive role has its place in medical practice\textsuperscript{1,2}. Consequently, there is a need to prepare medical professionals to employ AI and non-AI analytics in patient care\textsuperscript{2}. Additionally, the Accreditation Council for Graduate Medical Education (ACGME) places strong emphasis on care quality improvement (QI) and patient safety, both of which may benefit from clinical analytics and augmented intelligence to identify issues. More sophisticated AI of the future may lead to new cures for various medical conditions, thus further cementing the role of analytics and AI in medical practice. Physicians must understand strengths and limitations of predictive analytics and AI, and when and how it is appropriate to apply these technologies in patient care as well as organizationally in the acute patient care settings\textsuperscript{3,4}.

The current medical school curriculum does not prepare students for these new realities of digital medical practice and does not enable physicians to become active participants in the technology adoption process. We share results of implementing an innovative modular virtual elective in the College of Medicine that integrates Clinical Analytics and AI instruction with the existing medical school curricula, helping address this medical education gap.

Methods

This AI elective is offered to University of Illinois medical students in their final year of study. It is unique in design, as it requires no prior mathematical, computer science (CS), or statistics background. Rather than focusing on the underlying concepts behind complex AI applications, this course emphasizes physician roles in leading and adopting changes brought about by these AI algorithms. The virtually delivered course consists of 4 one-week blocks integrating clinical analytics, decision support systems, and AI with real-life practice scenarios from: (1) pathology, (2) QI, (3) Remote Monitoring and mobile health and (4) real world evidence (RWE) and patient safety. Each scenario includes lectures/discussion of critical analytics and AI concepts such as - how to develop a QI measure, algorithms and how they work, value-based care, integration of data from pharma and hospital environments. Students are divided into groups that remain static for the duration of the course, and every week has a similar structure to help students remain organized while facing topics unfamiliar to them.

Each weekly unit consists of: (1) recorded lecture and announcement outlining goals, learning objectives, and assignments; (2) group project focused on one of the four above-listed areas of AI; (3) multiple choice assessment quiz testing theoretical knowledge acquired from the textbook and other materials utilized in the course; (4) weekly reflections polling students in regards to application of their learning and assisting them with making connections between the week’s materials/assignments and professional practice. Students are challenged with hands-on assignments emphasizing physician role in providing clinical expertise for the AI and clinical analytics solutions as well as practicing professional leadership in each domain area. These aims enable students to practice everyday application of technology in medical practice and explore potential for assuming specific technology responsibilities in the healthcare organizations.

The interprofessional collaboration includes faculty from Medicine, Pathology, Health Informatics, Pharmacy, and Instructional Design each contributing in their area of expertise. Students develop competencies from online lectures and assigned readings and detailed feedback from faculty teams. Students work in groups to complete challenging assignments addressing real problems and solving some of the most relevant dilemmas in medicine today. By completing the assignments and consuming the required materials, the students are able to:
Interpret and explain foundational concepts of clinical analytics, decision support, and AI
Analyze the linkages between evidence-based medicine (EBM), medication safety, and predictive analytics
Employ AI to challenge traditional concepts of home health care by introducing cutting edge remote monitoring systems and data analysis algorithms
Develop their own clinical solution with a core AI component to augment population health
Apply algorithms to design clinical analytics systems for patient safety
Design data integration methods to produce actionable information and new clinical insights
Build real world scenarios of applied AI in Value Based Care.

Faculty are also divided into teams and collaborate weekly to review student assignments. Given the uniqueness of each project and the degree of flexibility allowed to construct innovative solutions by students, faculty have interesting opportunities to learn and debate student work.

Results
25 students from three different University of Illinois campuses completed the elective to date. Students demonstrated theoretical knowledge improvement with an average quiz score of 97% and achieved an average project assessment score of 89% reflecting development of hands-on skills. Student reflections expressed confidence in their ability to articulate ideas of implementation of AI in patient care settings, demonstrated appreciation for the role of AI in medicine, and gained insights into the intersection between the process of “quantification of medicine” and QI/patient safety.

Discussion
One of the biggest obstacles to AI instruction in medical schools is full integration of content in the daily medical practice. We present a unique modular and accessible course that can be adapted and embedded into any medical curriculum. This course demonstrates that AI can be taught to students without math and CS backgrounds, by choosing relevant topics of value to clinicians and engaging them exactly where real-life scenarios call for physician involvement with digital health technologies. The improvement in knowledge and skills we observed was impressive for a short course. Student reflections demonstrated maturity of thought in how they can apply the latest advances in AI and clinical analytics to their daily medical practice routines.

Lessons learned from the pilot course offerings helped faculty retune the curriculum to address challenges medical students face due to lack of technology coverage in their standard curriculum. Some technology areas assumed to be self-explanatory require more support, while students also expressed interest in some extra-credit opportunities related to value-based care and understanding of the financial landscape of healthcare in light of analytics.

*Authors contributed equally to this work

Abstract

In response to the novel coronavirus disease 2019 (COVID-19), the Food and Drug Administration (FDA) and the Veterans Health Administration (VHA) launched the COVID-19 Risk Factor Modeling Challenge to better understand the disease’s impact on the Veteran community. This challenge assessed the usefulness and improved our understanding of synthetic data for Machine Learning development of models addressing a real-world problem.

Introduction

The Veteran population has a higher prevalence of underlying risk factors for severe COVID-19 illness, such as obesity, heart disease, and diabetes1. While a better understanding of these underlying factors is gained by building predictive models with Veterans health records, the data itself is not easily accessible for research purposes. Therefore, in order to better understand risk and protective factors in this population, synthetic data was utilized for a Veterans Health Administration (VHA) Innovation Ecosystem and Food and Drug Administration (FDA) COVID-19 Risk Factor Modeling Challenge. This challenge, hosted on the secure collaborative cloud-based precisionFDA platform, called on the community to leverage Machine Learning (ML) to develop and evaluate computational models to predict COVID-19 related health outcomes in Veterans in Phase 1. In Phase 2, the challenge team assessed whether synthetic data is a reliable resource for researchers outside the VA to use for model prediction.

Methods

The first challenge phase asked participants to develop models for predicting COVID-19 outcomes, including COVID-19 status, alive or deceased status, ventilation status, number of days hospitalized and number of days in the Intensive Care Unit (ICU). Synthetic health records for 147,451 synthetic patients, generated using the Synthea synthetic patient generator2, was provided to participants for modelling. This synthetic data included conditions, encounters, observations, medications, procedures, and patient demographics. The synthetic data was split, with 80% provided to participants for model training, and 20% withheld as a test set for model evaluation. Model performance was evaluated separately for each of the five target COVID-19 outcomes. COVID-19 status, alive or deceased status, and ventilation status predictions were evaluated using the Area Under the Receiver Operating Characteristic (AUROC) metric. Predictions of days hospitalized and days in the ICU were evaluated using Root-Mean-Square Error (RMSE) and concordance index (c-index).

During Phase 2, top performing participants retrained and evaluated their models on two additional health record datasets, a second synthetic dataset generated by a Generative Adversarial Network (GAN), and de-identified real Veteran health records. Model performance on all three datasets was compared through test AUROC for binary health outcomes, and test RMSE and c-index for continuous health outcomes.

Results

The first challenge phase received 34 submissions, and a wide array of ML techniques were utilized, including Random Forest, Adaptive Boost (AdaB) Neural Network, and Ensemble approaches. Median model test AUROCs across all submissions outperformed a random prediction submission for the alive status and ventilation status health outcomes by .192 (.740>.548) and .145 (.668>.523) units respectively. Each of the top 3 submitters incorporated Gradient Boosting models for health outcome predictions. Across all submissions, model performance was generally better in predicting severe health outcomes (e.g., ventilation status, days in the ICU).
The top three participants in Phase 1 challenge were selected for Phase 2. These submissions, when trained and tested on GAN generated data, scored significantly higher in predicting COVID-19 status, and had similar results as compared with Synthea generated data across all other outcomes. Like phase 1, submissions markedly surpassed metrics generated by random guessing (.548 alive status, and .668 for ventilation status) Additionally, model performance comparatively outperformed in predicting severe outcomes such as Death Status and Ventilation Status.

We are currently testing the top performing models on real Veteran’s health data and results are forthcoming.

Conclusion

This cross-agency collaborative challenge assessed the usefulness of synthetic data for developing AI/ML models for addressing a real-world problem. In Phase 1, participants developed models trained on synthetic health records to predict COVID-19 outcomes. Phase 1 results stimulated discussions around the efficacy of synthetic data, which Phase 2 seeks to explore by comparing models trained on real Veteran health records to models trained on synthetic GAN generated and Synthea generated health record data. Models trained on synthetic GAN health records and Synthea health records have demonstrated similar results across all outcomes, except for COVID-19 status, which models trained on GAN synthetic data score higher on, suggesting that synthetic data generation methodologies can create similar COVID-19 health outcome model performances. Top performer models are currently being tested on real Veteran health data, and results will elucidate the relationship between the efficacy of synthetic data in predicting COVID-19 health outcomes in the Veteran population.

Responding to a Crisis of Veteran Suicide QUICKly: A Qualitative Interdisciplinary Collaboration

Andrea F. Kalvesmaki, PhD1,2, Alec Chapman, MS1,2, Kelly S. Peterson, MS1,2,3, Mary Jo Pugh, PhD1,2, Makoto Jones, MD1,2, Theresa C. Gleason, PhD4

1Salt Lake Veteran Affairs Medical Center (SLVAMC); 2University of Utah Division of Epidemiology; 3 Veterans Health Administration Office of Analytics and Performance Integration; 4Department of Veteran Affairs, Clinical Science Research & Development Service (CSRD)

Introduction: U.S. adult suicide rates have almost doubled from 2005-2017, with rates of Veteran suicide approximately 1.5 times higher than the general population. In early 2019, an Executive Order (EO) “PREVENTS” established an interagency task force to outline a national strategy to reduce Veteran suicide. An online survey was developed to collect data on Veteran suicide intervention perceptions by the public, stakeholders and organizations working with Veterans. The survey, comprised of 21 open-ended questions, was administered May-August 2019. The task force asked a team of interdisciplinary researchers affiliated with the Veteran Affairs (VA) to analyze the survey responses. Due to the pace of decision-making to enact the EO, the analysis had to be complete within months. This led to the development of a process for computer-assisted qualitative analysis: Qualitative Interdisciplinary Collaboration (QUICK). QUICK combined qualitative analysis and natural language processing (NLP) to accelerate the analysis of a large corpus of survey data in a short amount of time, in order to inform policy efforts. This methodology could be applied to other large-scale qualitative research efforts.

Methods: Our team developed a technology-assisted qualitative analytic method combining NLP text mining techniques guided by in-depth qualitative review, with experts in Veteran health, military culture, and risk factors for suicide. Qualitative analytic methods such as sensemaking2, grounded theory3, and sensitizing concepts3,4 grounded in qualitative health research theoretical frameworks of narrative inquiry,5 the medical explanatory model6 (to uncover less common topics), as well as the United Medical Language System (UMLS)7 (to identify more unified concepts) informed the text mining process. The corpus of survey data was analyzed using a three-stage approach to 1) explore the data, 2) define and extract concepts, and 3) provide a high-level synthesis and summarization of the findings. In Stage 1, the NLP analyst used medspaCy, a library built in the spaCy framework for clinical NLP, to identify term counts and phrases8, and Latent Dirichlet Allocation (LDA)9 to produce topic models for expert review. Data was jointly coded by the qualitative and NLP analysts using the annotation tool eHost12 to review word snippets and terms and to refine topics. In Stage 2, Python packages10, 11 were used to generate interactive visual representations of the topics to review themes and topics to ensure saturation of the data. Unlike typical annotation, this joint coding process allowed the research team to rapidly analyze the corpus of data to identify key terms and topics as the theoretical grounding was applied. In Stage 3, the qualitative analyst summarized and organized text by theme and theoretical base to either confirm relatedness to known research in Veteran suicide prevention or highlight new information.

Results: A total of 9040 free-text entries from 114 organizations and 608 individuals were analyzed in three months using this approach. Response findings mapped onto two major theories in suicide prevention research. Descriptions of risk factors associated with suicide were consistent with fluid vulnerability theory, which posits that a person’s potential risk for suicide at any given point in time changes depending on circumstance 13. Findings related to descriptions of prevention and interventions echoed the approach used in the crisis risk planning model (CRP)14. Other themes such as “barriers to care,” and “data collection and collaboration” were identified within the responses. Systemic differences between organizational and individual responses indicated that many organizations were more likely to describe specific interests in therapy modality, and a lack of funding and resources being barriers to effective treatment. Individual respondents were more likely to describe a story that began at the time of separation from the military. They were also more likely to describe the complicated nature of access to care and a lack of services tailored to Veteran and Military culture.
Discussion: The need for a rapid analysis of a large body of qualitative data collected to respond to a national crisis led to a novel process of applying NLP to assist a large-scale qualitative analysis grounded in traditional qualitative methods. The data findings provided the national suicide task force insights they were able to use to meet the mandate to inform a national strategy. On June 17, 2020, the President’s Roadmap to Empower Veterans and End a National Tragedy of Suicide was published outlining policy and practice strategies based in part on the results of this analysis. This analytic process could provide a useful technique for large-scale and timely qualitative analysis. The stages of analysis and process of joint coding by the qualitative and NLP analysts allowed our team to analyze a large corpus of text with the sensitivity of traditional qualitative methods while doing so at accelerated pace. The QUICk method outlined here was submitted for VA invention disclosure (VA ID 2020-530) in 2020, and a publication is being developed. We present this process to accelerate knowledge across diverse disciplines and fields where combining qualitative and computational methods could accelerate analytic methods and produce results grounded in data derived from personal experience. From a very practical perspective, it offers a way forward that can be applied broadly to open-ended surveys such as described here, and which has application to tasks soliciting feedback from a diverse audience of stakeholders.

Improving Outcomes for Pediatric Patients with Metabolic Conditions in the ED using User Centered Design for Order Sets

Swaminathan Kandaswamy, PhD¹, Shabnam Jain, MD¹,², Dwight Chambers, MD³, William R. Wilcox, MD, PhD¹,², Beesan S. Agha, DO²,⁴, Sara P. Brown, RN², Evan W. Orenstein, MD¹,²

¹Emory University, Atlanta, GA; ²Children’s Healthcare of Atlanta, Atlanta, GA; ³Boston Children’s Hospital, Boston, MA; ⁴Pediatric Emergency Medicine Associates, Atlanta, GA

Introduction

Patients with metabolic diseases are at risk of rapid decompensation due to acidosis, hyperammonemia, or hypoglycemia. Timely interventions such as dextrose containing fluids can reduce deterioration and prevent ICU admission.¹ Early identification and rapid management of these patients can be challenging, especially during high volume periods in the ED and lead to delays in treatment initiation. To improve the care process, we used User Centered design (UCD) to implement Clinical Decision Support by creating: (1) an alert to notify providers about the patient’s high-risk status, and (2) an Order Set to place appropriate orders more easily. The aims of the CDS intervention were to (1) Reduce ICU admissions from ED and (2) Decrease median time to IV fluids.

Methods

 Phase 1: We first developed an order set with the help of specialists familiar with various metabolic disease conditions. Next, we adopted UCD and performed formative usability testing. End-users were given clinical scenarios for a patient with a metabolic disease diagnosis with 3 different presentations based on acuity and need for intervention. Case A: Patient with complaint of ear pain and diagnosis of acute otitis media who does not require IV fluids, Case B: Patient with complaint of vomiting thought to be due to an infectious GI problem requiring IV fluids and labs, and Case C: A septic listless patient who requires immediate IV fluids. Users of the order set were asked to place orders in a simulated test environment and asked to think aloud as they completed the task. We also obtained qualitative feedback at the end of the session. We iteratively improved the design of the Order Set based on participant feedback until no new input was identified with 2 consecutive participants.

 Phase 2: After implementation of the Order Sets, we compared the outcome measures (percent of patients admitted to the ICU) and process measure (median time to dextrose containing fluids).

Results

 Phase 1: A total of 6 providers (4 Attendings, 2 Residents) participated in the formative testing. We made 6 design changes based on formative testing. The design changes and rationality for the changes are shown in Table 1. The alert is shown in Figure 1. The final order set design is shown in Figure 2. Participants gave positive feedback about the alert language; appreciated the repetition of the alert criteria on the order set, and master list of relevant diagnoses.

Table 1. Order Set issues and design changes

<table>
<thead>
<tr>
<th>Issue Identified</th>
<th>Design Change</th>
<th>Rationale</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants accepted order set recommendations and ordered fluid in Case A when these were not required.</td>
<td>Made orders into a panel that encouraged providers to a priori make decision on need for IV fluids based on patient clinical appearance and hydration status (see figure 2)</td>
<td>Enable decision making based on what users know – providers are more likely to know patient’s clinical appearance and oral intake status than knowing if fluids are required for specific conditions.</td>
</tr>
<tr>
<td>Participants placed fluids as 1x Maintenance Rate instead of 1.5x Maintenance Rate (MR).</td>
<td>Provided rate reference: fluid specific instructions asking them to order D10 fluids at 1.5x MR.</td>
<td>Reduce reliance on provider memory.</td>
</tr>
<tr>
<td>Participants voiced uncertainty about disease specific workups and labs required for patients.</td>
<td>Included a list of all relevant labs specific to the disease after consultation with experts.</td>
<td>Reduce reliance on provider memory. Allow recognition instead of recall.</td>
</tr>
</tbody>
</table>
Missing orders in the Order Set
(1) Change order to Venous iSTAT for gas. (2) Added Normal Saline Bolus (3) Changed carnitine dosing instructions to single dose
Include all relevant orders in the order set and default order details matching ED requirements.

Participants placed duplicate orders as there was a pre-selected diagnosis (order panel) and they re-selected the diagnosis in the master list of metabolic conditions.
Included only either pre-selected diagnosis or master list of diagnosis.
Design to eliminate errors.

Participants felt forced to open order set out of concern for not being able to get valuable information before they were ready. They did not notice Acknowledgement reason (“Remain active for me”) applicable to this concern.
Included acknowledgement reason “Yet to see the patient, show again later.”
Match design with users’ mental model

Figure 1. Alert for patients at risk of metabolic decompensation.
Figure 2. Order set Design.

Phase 2: There were 3055 eligible encounters prior to intervention (May 01 2009 - Sep 15 2020) of which 1525 got admitted; and 185 encounters post intervention (Sept 16 2020 to – May 31 2021) of which 109 got admitted. The alert acceptance rate was 44%. Post-intervention, ICU admission rate decreased from 32% (489/1525) to 26% (28/109) p 0.2. The median time to dextrose fluids administration decreased from 172 minutes to 104 minutes (p < 0.01).

Conclusion
UCD helped ordering providers recognize metabolic disease faster and know what to do for different metabolic diseases. Formative usability testing led to design changes relative to design based on CDS design principles alone. CDS design can be improved by (1) enabling decision making based on what providers know e.g. whether patient is ill appearing and not details of underlying disease (2) reducing reliance on provider memory and allowing recognition instead of recall e.g. providing disease specific recommended labs and (3) changing representation to match provider mental models e.g. rewording acknowledgement reasons.

How Robust is Your Risk Model? Assessing Subpopulation Performance Heterogeneity in Risk Models Based on Discrimination, Calibration, and Fairness Measures: An Atrial Fibrillation Use Case

* Authors contributed equally.

**Introduction:** Atrial fibrillation (AF) is a cardiovascular condition linked to life-threatening outcomes, such as heart failure (HF) and stroke. Using mechanisms such as the electronic health record-AF (EHR-AF) score \cite{1} can assess a patient’s risk at the point-of-care to help physicians more accurately apply a variety of preventive strategies. Such strategies include, for example, weight-loss interventions and blood pressure control as well as inform screening to detect asymptomatic AF earlier. Widely used metrics of risk model performance (e.g., discrimination, calibration) as well as more novel ones such as fairness-based metrics to assess biases for underprivileged subpopulations are commonly applied to an entire eligible population (e.g., patients 45 years old or older). However, when applied to specific subpopulations (e.g., different age ranges, sex, races, and prevalent comorbidities), the measures may yield important differences in risk score performance. In this study we aimed to raise awareness about the robustness and applicability of risk models by characterizing performance heterogeneity across subpopulations of clinical relevance on the EHR-AF risk score.

**Methods:** From the 502,521 patients enrolled in the UK Biobank, we included the subset of patients aged 45 years or older at enrollment, without a history of AF and with available height, weight, and systolic and diastolic blood pressure measurements. These 4 measurements, along with additional covariates, such as sex, race, and comorbidities, were used to calculate all patients’ EHR-AF scores at enrollment. The patients were then followed for up to 5 years (consistently with EHR-AF’s original design) to assess associations between their EHR-AF scores and incident AF. Analyses included stratification of the population into a variety of subpopulations, including by sex, race, prevalent comorbidities including HF and/or stroke, and age strata (45–49, 50–54, etc.). Common performance measures were then applied to all combinations of subpopulations (as well as the population as a whole). These included traditional measures, such as concordance indices, calibration slopes, and standardized hazard ratios. To identify additional differences between the subpopulations within the context of possible underprivileged subpopulations (white versus nonwhite, males versus females), we further applied fairness-related measures, including the statistical parity difference and true positive rate difference \cite{2}. To calculate confidence intervals, we used bootstrapping.

**Results:** We identified 445,329 patients who met our inclusion and exclusion criteria. Notably, discrimination of incident AF for patients with prevalent HF was the lowest, secondary to stroke and the overall population (Fig. 1). With respect to calibration, HF was the only subpopulation in which AF risk was overestimated using the score. The differences across races were minor, and risk appeared underestimated among females as compared to males. Note that we conducted additional analyses, and the accompanying charts are available and include over 100 subpopulations stratified by age ranges, races, and sex, highlighting intriguing conclusions. Regarding the assessment of fairness measures (Fig. 2), notably, EHR-AF generates higher risk scores for males compared to females in the age range of 55–69. Additionally, the true positive rate was lower for females compared to males in the same age ranges. For the extreme age ranges, however, there was little to no bias.

**Discussion:** This work reveals potential robustness limitations in a well-validated clinical risk model. We observed that performance appears to vary substantially when analyzed within specific subpopulations as opposed to the overall population. Understanding these model behaviors can help clinicians know when it is appropriate to apply the risk model. Assessing these limitations can also help improve model robustness by targeting mitigation strategies such as recalibration or retraining to certain subpopulations which we plan to do in subsequent studies. Similarly, calculating fairness-related measures to identify potential biases may be more useful if applied to specific subpopulations because
such a methodology may be capable of identifying specific subpopulations with biases versus those that are free of bias.

Concordance index values typically range between 0.5 and 1.0. An optimal calibration slope equals to 1; values above indicate underestimation and values below indicate overestimation of the risk.

Fig. 2. Fairness-related measures applicative to sex stratified by age ranges. EHR-AF = 7 (median) was selected as the classifier threshold. Inc. = Incidence per 1,000-patient years.
Informatics-Driven COVID-19 Vaccine Enterprise: Lessons for the Future

Nitu Kashyap, MD FAMIA1,2; Sarah Kelly, PharmD MHA1, Rebecca McCray, MS BSN RN1, Allen Hsiao, MD FAAP1,2
1Yale New Haven Health, New Haven, CT; 2Yale School of Medicine, New Haven, CT;

Abstract

Connecticut (CT) has sustained high rates of COVID-19 vaccinations as one of top 3 States in the country1. We share experience from a large academic medical center that used EHR and informatics tools to support a vaccine enterprise with rapid ramp up, high volumes, low waste and high safety track that was recognized by the CDC. We have administered ~440,000 doses with a waste rate of ~0.1%.

The objective of this presentation is to understand challenges in setting up a large-scale vaccine administration campaign and to learn best practices for future similar campaigns for other public health and population health issues.

The Emergency Use Authorization (EUA) for COVID-19 vaccines was a welcome development in the fight against the pandemic. The unprecedented public health response also required health systems to stretch their resources and play a key role2. In CT, the State Department of Health (DPH) managed vaccine allocations, while distribution and patient connections were managed by healthcare delivery organizations. Key elements of this vaccine enterprise included a robust pharmacy and supply chain to manage cold chain, PPE and other supplies. The CDC site visit team noted Yale’s process for cold chain monitoring as a best practice. Efficient self-service scheduling via a web-based screening decision tree that performed all safety checks prior to scheduling allowed us to manage throughput and social distancing at vaccination sites. Several Clinical Decision Support (CDS) tools to identify correct intervals with any prior infection or treatment, correct vaccine type, dose intervals, allergies, age restrictions and reactions to prior dose were developed to allow for a safe mass vaccination program. The same systems also helped in early detection and management of conditions observed post vaccination3.

We created a process of bidirectional vaccine information exchange with real time submission of all administrations and nightly queries (Figure 1) to verify the up-to-date vaccine status of individuals scheduled for vaccination. This helped anticipate no shows to manage waste and get more shots into arms. CDC noted that this was a novel approach of data driven vaccine safety. Robust real-time analytics on vaccination trends, schedule utilization, population outreach, potential no shows, vaccine mismatch were tools utilized at all levels of the enterprise from planning to operations to call center.

Results

Across the vaccine enterprise at Yale New Haven Health, 443,135 doses have been administered to 232,211 unique patients. Vaccination rates ramped up rapidly after the Pfizer vaccine EUA was granted and have rapidly tapered off since June. CT continues to maintain above average rates for vaccinating its population.

Conclusion

Rapidly creating a large vaccine enterprise to safely administer covid vaccines in an equitable manner requires a strong informatics infrastructure that supports all aspects from planning and execution to descriptive analytics and interoperability across multiple systems. This is a great example of public-private partnership highlighting the importance and use of standards.

NLP-Driven Automated News Monitoring Solution for COVID-19 Response

Mary Kennedy-Moore¹, Stephen A Mustillo¹, Conor Kennedy¹, Zakir Hussain¹, Jessica D. Tenenbaum, PhD²,³

¹Ernst & Young, New York, NY, ²Duke University, Durham, NC, ³NC Dept. of Health & Human Services, Raleigh, NC

Introduction
In the current information age, stories on new COVID developments are often released to the media right away, sometimes before the State has been notified of the situation.¹ This lag in information may prevent public health officials from responding proactively. Stories are often posted on local town or county news sites, rather than well-publicized national sites, and there is a considerable amount of noise in the news on COVID, making manual news searches time consuming, and neither scalable nor exhaustive. Beyond actual news content, it is often useful to note overall sentiment of coverage, whether in mainstream or social media.²⁻⁴ Therefore, the NLP-driven Automated News Monitoring Solution was developed to scan local and national news sites, and automatically surface and analyze gathered insights at scale. This approach was applied to two different use cases to support the State of North Carolina’s COVID-19 response.

Methods
The first use case was identification of COVID-19 clusters/outbreaks across the state. In late Summer 2020, with daily new cases continuing at an alarming rate, return-to-school considerations on the horizon, and a continued media focus on the pandemic, local news outlets in particular were rapidly publishing breaking news stories on new groupings of COVID-19 cases. Often, these news stories would break before the state was made aware of a cluster/outbreak via traditional monitoring processes.

The second use case was regional vaccine supply and demand alignment. Again, monitoring the news manually would be impossible to do exhaustively at scale. Instead of simply identifying certain entities from news articles, the State needed a way to quickly digest the news and understand if it was positive or negative, and anything that could help inform allocation decisions to vaccination providers across the state.

Both use cases feature a similar technical structure and process:

1. **Gathering the news data.** A wide net is cast to gather all news that could potentially be relevant to the given use case, leveraging a leading consumer intelligence tool’s API. The titles are saved and a web scraper used to pull the full text of the articles, along with other pertinent data.

2. **Preprocessing and tagging data.** The data are cleaned, and the article text matched against sets of keywords that help identify the location (e.g. city, county) and setting (e.g. school, church, etc.) of an outbreak for the Clusters/Outbreaks use case, and the topic and demographic of an article for Vaccines use case.

3. **Entity extraction and categorization (Clusters/Outbreaks use case only).** NLP methods are employed to extract entities from the articles – such as “Duke University” – which provide a stronger basis for classifying both the setting and relevance an article, as well as aiding in identifying the county in which the article takes place.

4. **Contextualized Sentiment Scoring (Vaccines use case only).** Different from typical sentiment analysis, the headlines of articles were run through two models – one trained to evaluate how well the State was handling the vaccine rollout, and another trained to evaluate how willing the populace were to get vaccinated. Both output a score between -1 (bad news) and 1 (good news).

5. **Filtering.** A set of decision trees based upon the results of the keyword tagging and setting extraction is employed to filter the set of articles. A different set of keywords and tags is used for each use case. For the Clusters/Outbreaks use case, a logistic regression model trained on a set of manually tagged data is employed to aid in the classification of these articles. This system achieves 98% accuracy, and an F1 score - more useful due to the large number of True Negatives - of 91% against manually classified data.

6. **Grouping of similar articles.** For a succinct and useful update, NLP methods are used to group articles that are reporting the same story – both in the same day and over the past week – so that each story is only reported once.

7. **Automated email and further use of data.** For the Clusters/Outbreaks case, an email that offers a succinct bullet-point list of articles reporting new clusters/outbreaks along with the setting of the story and a link to the article is automatically generated and distributed. For both cases, the daily data is also loaded into a dashboard for the respective use case for further insight exploration and use by the State.
Results
For both use cases, the Automated News Monitoring solution enables gathering and tracking of trends to inform key response activities. The dashboards provide individual links to relevant news stories – providing both details and transparency – as well as analysis of trends across categories and locations over time. (See Figure.) The automated cluster/outbreak identification allowed the state to immediately respond and allocate resources (e.g. contact tracers) where applicable, as well as to track trends of cluster/outbreak settings overall to inform prevention measures. This complements and supplements the tracking that is already done through required public health reporting of COVID-19 cases. The vaccines use case allowed the state to monitor public perception of the vaccine rollout, as well as track willingness of certain populations and regions. This helped support vaccine allocation decisions, including quick notification of distribution bottlenecks and planning of community vaccination events.

Discussion
The Automated News Monitoring Solution was developed to address the need to keep abreast of new clusters and outbreaks in near real-time as a complement to mandatory public health reporting. The solution also helped to promptly identify and track any news, emerging complaints, events, and bottlenecks related to the State’s performance in vaccine distribution, as well as regional willingness of State residents to take the vaccine, thus impacting demand. Through the application of a variety of data wrangling, data analysis, NLP, and automation techniques a generalizable and automatable framework was created that can be applied both to these same use cases in other states, and to other use cases across industries. This solution can be easily scaled to handle large volumes of articles and modified to provide targeted insights on different topics, with links to the tagged article titles and body texts themselves. It can also be easily applied by other states to the same pressing issues or generalized by other actors to fit their needs and – with minimal human input – provide a highly accurate and succinct output.

COVID-19 Clinical and Social Surveillance System for After School Programs

Ellen K Kerns, PhD MPH¹, Russell J. McCulloh, MD¹, Chad J. Abresch, PhD¹
¹Dept. of Pediatrics, University of Nebraska Medical Center, Omaha, NE, United States

Introduction

The COVID-19 pandemic has created medical, social, and economic hardships for families, particularly in communities of color. School based programs play a key role in addressing household challenges; however, there is a critical need for scalable tools schools can use to keep their facilities safely open and adequately respond to household challenges. We designed an mHealth program to fill this need by providing after school programs an app with two decision-support tools: a daily COVID-19 Household Symptom Checker and a bi-weekly Household Challenges Tracker. Our overall program includes: 1) app-based feedback for families, delivering current guidance from their local health department and CDC; 2) custom dashboards for the after-school programs, summarizing households’ responses to inform infection mitigation strategy; and 3) community navigators, who expedite public aid and community assistance to requesting families. Our research objective is to measure the program’s feasibility and acceptability by piloting it in two after school programs in Omaha, NE: NorthStar and Girls Inc.

Methods

A flow diagram of the mHealth program components is presented in Figure 1. Each after school program received a health department approved daily symptom screening tool (COVID-19 Household Symptom Checker) and a bi-weekly household challenges screener (Household Challenges Tracker) accessible via website or by app customized with their local context (colors, logo, distance learning/attendance procedures, etc.). Prior to release, the tools were usability tested with families from participating schools prior to release and were revised based upon feedback from these families, the after-school program administrators, and the family navigators. Both tools were provided in English, Spanish, and Nepali. Household preferred language, contact information, and student demographics are entered upon first use (Figure 2A). Tool translations were provided by certified medical translators familiar with the community served by the after-school program. After this initial registration, households are presented with the two tools upon opening the app or website (Figure 2B). The symptom checker uses health department guidelines to advise staying home or go to school based on exposure, testing, and both household and student symptoms.

The challenges tracker assesses the household for challenges experienced (listed in Figure 2C) in the last 14 days (based on those included in the PhenX Measures of the Social Determinants of Health¹), whether or not they have received assistance for those challenges, and whether they would like a family navigator to reach out to them to provide assistance with their reported challenges.

Figure 1. Flow Diagram for the mHealth Program
Every interaction made within the tool is tagged and tracked, along with the registered household that used it, the date, time, and location of each session. This data is written to a FERPA/HIPAA compliant database upon which refreshable dashboards for both the after-school program administrators and the family navigators are derived. The program administrator dashboard includes summaries by grade and school of symptoms experienced, whether households were advised to keep their student(s) home, reasons for the stay-at-home advisement, and challenges experienced. They also include named lists of students registered and day by day screening results. The navigator dashboard includes a list of households wishing to be contacted and their reported challenges.

For this pilot, a community navigator will be embedded within each after school program and households will receive gift card incentives upon registration and again upon reaching one month of weekly use sessions. Navigators will assist households with the process of finding and applying for aid for their specific challenges when possible. Some challenges are larger system issues which we are collecting to better advocate for future changes. This is made clear to households on each of the final screens within the challenges tracker. These navigators have worked in other roles with these programs before and are familiar with their households. Although not formally assessed for or tracked, the after-school programs had a history and reputation for assisting their families with challenges when they are confided in about them. The navigators will document all contact attempts and their results.

Results

We deployed the symptom screener alone in 2 public districts and 2 private schools in fall 2020, achieving an average of 80% registration and a median weekly screening rate of 40% in the first 8 weeks post deployment. The after-school program pilot went live on June 1st, 2021 and enrolled 46 students (of 200 enrolled for the summer) in 28 households within the first 2 weeks. Demographics of student tool registrations will be compared to those of the after-school program enrollees to determine whether those who register are representative. Proportion of students enrolled whose households used the symptom checker will be tracked on a daily and weekly basis. Proportion of students enrolled whose households used the challenges tracker, who report any of the challenges, and specific challenges reported will be tracked on a bi-weekly and monthly basis. Navigator requests, time to contact, and result of contact will be assessed weekly. Finally, participating households, after school program administrators, and family navigators will be interviewed periodically throughout the pilot to provide feedback on their experience with the program, the app, and the family navigation process.

Conclusion

The proposed program has the potential to enhance the ability of school-based programs to operate safely during the pandemic and to address the social and health disparities that arise. Study results will determine the feasibility and acceptability of such a program. If found to be feasible and acceptable, the program will provide scalable resources for deployment in future pandemics, natural disasters, and localized hardships.

Improving the Prediction of Healthcare Costs and Utilization Using the Area Deprivation Index and Statewide Insurance Data

Hadi Kharrazi, MD, PhD1, Hsien-Yen Chang, PhD1,2, Elham Hafez, MD, PhD1, Xiaomeng Ma, MS1, Jonathan P Weiner, DrPH1

Introduction

Traditionally, risk adjustment models have relied on individual-level variables to predict and explain healthcare costs and utilization. However, as the performance of risk adjustment models fails to gain significant improvements with additional individual-level variables, utilizing aggregated information is increasingly being proposed as an alternative method to improve risk stratification and population health management efforts. Place-based determinants of health (i.e., the characteristics of the neighborhoods of patients’ residence) are powerful drivers of morbidity, mortality, and future well-being, yet they mostly remain outside the conventional medical care delivery systems. Adopting Area Deprivation Index (ADI) to represent place-based determinants, we aimed to evaluate its added values on claims-based risk adjustment models in predicting a range of utilization and cost outcomes.

Methods

This was a retrospective cohort study using 2013 and 2014 Maryland Medical Care Database (MMCD) from the Maryland Health Care Commission (MHCC). From 8,403,458 enrollees that had any record in MMCD between 2012 and 2016, we applied the following inclusion criteria: (1) aged 18-63 in 2013 with known sex; (2) Maryland residence in both 2013 and 2014; (3) 6+ month medical and pharmacy enrollment in both 2016 and 2017; and, (4) living in ZIP codes with 1000+ residents. Eventually, study population had 1,150,984 eligible enrollees. An individual’s ZIP code was assigned based on the most frequently occurring ZIP code and then the most recent ZIP code based on enrollment. The Area Deprivation Index (ADI) was adopted to represent place-based determinant of health, which is a validated measure of community disadvantage calculated at multiple geographical levels. ADI allows for rankings of neighborhoods by the socioeconomic disadvantage in a region of interest. ADI includes factors for the domains of income, education, employment, and housing condition; it can be used to inform health delivery and policy, especially for patients in the most disadvantaged neighborhoods. A percentile based on the national ADI ranking was assigned to each ZIP code and then attached to an individual through the geographic linkage. We generated three types of costs and five utilization markers in the concurrent (2013) and prospective (2014) calendar year at the individual level. Three types of costs were total costs, medical costs (non-pharmacy costs) and pharmacy costs; all costs were truncated at the respective top .5% of all positive costs. Five utilization markers included being top 5% top users, having any hospitalization, having any emergency department (ER) visit, having any avoidable ER visit, and having any readmission within 30-day of discharge. Control variables included two demographic variables (i.e., age and sex) and one morbidity measure. Age was divided into the following five categories: 18-24, 25-34, 35-44, 45-54, and 55-63 years old. Age was restricted to 63 in 2013 since people aged 64 in 2013 would enter Medicare in 2014 and we would not have their claims information. The morbidity measure was the DxRx-PM score, derived from the Johns Hopkins Adjusted Clinical Group (ACG) system. The DxRx-PM score is a comprehensive diagnosis-based predicted score constructed from various ICD and NDC-based indicators. The DxRx-PM score has been demonstrated to be a valid measure of morbidity. We applied linear regression for costs and logistic regression for binary utilization markers. We constructed two base models: one with demographics only and another with demographics and DxRx-PM score; for each base model, we constructed three ADI-enhanced models. Three sets of ADI variables entered separately to the base models: (1) ADI national percentile as a continuous variable; (2) ADI national decile as a categorical variable; and, (3) five components of ADI index, which contribute to more than 90% of variation of the ADI (i.e., median family income, home value, gross rent, monthly mortgage, and income disparity). The performance measures included R² from linear regression and AUC from logistic regression.

Results

Among 1.15 million eligible study subjects, 47.55% were male and the mean age was 41.2 years old. The average ADI national rank percentile was 47.3, suggesting that on average the sample lived in an area slightly more advantageous than the average American. Only 8.73% lived in the bottom 10% socioeconomic areas while 10.69% lived in the top 10% socioeconomic areas. The average total healthcare costs in both years were about $2,500, among which $1,600 were medical costs while $900 were pharmacy costs. About 2.7% had at least one hospitalization in
either year, about 12% had at least one ER visit, 7.7% had at least one avoidable ER visit, and .27% had at least one 30-day readmission. Adding ADI national rank percentiles (continuous variable), adding ADI national rank deciles (categorical variable) or adding the five components of ADI in either base model had minimum impact on the $R^2$ of total, medical or pharmacy costs (Table 1). Across five binary utilization markers, adding ADI only had the impact on two ER-related utilization markers (Table 2). For example, adding ADI national rank deciles to base model 2 statistically significantly increased AUC of predicting any avoidable prospective ER visit from .610 (95% CIs: .609-.612) to .613 (95% CIs: .611-.15), while doing so had no impact on predicting any prospective hospitalization (AUC of base model 2: .729, 95% CIs .726-.732; AUC of the base model 2 with ADI: .729, 95% CIs .726-.732).

### Discussion

Our study is one of the first to evaluate the impact of neighborhood characteristics on the performance of risk adjustment models. The only similar study we identified did not find neighborhood characteristics contributing to risk prediction beyond demographic (e.g., age and race) and clinical data in the EHR from a ~90k participants of a single county. Thus, our study added considerably to the limited literature on the impact of incorporating place-based determinants of health into risk adjustment models. The only significant impact of adding ADI on the performance of risk adjustment models was on binary indicators of an ER visit, especially an avoidable ER visit. It can be hypothesized that patients living in neighborhoods with lower SES were less likely to be able to afford seeking healthcare under the regular setting given the cost burden and the lack of healthcare providers; therefore, they were more likely to use ER as their regular source of healthcare.

### Conclusion

Adding ADI to the claims-based risk adjustment models improves the ability of risk adjustment models in predicting the probability of having any ER visit or having an avoidable ER visit. Future research should focus on patients with higher-need for social services (e.g., Medicaid patients), assess more granular place-based determinants (e.g., Census block group), and evaluate the added-value of individual social variables instead of a composite index such as ADI.

FHIRedApp: A LEAP in Health Information Technology for Promoting Patient Access and Health Equity
Anjum Khurshid, MD, PhD, Eliel C. de Oliveira, MS, MBA, Vidya Lakshminarayanan, MS, Vishal Abrol, BS.
Dell Medical School, The University of Texas at Austin, Austin, TX

Introduction
Nearly a year ago, the Office of the National Coordinator for Health Information Technology (ONC) and the Centers for Medicare & Medicaid Services (CMS) released final regulations to implement the information blocking and patient access provisions of the 21st Century Cures Act. These regulations underscore the United States government’s recognition that healthcare information technology has not kept pace with other industries when it comes to the adoption and utilization of modern interoperable technologies and in empowering consumers.

We developed the FHIRedApp as an App Platform that allows patients to gain access to their medical data and share that access as HL7® FHIR® (Fast Healthcare Interoperability Resources) APIs with third party App developers. This allows for innovative solutions to be built and provided to patients to harness the value of their medical data. This effort was funded by ONC in 2019, as part of ONC’s Leading Edge Acceleration Projects (LEAP), to design, develop and demonstrate an enhanced PET platform. The goal of the ONC program was to modernize patient engagement tools, engage diverse populations including the underserved, enhance opportunities for underrepresented populations to participate in research while addressing security and privacy concerns, allowing data transport from various digital devices, and applying user-centered design principles.

Methods

Design through Community Engagement Studios and Human-Centered Design
The overall development of FHIRedApp was informed by Community Engagement Studio (CES) and Human-Centered Design (HCD) methodologies. CES is a structured-forum, designed to gain valuable community insights on a research topic. (2) CES provides researchers with a real-time, in-person opportunity to share their research projects and goals with community members, advocates, and other stakeholders, and to receive direct feedback and guidance via a facilitated conversation. CES meetings are led by a community navigator. We ran CES sessions engaging community experts from the local African American, Asian American and the Latinx communities.

The insights gained from CES sessions informed the HCD work to uncover the features and capabilities that underserved community desired from an App platform such as FHIRedApp. The HCD methodology included: a) a competitive analysis of current similar platforms; b) scenario creation based on input from CES meetings and surveys; c) development of early low-fidelity designs; d) usability tests; and e) iterative one-on-one design sessions with users to develop high-fidelity designs.

Results

Figure 1 depicts a flow diagram on how the FHIRedApp back-end infrastructure is able to aggregate clinical data and seamlessly deliver such data as APIs to users of the FHIRedApp Platform. We partnered with the Integrated Care Collaboration (ICC), an HIE in Central Texas, that aggregates data of over a million patients across various healthcare providers in the region. ICC data contributors include three hospital systems accounting for about 80% of all hospital services in the region, federally qualified health centers, behavioral health providers, the Austin-Travis County Emergency Medical Services (EMS), and several primary care provider organizations sharing Medicare, Medicaid and uninsured patients’ data across all participants in the exchange.

Additionally, we adopted a Privacy-Preserving Record Linkage (PPRL) solution that is utilized by several large national data research networks such as PCORnet to link patient records without storing Personally Identifiable Information (PHI) such as names, addresses, or phone numbers and enhance the security and privacy of the data.

The process of data integration and linkage for FHIRedApp back-end infrastructure happens on Amazon Web Service (AWS) accounts managed by our team through the following steps:

1. ICC deploys a Hashing Tool that accesses demographics information (names, date of birth, gender, etc.) to generate salted hashes that comply with HIPAA’s de-identification methods and a cross-table of IDs between the hashes generated and the CDR. The salted hashes are then submitted to our team along with a limited dataset as defined by HIPAA which excludes most PII elements except for dates and zip codes through Extract, Transform and Load (ETL) processes;

2. when a user signs up and consents to use the platform, FHIRedApp collects basic demographic information from the user (name, email, phone number, and gender) that will be used by the PPRL solution (hashing and matching tools) to link users to their medical records. The hashing tool deployed at the back-end receives the user’s demographic information and also generates salted hashes and a cross-table of IDs that links users to their hashes;
3. Finally, an ETL process utilizing the IDs linked by the Matching Tool combines the records from the LDS and the users’ database (DB) to generate the FHIRedApp DB. That database is transformed into FHIR APIs and exposed using a HAPI Server to the mobile FHIRedApp front-end App.

Hash function is any function that can be used to map digital data of arbitrary size to digital data of fixed size, with slight differences in input data producing very big differences in output data. The unique aspects of using a hash function are due to the following properties:

1. Each hash is unique but always repeatable - that means that a word such as 'car' will hash to something that no other word hashes to, but it will always hash to the same thing;

2. The function is 'one way' - meaning that if you are given the value of what 'car' hashes to but you didn't know what made it, you would never be able to find out that 'car' was the original word.

Discussion
We describe the design and development of FHIRedApp, an App platform that allows patients to access their data and to share that access as HL7® FHIR® (Fast Healthcare Interoperability Resources) APIs with third party App developers. As a Leading Edge Acceleration Project for health information technology sponsored by ONC, we are accomplishing two major tasks: first, to demonstrate the use of interoperability and authentication standards approved by ONC and the industry, such as HL7® FHIR and OAuth2, to help develop responsive patient engagement technologies, and second, to co-develop and co-design FHIRedApp with active involvement of African-American, Latinx, and Asian-American community members to help address health disparities in the use and benefits of PETs in our populations. We hope that the methodology and design of FHIRedApp will facilitate further development of these approaches and meaningful engagement of vulnerable populations in fulfilling the mandate of 21st Century Cures Act to allow patient to “access, exchange, and use” their health data “without special efforts”.

Clinical Concept Extraction Using Contextual String Embeddings

Youngjun Kim, PhD\(^1\), Paul M. Heider, PhD\(^2\), Stéphane M. Meystre, MD, PhD\(^2\)
\(^1\)Sema4, a Mount Sinai venture, Stamford, Connecticut, USA
\(^2\)Medical University of South Carolina, Charleston, South Carolina, USA

**Introduction:** Identifying mentions of concepts in electronic health record (EHR) narrative text is a fundamental problem and its importance is still growing as a prerequisite for other high-level tasks. Clinical concept extraction has often been framed as a sequential labeling problem to assign a semantic category label to each word in a sequence. Deep learning-based algorithms with pre-trained word embeddings\(^1\) have provided a robust solution. Recently, context-dependent embeddings\(^2-4\) have been used to construct vector representations of words as input to neural networks. Several studies leveraging these embeddings have demonstrated improved accuracy for concept extraction from unstructured clinical narratives.\(^5,7\) Our research aims to improve clinical concept extraction using syntactic and semantic knowledge acquired from large amounts of unlabeled clinical text. We employ contextual *string* embeddings called *Flair*\(^3\) to transfer that knowledge into our target tasks. These embeddings learn a word as a sequence of characters and generate the word representation differently depending on its context. Although Flair embeddings have achieved state-of-the-art performance in general text NER (named entity recognition)\(^1\), few studies\(^5,9\) have used them in clinical NLP. If compared to BERT\(^4\), a popular transformer-based word embeddings resource applied in clinical NLP, Flair offers a convenient way to handle longer sequences of words. To our knowledge, this is the first work that applies Flair embeddings for de-identification of EHR narratives.

**Methods:** We focus on three representative clinical natural language processing (NLP) tasks. The first task was defined for the 2010 i2b2 (integrating biology and the bedside) challenge\(^10\) and involved extracting three categories of medical concepts: Problem, Treatment, and Test. The next task is text de-identification introduced for the 2014 i2b2 challenge\(^11\). It aims to detect pre-defined categories of personally identifiable information (PII). These categories include Name, Profession, Location, Age, Date, Contact, and ID. The final task was introduced in the 2018 national NLP clinical challenges (n2c2) shared task\(^12\) and focuses on extraction of medications and related information (e.g., dosage, route, frequency) from clinical text.

In this study, we pre-trained two versions of the language model from clinical text. One was trained using fastText\(^1\) as static word embeddings and the other was trained using the Flair\(^3\) software library. We used clinical notes from the MIMIC-III clinical database\(^13\) v1.4 (we call it ‘MIMIC embeddings’). Models were trained with all 2,083,180 clinical notes. We created a 300-dimensional skip-gram fastText model. The learning rate and number of epochs were set to 0.02 and 10, respectively. Flair embeddings were trained on the same corpus. We set the number of hidden states of the LSTM (long short-term memory) to 2048 and trained the Flair model for 10 epochs. Pre-training was performed on a NVIDIA Tesla P4 GPU and took about 1 month. For a comparative assessment with our MIMIC word embeddings, the publicly available fastText\(^1\) and Flair\(^3\) models were used as general text embeddings.

We used the bidirectional LSTM (Bi-LSTM) algorithm to solve the structured prediction problems. A CRF (conditional random fields) classifier was added as the last layer in the network. We created four different variations of LSTM-CRF models for each task: 1) fastText with general text embeddings, 2) fastText with MIMIC embeddings, 3) combined fastText and Flair vectors with general text embeddings, and 4) fastText and Flair with MIMIC embeddings. We set the learning rate to 0.001 and trained the Bi-LSTM models for 10 epochs with 50% dropout. We calculated the average value between five trials of each model because of its non-deterministic results. Instead of ignoring the individual trial outputs, we created a voting ensemble method that combined these trial predictions to further improve performance. The voting ensemble selected all concepts that received at least three votes.

**Results:** We used the official evaluation script provided for each shared task to calculate primary performance metrics. For the 2010 and 2014 i2b2 shared tasks, a true positive is obtained when both the text span and concept category exactly match the reference annotation. For the 2018 n2c2 shared task, a match is counted if there is any overlap between the reference standard text span and the concept detected by the system. Table 1 shows the results produced with combinations of NLP tasks, text sources of pre-trained models, and embedding approaches. The impact of contextual embeddings varies across the tasks (when comparing rows 1 and 2). Adding Flair representations allows for substantial performance gains for the 2010 i2b2 task. This implies that contextual embeddings can more effectively handle medical concepts involving long modifiers or unseen words. The F\(_1\)-scores of the general text and MIMIC embeddings increased from 85.4% and 86.4% to 86.2% and 88.6% respectively. In the 2014 i2b2 task, Flair embeddings increased the F\(_1\)-scores between 0.6 and 0.8%. In the 2018 n2c2 task, Flair embeddings further benefited
concept categories that were recorded in a more unstructured manner with rich terminologies, such as reason (for prescription) and adverse drug event (ADE). We created BERT models with the BlueBERT-Large version14 for comparison. BERT embeddings produced a slightly higher F1-score (93.6%) than Flair embeddings in the 2018 n2c2 task. Detailed comparisons will be provided in a more extended publication.

MIMIC embeddings allowed for an improvement over their counterpart general text embeddings (when comparing the column “General text” with the column “MIMIC text”). Both fastText and Flair embedding pre-trained with the MIMIC corpus improved performance. For the 2010 i2b2 and 2018 n2c2 tasks, MIMIC embeddings increased the F1-scores between 0.4 and 2.4%. As with the results reported by Alsentzer et al.6, text de-identification was an exception, presumably because PHI phrases in MIMIC texts were re-synthesized with tags describing the type of information (e.g., “[ Name ]” instead of “Mary Jones”). We also confirmed that each voting ensemble consisting of multiple trials outperformed the individual classifiers. The voting ensemble increased the F1-scores between 0.3 and 1.2%. The best result for each task (bold in Table 1) was significantly better than all other methods at the 95% significance level.

**Conclusion:** We demonstrated that contextualized string embeddings, especially trained with text resources that share similar syntactic and semantic word distributions, could be beneficial to clinical concept extraction. We confirmed that vector representations learned from such corpora (e.g., MIMIC-III clinical database) can more accurately detect concept boundaries and identify unseen concepts from the training data. To advance our neural network architectures, we will augment the vector representation using ELMo2 and BERT4 context embeddings.

Feasibility and efficacy of using commercially available mHealth technologies and tailored text messages to improve self-care in patients with heart failure: Phase I clinical trial of the iCardia4HF intervention

Spyros Kitsiou, PhD1, Susan J. Pressler PhD, RN2, Mayank M. Kansal, MD1,4, Susan W. Buchholz, PhD, RN3, Jinsong Chen, PhD, Jonathan Leigh, MPH, Ayomide J. Owoyemi, MBChB, MPH1, Ben S. Gerber, MD, MPH5

Introduction

Heart failure (HF) is a chronic condition associated with substantial morbidity, mortality, and hospital readmissions1. Evidence shows that effective HF self-care is crucial to improving HF outcomes2. Self-care is a naturalistic decision-making process that involves self-care maintenance (taking medications as prescribed, restricting sodium intake, and staying physically active), symptom perception (monitoring and interpreting HF signs and symptoms), and self-care management (response to symptoms when they occur)3. Self-care is poor among HF patients, especially older adults and underserved ethnic minorities due to lack of skills, confidence, knowledge about HF, and health beliefs2. There is an urgent need for low-cost and scalable interventions to assist patients with HF self-care at home. The objective of this study was to assess the feasibility, acceptance, and effects of a patient-centered intervention (iCardia4HF) that uses commercially available mobile health (mHealth) technologies and text-messages (TM) to improve HF self-care.

Methods

Study design: A prospective randomized controlled trial was conducted between January 2019 and February 2020 (trial registration: NCT03642275). Study participants were actively recruited from the University of Illinois Health Sciences and Hospital System (UI Health). Key research personnel used the electronic medical record system to screen patients admitted to the hospital due to HF and outpatients with upcoming appointments to the HF clinic. Potentially eligible patients were approach for further screening and consent. Randomization was performed after baseline assessment, using QMinim (a free online minimization software) to ensure better-than-chance group balance in terms of age, gender, and HF severity based on the New York Heart Association (NYHA) class as in previous trials5.

Eligibility criteria: Patients were eligible to enroll in the study if they had Stage C HF (i.e., current or prior HF symptoms), were ≥40 years of age, spoke English, owned a smartphone, and lived within a 30 mile-radius from UI Health. Patients were excluded if they had end-stage renal disease/dialysis, end-stage HF, active cancer, cognitive impairment (Montreal Cognitive Assessment score of <22), were unable to perform self-care, or lived in nursing home.

Control group: Participants in the control group received usual care consisting of patient education (literacy-sensitive material about HF self-care developed by the Sheps Center for Health Services Research) before hospital discharge and follow-up visits at the outpatient HF clinic 1-2 weeks after discharge and 1-3 months thereafter.

Intervention: In addition to usual care, participants in the intervention group received the iCardia4HF intervention which comprises: (1) the Heart Failure Storylines mobile app; (2) three connected health devices (Withings Body Cardio Scale and Blood Pressure Monitor, and Fitbit Charge 2 activity tracker) along with their respective apps (Health Mate and Fitbit); and (3) three individually tailored TMs per week targeting health beliefs, self-efficacy, and HF-knowledge. HF Storylines is a free, web-based app developed by Self Care Catalysts in collaboration with the Heart Failure Society of America. It interfaces with the Withings and Fitbit devices and provides patients with a number of tools to support self-monitoring of HF sing and symptoms, including medication adherence and low-sodium diet.

Outcomes: The primary outcome was change in HF self-care including self-efficacy, measured with the Self-care Heart Failure Index (SCHFI v6.2)3 at 30 and 60 days. Outcome assessors were blinded to the group allocation. Feasibility was assessed in the domains of recruitment and retention. Intervention acceptance was assessed with the Technology Acceptance Model3 and semi-structured interviews post-intervention. Adherence to daily self-monitoring was objectively assessed using time-stamped data transmitted from the mobile apps to our study server via Web APIs.

Study procedures: Intervention participants received 1-hour training at baseline along with printed instructions on how to use the devices and mobile apps. Daily self-monitoring included weight and body composition measures (e.g., fat mass, water mass, and muscle mass) with the Withings Body Cardio scale, blood pressure (BP) and heart rate with the Withings BP cuff, and physical activity/inactivity measures (e.g., steps, intensity of activity, sedentary minutes, continuous heart rate, and sleep) captured by the Fitbit activity tracker.
Results

Twenty-seven patients were enrolled and randomly assigned to the intervention (n=13) or control group (n=14). One patient from the intervention group was lost to follow-up, while a second one was admitted to a nursing home and became ineligible before allocation of the mHealth apps and devices. Thus, a total of 25 patients (mean age 56, standard deviation [SD] ±8.3, 44% female) were included in the full analysis set (11 intervention, 14 control).

Baseline characteristics (age, gender, race, education, income, weight, BP, and HF severity) were similar between the two groups. Most patients were Black (91%) with no more than high school education (73%), functionally compromised (76% had NYHA Class II or III), and obese (mean weight: 110.8 kg, SD ±33.1; mean Body Mass Index: 36.6 kg/m², SD ±10.1). Mean left ventricular ejection fraction was 35.8% (SD ±12.4). Although not reaching statistical significance due to the small sample size, participants in the intervention group experienced greater improvements in HF self-care maintenance, symptom perception, and self-efficacy, compared to the control group over 60 days (Table 1). Effect sizes ranged from small (0.20) to moderate (0.50) based on Cohen’s D.

</tr>
</tbody>
</table>

Adherence to daily self-monitoring of weight and BP with the devices and app was high during the intervention period (mean ±SD: 89.8 ±7.04% and 83.3% ±6.29%, respectively), with no statistically significant decline over time. Participants adhered well to wearing the Fitbit tracker with the mean participant logging 600 minutes/day or more on 85.3% of intervention days (51/60). Mean Fitbit wear-time was 1031 ± 305 minutes/day during the intervention period. Participants perceived the iCardia4HF intervention to be useful (mean 2.94±0.07 on a 3-point Liker scale, where 1=disagree and 3=agree) and easy to use (2.97±0.08). Mean user satisfaction was 2.94±0.07.

Discussion

The results of this small RCT provide initial evidence that iCardia4HF might be a feasible and acceptable intervention for promoting HF self-care in patients with HF. Participants were satisfied with the intervention and found the multi-connected app kit easy to use. Minor technical challenges such as forgetting how to charge/sync the Fitbit tracker or receiving a measurement error message from the weight scale or BP monitor when not properly positioned were addressed in a timely manner (within 48 hours) via telephone. Findings provide support for the conduct of a larger trial with longer follow-up (currently underway with funding from the National Institute of Nursing Research R21NR018281, NCT 04262544) to determine the efficacy of iCardia4HF intervention. To our knowledge, this is the first RCT that evaluated the feasibility of using commercially available mHealth technologies to promote self-care in patients with HF. In a recent systematic review\(^2\), we found that previous RCTs have evaluated either research-based mHealth apps that are not commercially available or apps that are part of a larger remote patient monitoring system in which clinicians are actively monitoring the incoming data to provide patients with clinical feedback when needed. The iCardia4HF study represents a meaningful advance in standalone, patient-centered mHealth interventions, and an important step in identifying a scalable solution that has the potential to bring about a new paradigm in HF self-care. The combination of smartphones and commercially available mHealth technologies make the iCardia4HF intervention portable to different clinical settings and create exciting opportunities for scalability and broader impact.

Challenges and Solutions to Promoting Evaluation Practices in Software Development Process within an Academic Medical Center

Polina Kukhareva, PhD, MPH, MS; Charlene Weir, PhD, RN; Thomas Reese, PhD, PharmD; Teresa Taft, PhD; Guilherme Del Fiol, MD, PhD; Kensaku Kawamoto, MD, PhD, MHS

University of Utah, Salt Lake City, Utah

Introduction: Electronic health records (EHRs) are evolving into platforms for EHR-based apps, enabling an emerging EHR app ecosystem. With millions of patients affected by locally-developed EHR apps, it is critically important to rigorously evaluate these apps across all stages of their lifecycle. The software development process could be improved by applying concepts, methods, and evaluation strategies from human-centered design, implementation science, and health technology assessment (HTA) domains. We sought to demonstrate the feasibility of promoting standardized evaluation practices in local software development. University of Utah’s ReImagine EHR initiative developed and implemented into clinical practice several interoperable apps and was a perfect place for demonstrating the value of standardized evaluation approaches. The resulting EHR-based Digital Innovation Evaluation Framework (EDIEF) is described.

Methods: We aimed to develop and apply a pragmatic, mixed-methods, full-lifecycle evaluation framework for EHR-based apps. Drawing from human-centered design, implementation science and health technology assessment perspectives, we selected evaluation approaches that could be used at all EHR apps lifecycle phases: exploration, preparation, implementation and sustainment (1). The novel EDIEF was iteratively developed through literature review, expert consensus, and evaluating apps in real-world settings. We tested the feasibility of using EDIEF in the development of a representative app (a SMART on FHIR Neonatal Bilirubin App, which won the 2019 AMIA/Health Level Seven (HL7) FHIR App Showcase). We describe here the challenges encountered and our recommendations.

Results: We designed a new evaluation framework known as EDIEF and implemented it across the software development lifecycle (Figure 1). Examples of assessments for each evaluation step are provided in Table 1.

</table>
To test and improve the EDIEF, we used all 12 evaluation steps in the evaluation of the Neonatal Bilirubin App including engagement of pediatrics in business case analysis, the application of usability heuristics principles, comparative efficiency testing, user adoption assessment, user satisfaction assessment, and the evaluation of process and clinical outcomes.(2) The use of the app resulted in 66 seconds saved per bilirubin assessment (95% CI, 53-79); the app was used for 90% of babies; system usability score for attending providers was 91 (95% CI, 86-96) which corresponds to “best imaginable” usability; clinically appropriate phototherapy during hospitalization increased for newborns with bilirubin levels above the guideline-recommended threshold (odds ratio, 1.84; 95% CI, 1.16-2.90; P = .01).(2) Additionally, we evaluated technical portability of the app software.(3)

As we utilized the EDIEF, we encountered challenges such as high cost involved in conducting rigorous evaluations, timeline pressures leading to skipping evaluation steps; and the need to evaluate a moving target. Table 2 outlines the key challenges encountered and our proposed solutions.

</tbody>
</table>

Discussion: Inadequate evaluation during the development of EHR-based apps could lead to disjointed EHR user experiences with the final products, wasted resources, and unintended consequences including patient harm. As EHR-based apps become increasingly important in healthcare systems’ strategies to support clinical decisions, a pragmatic and comprehensive evaluation approach is critically needed. The EDIEF described here could facilitate these needed evaluations of emerging apps.

Conclusion: Commitment to systematic evaluation is critical to ensure the emerging EHR app ecosystem results in intended outcomes. This study demonstrates feasibility of promoting evaluation practices in local software development in medical centers. The evaluation framework described was successfully used to evaluate a number of locally developed EHR-based apps. Further research is needed to test and refine this pragmatic framework for evaluating EHR-based apps.

Improving MHC Class I Antigen Processing Prediction via Representation Learning and Cleavage Site-Specific Kernels

Patrick J. Lawrence¹, Xia Ning PhD¹,²,³

¹Biomedical Informatics Department, The Ohio State University, Columbus, OH, US; ²Computer Science and Engineering Department, The Ohio State University, Columbus, OH, US; ³Translational Data Analytics Institute, The Ohio State University, Columbus, OH, US

1 Introduction
The major histocompatibility complex (MHC) Class I protein is a vital part of the immune system’s response to intracellular invasion by viruses, bacteria, parasite and tumorogenesis [1]. Its primary responsibility is to present antigens – typically, short peptides cleaved from proteins and are only 8-10 amino acids in length – into the extracellular environment to be recognized by cytotoxic (CD⁸⁺) T cells, which subsequently eliminate compromised cells via apoptosis. Thus, these peptides can be leveraged for the development of both vaccines that prime CD⁸⁺ T cells against a pathogen and drugs that elicit cytolytic activity in tumor cells. As a result, computer-aided methods have been developed to identify candidate peptides [1]. Among them, methods that rank peptides’ binding affinities to MHC class I molecule(s) have achieved the superior performance [2]. However, these methods may biological relevance; there is no guarantee highly ranked peptides will be selected for presentation by upstream proteins [3]. Recent attempts have been made to produce models that rank the likelihood of peptides being processed within the MHC class I presentation pathway [3][2]. In this work, we propose a novel antigen processing prediction model: mhcRank. Based on the architecture used by O’Donnell et al [3], our model imparts additional biological relevance, focusing on the carboxyl (C)-terminal cleavage site of the antigen and pre-processing antigen sequences to simulate what is observed in vivo [3]. Our model, mhcRank, also departs from the widely used BLOSUM62 matrix for amino acid representations in favor of learning problem-specific embeddings for each amino acid. Our experiments over benchmark data set demonstrate that mhcRank achieves significant performance improvement over the gold standard methods netMHCpan-4.0 eluted ligand and MHCflurry-2.0 antigen processing, referred to as netMHCpan and MHCflurry, respectively.

2 Methodology
The model architecture of our mhcRank is presented in Figure 1. In mhcRank, peptides are first processed to a uniform length via the process outlined in Figure 2. Processed peptides and flanks are represented using amino acid-specific learned embeddings. The proposed mhcRank has multiple components, each containing a series of 1-D convolutional layers aimed at (1) determining the probability of C and N terminal break at both the cleavage sites and within the peptide itself, (2) identifying characteristics of both flanking regions, and (3) capturing the C-terminus cleavage site. Components (1) and (2) are similar to those employed by MHCflurry [3]. Component (3), the cleavage site-specific kernel (CSSK), utilizes a global kernel to capture a representation of the entire cleavage site (purple box on right of Figure 1). Results from the convolutional layers and the peptide’s original length (light blue box on left of Figure 1) are all concatenated and enter two fully-connected layers before reaching the output layer. Models were trained identically to MHCflurry-2.0, including the dataset and training process [3]. This involved a binary cross-entropy loss function and Adam optimizer over maximum 500 epochs with a patience of 30 epochs. Post training, models were selected for inclusion in ensembles based on their respective AUC values on validation data. Mean precision and NDCG at k (with a 95% CI) were obtained using bootstrap resampling. Significance was determined by whether or not the CIs overlapped. These metrics were selected to evaluate how well mhcRank ranks peptides compared to the baseline methods. The values of k selected (10, 25, 50, 100, 250, 500) were those which might be realistically used in drug and vaccine development.
A. Peptides shorter than the desired length are padded with an ambiguous amino acid 'X' to the center. Raw peptides with an odd length have padding offset from the center by one amino acid towards the N-flank.

B. Peptides longer than the desired length are trimmed from the center.

C. Trimming to odd-length peptides requires the trim to be offset from the center by one amino acid towards the N-flank.

Figure 2: Peptide pre-processing

3 Experimental Results

Table 1 highlights the percent improvement in performance obtained by mhcRank compared to both netMHCpan and MHCflurry. The model mhcRank demonstrated statistically significant improvement over MHCflurry-2.0 for both metrics and at all values of $k$. Specifically, mhcRank had a mean improvement for all examined values of $k$ of about 9.83% and 10.12% over MHCflurry for precision and NDCG, respectively. The performance of mhcRank was much more comparable to the netMHCpan baseline with a mean percent improvement in precision and NDCG of roughly 1.79% and 2.35%, respectively. Even so, mhcRank still outperforms netMHCpan for most values of $k$. While not displayed here, it should be noted that the percent improvement increases further for both metrics as the values of $k$ increase, reaching a maximum of roughly 12-15% boost on both baseline methods.

4 Discussion

Peptide representations are enhanced through both pre-processing and learned embeddings. First, during pre-processing, we leverage biological knowledge to retain only the most relevant information. The dearth of enrichment in the central amino acids of the top 100 ranked peptides as shown in Figure 3 (generated using Seq2Logo [4]), paired with our improved performance, confirms the central amino acids are irrelevant features, whose removal promotes model generalizability. With respect to the embeddings learned for amino acids, the enrichment illustrated by Figure 3 highlights their capability to identify features not imparted by the BLOSUM matrix. At the terminal position in mhcRank’s top predicted peptides, all but one of the hydrophobic amino acids are enriched to comparable levels. Not only does this coincide with biological observations, but it also suggests that mhcRank has learned to identify, and favor, certain physiochemical properties of amino acids, such as hydrophobicity, despite no a priori knowledge [1]. Thus, even for the values of $k$ where the performance of mhcRank and netMHCpan were not significantly different, mhcRank is still superior as it is the more generalized predictor. Furthermore, the substantial improvement in performance over MHCflurry is aided by the implementation of CSSK. It is likely that these garner a boost in performance by identifying commonalities amongst protease cleave site motifs. Altogether, the proposed mhcRank demonstrates strong performance compared to existing methods, and could have vast applicability to aid drug and vaccine development.

References

Robert Leaman, Ph.D.\textsuperscript{1}, Qingyu Chen, Ph.D.\textsuperscript{1}, Alexis Allot, Ph.D.\textsuperscript{1}, Zhiyong Lu, Ph.D.\textsuperscript{1} 
\textsuperscript{1}NCBI/NLM/NIH, Bethesda, Maryland, USA

A substantial percentage of COVID-19 survivors experience debilitating symptoms long after the acute phase has resolved\textsuperscript{1}. This complex condition, called “long COVID” by patients, is not yet well understood, but it is becoming clear that many COVID-19 survivors will retain some degree of impairment for an extended period\textsuperscript{2}. Moreover, those at risk of long COVID include those not at high risk of mortality from COVID-19 due to mild/asymptomatic disease, youth, and good general health\textsuperscript{3}.

Despite the pressing need for information on long COVID, locating relevant research articles is challenging because the terminology used to refer to long COVID varies considerably. As a result, precise queries (e.g., “long COVID”) return limited results, but broader queries (e.g., “COVID sequelae”) suffer from low accuracy. We therefore created a comprehensive, searchable collection of long COVID articles, as an extension to LitCovid, a widely used literature hub with over 150,000 articles specific to COVID-19\textsuperscript{4}. We hope that the long COVID collection, updated weekly, will help researchers, healthcare professionals, and the general public keep up with the latest research.

Methods

We employed a human-in-the-loop process to identify all PubMed articles likely to be relevant to long COVID without requiring manual review of every article. Following previous definitions of long COVID\textsuperscript{1}, we defined an article to be relevant to long COVID if it considers “persistent symptoms and/or delayed or long-term complications [from COVID-19] beyond 4 weeks from the onset of symptoms.”

Starting from a small seed set of relevant articles, gathered manually, we split the data into four non-overlapping samples and trained a supervised classification model on each, using the LitSuggest web-based literature curation tool\textsuperscript{5}. We also extended our previous identifying variations in COVID-19 and SARS-CoV-2 terminology\textsuperscript{6} by creating a high-precision pattern-based named entity recognition (NER) system for mentions of long COVID.

We applied the LitSuggest classifiers and the NER system to all articles in the LitCovid portal\textsuperscript{3}, which includes all PubMed articles related to COVID-19. We then combined these relevance predictions and those of an external resource, CoronaCentral\textsuperscript{7}, into a single probabilistic prediction using triplet data programming\textsuperscript{8}, which estimates the accuracy of each input from the agreement rates between input pairs. Triplet data programming does not use labeled data or require training, enabling rapid analysis; our application generates predictions for all articles in LitCovid (154,429) in under 30 seconds.

We developed two powerful extensions to triplet data programming. First, the initial formulation only allows inputs to indicate relevant, irrelevant, or abstain; our method utilizes the full range of probabilities. Second, we improved the reliability of the accuracy estimates by ignoring input pairs where the 95% confidence interval on their agreement rate cannot rule out random chance.

Results

We applied our human-in-the-loop process to iteratively select articles for manual annotation – noting new long COVID terms and updating the NER patterns as needed. After 14 rounds, this iterative annotation resulted in 2,909 manually annotated articles (1,840 relevant, 1,069 irrelevant). Initial annotation rounds focused on articles that were likely to be relevant to long COVID; middle rounds focused on articles near the classification boundary and articles where inputs disagreed. The final rounds focused on likely false positives. In the final round, the f-score of the triplet data programming classifier is 0.831.

Of the 154,429 articles in LitCovid (as of July 26, 2021), we identified a total of 2,063 articles as relevant to long COVID. Figure 1a shows the number of articles on long COVID over time. Figure 1b compares the set of articles relevant to long COVID to the articles returned by querying PubMed for various long COVID terms and those in CoronaCentral. Note the low recall of precise queries (e.g., “post COVID syndrome”) and low precision of broad queries (e.g., post covid 19 sequelae), demonstrating the difficulty of locating long COVID articles by query alone. The NER system identified a total of 1,917 long COVID mentions in LitCovid (616 unique). Figure 1c shows the terms for long COVID found most frequently.
Figure 1. (a) Number of articles relevant to long COVID in PubMed per week. (b) Comparison of articles relevant to long COVID with articles returned by various PubMed queries and CoronaCentral. Precise queries (e.g., “post COVID syndrome”) return few results, broad queries (e.g., “post covid 19 sequelae”) return many irrelevant results. (c) Most commonly used terms for long COVID (case normalized and non-alphanumeric characters removed).

Conclusion

Abstract
VA’s Clinical Resource Hub (CRH) program provided contingency staffing in primary care and mental health care using telehealth, with a focus on rural and/or under-resourced clinics. This retrospective cohort study examined 180,068 patients with at least one CRH visit between 10/01/2019 and 6/30/2021 (n=558,384 visits). We observed divergent use of CRH telehealth modalities between primary care and mental health patients over time. Results support growing telehealth capacity as a public health tool for national disasters.

Introduction
Telehealth is increasingly used to connect patients to providers and reduce access barriers related to distance or time.1 Veterans Health Administration (VHA)’s Clinical Resource Hub (CRH) telehealth program started October 2019 in all 18 VHA multi-state administrative regions.2 CRH aimed to address contingency staffing needs in primary care and mental health care through telehealth, with a focus on rural and/or under-resourced clinics. To obtain CRH support, clinics within a hub’s geographic and administrative catchment area requested contingency staffing; CRH hubs then could offer telehealth visits to patients at remote clinic clinics. Shortly after CRH implementation, the COVID-19 pandemic ensued, expanding the role of telehealth and providing an opportunity to observe a large telehealth program during a pandemic. This study tracks differential use of CRH visit types across specialties over time, comparing before and after the onset of the pandemic.

Methods
In this retrospective cohort study, we included all VHA patients with at least one CRH visit between 10/01/2019 and 6/30/2021 (n=558,384 visits). We counted CRH in-person, telephone, primary care clinic-based video, and patient home-based video visits3 by specialty (mental health, primary care, other). We compared primary care and mental health patterns of visit types used in the first year to focus on the early pandemic course. We used X2 and t-tests to determine significance using a two-tailed α of 0.05, with SAS version 9.4. This study was part of a VHA Office of Primary Care quality improvement project and exempt from Institutional Review Board review.

Results
Over 21 months, 180,068 patients (mean age 60.1[SD=16.14] years; 160,142[89%] men; 127,628[71%] White; 87,860[49%] rural) received CRH services. Only 895 (0.2%) visits were conducted in-person. Despite COVID-19, we observed a consistent, almost 3-fold increase in services. This was driven near-equally by telephone (254,177) and video (296,092) visits, the latter of which shifted largely from primary care clinic-based to patient home-based. Approximately half of visits were delivered by primary care (231,131) and mental health specialists (288,596).

With COVID-19’s onset, CRH primary care, compared to CRH mental health, relied increasingly on telephone (66,184[64%] versus video (37,543[36%]) visits, comprising typically of primary care clinic-based (30,879[30%]) rather than patient home-based (6,664[6%]) video. In contrast, CRH mental health increasingly relied on home-
based video visits (53,763[41%]), mostly replacing clinic-based video visits (30,879[30%]) while maintaining a steady, but lower rate of telephone contacts (40,081[31%]). (Figure 1)

Figure 1. Clinical Resource Hub Mental Health versus Primary Care Visits, 10/01/2019 and 9/30/2020

Conclusion

Early implementation findings suggest that unlike some healthcare programs, VHA’s CRH continued robust and increasing delivery of primary care and mental health care throughout COVID-19. Results support growing telehealth capacity as a public health tool for national disasters. CRH providers completed half of visits with rural patients, for whom disparities in telehealth use have been well documented. Geriatrics patients as old as 103 years, traditionally stereotyped against telehealth services, used CRH video visits.

CRH telehealth infrastructure is similar for VHA primary and mental health care; yet, observed differences in patterns of use (of telephone, primary care clinic-based, and patient home-based visits) between primary care and mental health specialties may reflect differences in care needs between patients and providers. For example, telephone visits may meet primary care needs for patient requests ranging from urgent problems (e.g., forms) to brief chronic condition care (e.g., medication refills). Video visits done from a primary care clinic may enable key elements of physical examination. Mental health visits, in contrast, may benefit from video-enabled visual cues and from patient comfort when communicating from home. Rather than focusing on baseline telehealth infrastructure as the main reason for differential telehealth utilization patterns, our data suggest the importance of considering intrinsic practice style differences and patient preferences when planning for telehealth expansion.

Impact of Sex and Gender Disparities on Computational Phenotyping: A Potential Barrier to an Equitable Learning Health System

Rebecca T. Levinson, PhD¹, Jennifer R. Malinowski, PhD², Luke Rasmussen³, Suzette J. Bielinski, PhD⁴, Veronique L. Roger, MD, MPH⁵, Quinn S. Wells MD, PharmD⁶, Laura K. Wiley, PhD⁷
¹Heidelberg University Hospital, Heidelberg, Germany; ²Write InScite LLC, South Salem, NY; ³Northwestern University School of Medicine, Chicago, IL; ⁴Mayo Clinic, Rochester, MN; ⁵NHLBI, Washington, DC; ⁶Vanderbilt University Nashville, TN; ⁷University of Colorado School of Medicine, Aurora, CO

Introduction
Health disparities stem from both sex-based biological differences in disease prevalence, symptomology, and responses to treatment and gender-influenced differences in care access and delivery. The impacts of sex and gender on health and healthcare are well-documented, however little attention has been paid to how these disparities are propagated or exacerbated by cohort identification (i.e., “computational “phenotyping”) algorithms using electronic health record (EHR) data. Phenotyping algorithms can be as simple as a list of diagnosis codes, or involve more complex approaches (rule-based logic, NLP, machine learning, etc.) and multiple types of clinical data to identify the population of interest. Biases in the data used to construct these algorithms could result in the systematic underrepresentation of women, transgender, and non-binary patients.

Here we present an illustrative example of this effect in heart failure phenotyping. Heart failure (HF) is a complex syndrome with a heterogeneous presentation identified through history and clinical presentation rather than specific tests. However, HF subtype is determined by left ventricular ejection fraction (EF) measurement. Populations with preserved EF (HFpEF) skew female, older, and have more comorbidities than populations with reduced EF (HFrEF). EF is an easy and objective measure of HF, but when used in phenotyping algorithms it would preferentially identify HFrEF patients. This could lead to underidentification of women who are more likely to have HFpEF. Here we present a multimodal study of this effect through both EHR analyses and a systematic evidence review of the literature to determine the scale of this potential problem.

Methods
We applied three HF algorithms across the Vanderbilt University Medical Center Synthetic Derivative (de-identified EHR database): 1) the “eMERGE” algorithm; ² 2) a “Simple” algorithm with Boolean logic combining diagnosis codes, BNP lab tests, and loop diuretic prescriptions; and ³ a “Random Forest” algorithm using diagnoses, laboratory tests, medications, and text data. We identified the demographics and HF subtype for each population.

We also performed a systematic review of the heart failure phenotyping literature to identify the gender representation of published algorithms. ² Briefly, we identified studies from MEDLINE using terms for EHRs, phenotyping methodologies (e.g., NLP, machine learning, etc.), and heart failure. Blinded reviewers assessed studies in duplicate and extracted details about the algorithm and heart failure population demographics. Conflicts were adjudicated through discussion or the input of a third reviewer. We compared extracted demographics to the expected national female prevalence rate with Chi-square testing.

Results
EHR Analysis: A total of 54,608 patients were identified by one or more HF algorithms. All algorithms identified fewer women than expected (44% eMERGE, 45.1% Simple, 44% Random Forest) compared to national HF prevalence (51%) and representation in the Synthetic Derivative (53.7%). The Simple algorithm identified more women, possibly driven in part through increased identification of the HFpEF subtype (Figure 1).

Figure 1. HF phenotyping algorithms identify fewer women (pink) than expected from national prevalence estimates (black bar), and those that identify more HFpEF patients (green) also identify more women.
**Systematic Review:** Out of the 313 studies identified by our literature search, 25 studies developed 30 HF phenotyping algorithms. However, only 7 reported the demographics of their algorithm identified all-subtype HF population. Of these, 5 identified majority male populations and 6 identified cohorts that were statistically different from the expected national female prevalence rate of 51.6% by Chi-square testing (Figure 2). All 6 algorithms that were statistically different from the national prevalence rate used echocardiography data. The one algorithm that identified the expected patient proportion did not use echocardiography data.

**Discussion**

We found that both within a single institution and across the published literature the majority of HF algorithms identified significantly fewer women than expected from national prevalence estimates. We posit that one driver of this selection bias may be the reliance on echocardiography by the majority of algorithms that preferentially identifies HFrEF, a HF subtype more prevalent among men. Additional research is needed to confirm this effect and investigate other potential explanations for this observed bias.

Although we only examined the HF phenotype in this abstract, we expect that sex and gender disparities will affect algorithms across many phenotypes. Diagnosis codes are the most common data element used for phenotyping but rely on patients receiving a proper diagnosis. Research has shown that women are often subject to long diagnosis delays, reducing the number of women identified and potentially selecting for women with more severe or later disease presentations. Algorithms also use medications and procedures as a way to infer case status, but in the case of acute myocardial infarction there has been underuse of evidence-based treatment in women that would reduce the efficacy of these data to identify women. There are similar sex- and gender-based differences in laboratory and clinical measurements used in phenotyping algorithms, which are often more pronounced in transgender patients.

The potential impact of sex and gender bias is significant, affecting not only research participation (and therefore study finding generalizability), but also clinical care as similar approaches are used throughout the learning healthcare system including clinical decision support, population health management, and clinical quality evaluation. In order to minimize the effect of potential bias within phenotyping algorithms, we must: 1) understand how sex and gender have been considered in existing algorithms; 2) develop a framework for evaluating the impact of health disparities on phenotyping; 3) develop standards for reporting algorithms that allow the proactive assessment of potential bias.

Digital Readiness: Are Low-Income Populations Prepared for Telehealth?

Sunny C. Lin, PhD, MS,1 Julie Reeder, PhD, MPH, CHES2, Mary Vest, BA1, Kathy Harris, PhD3, Jill Castek, PhD, MS,4
1OHSU-PSU School of Public Health, Portland, OR; 2Oregon WIC, Portland, OR; 3Portland State University, Portland, OR; 4University of Arizona, Tucson, AZ

Introduction
Videoconferencing is increasingly viewed as a way to make health services accessible and affordable. Yet videoconferencing may not benefit their intended populations equitably if disparities exist in access to Internet and videoconference devices (i.e., smartphones, computers with webcams) and/or preferences for videoconferencing. Despite the widespread belief that videoconferencing will improve the accessibility of health services, few studies have examined whether people in marginalized communities have the interest or ability to use videoconferencing for health services. While prior studies have found that low-income populations are increasingly interested in using technology to access medical information asynchronously such as through patient portals, little is known about whether videoconferencing is a viable method for expanding synchronous health services access, and what help people need when using videoconferencing for health services access (1). Understanding this knowledge gap is critical to crafting telehealth policies and interventions that do not exacerbate existing disparities (2). The Oregon’s Women, Infant, and Children’s Supplemental Nutrition Program (WIC) offers supplemental nutrition, education, breastfeeding, and lactation consultant services to low-income communities in Oregon. We conducted an assessment of participants’ Internet and device access, experience with, needs for supporting, and preference for using videoconferencing compared to telephone and in-person visits for WIC services.

Methods
All currently-enrolled English, Spanish, or Russian-speaking Oregon WIC participants were sent a text message inviting them to participate in the survey in early December 2020. The survey remained open from December 2020 through March 2021. The survey was offered in three different languages: Spanish, Russian, and English. To improve participation rates among participants who may not have access to Internet-enabled smart phones or computers, participants with an education level of less than high school completion were also given the option to complete the survey over the phone. Due to resource constraints, we limited the phone survey option to those with education level of less than high school completion only. To determine participants’ Internet access, we asked whether they had the following kinds of Internet access where they live: monthly internet service plan (ISP), monthly cell phone data plan, or prepaid cell phone plan. To determine participants’ device access, we asked what devices participants had and how often they used each (i.e., don’t have, use almost every day, monthly, rarely). To determine participants’ preferences for videoconference modality, we asked participants, “If video conferencing were to become a regular option for WIC appointments in the future, would you choose to: go back to in-person appointments, keep having telephone calls, or have a videoconference appointment using a smartphone, computer, or tablet.” Chi-squared tests were used to determine answers to these questions differed by characteristics (i.e., language, urban/rural location, race, and ethnicity). Additional survey questions asked whether participants ever ran out of mobile data and how often, accessed data outside their home due to unreliable Internet access, prior experience with videoconferencing for telehealth, and what help participants need to access videoconferencing.

Results
Out of 62,418 currently-enrolled WIC participants, 61,248 WIC participants were identified from current records as those who spoke English (n=51705, 82%), Spanish (n=9033, 14%), or Russian (n=502, 1%). Of those, 44,927 were sent a text message invitation to participate in the survey 76% in English (n=5713), 23% in Spanish (n=1740), and 1% in Russian (n=103), 1,704 Spanish (n=9033), or Russian (n=502). Fifty-six English speakers, 5 Russian speakers, and 238 Spanish speakers opted to take the survey by telephone. Survey participants were similar to the overall WIC population by geography and race/ethnicity. Survey responses about Internet and device access, and preferred modality are presented for all respondents and by language, geography, race, and ethnicity in Table 1. In addition, we found that 18% of participants report running out of mobile data every month, 14% every few months, 12% once or twice a year, and 56% never. Nearly half (48%) of participants said they sometimes need to connect to the Internet in creative places outside their homes such as at a school, public library, church, or the parking lot of a business with a strong wireless Internet signal. When participants were asked about their
experiences with and needs to support telehealth, 47% indicated they had ever used telehealth and liked it, 37% indicated they had ever used telehealth but did not like it, 10% reported never having used telehealth but would try it, and 6% reported never having used telehealth and were not interested in using it. When asked what help they would need for accessing video visits for WIC services, the most commonly reported needs were: finding a private or quiet enough place (40%), reliable Internet access at home (17%), support logging in to the visit (12%), device access (11%), and support downloading the video conference platform or app (10%). Of those that responded to the survey in Russian or English, 12% reported needing help navigating the appointment in English.

Discussion

In this study, we found significant differences in videoconference access and preference by language, geography, race, and ethnicity, suggesting moving too quickly to advanced technologies (e.g., video versus phone visits) for health services related may alienate a large portion of low-income populations. Our findings suggest that possible patient-centered videoconference solutions such as designated quiet spaces, childcare, device and hotspot libraries, not requiring visual components to synchronous appointments, and language interpreters. Limitations include potential bias due to survey non-response, and limited generalizability outside of the Oregon area. Future research ought to examine association between videoconferencing preference and COVID-19 prevalence and perceived threat as well as correlation and prediction with outcomes such as satisfaction and adherence, or type of care received.

COVID-19 Mortality Prediction among Patients with Cancer Using a Large National Cohort

Introduction
Globally, more than 2 million people have died due to COVID-19 infection.1 An international study reported an increased COVID-19-associated mortality rate among cancer patients compared to non-cancer patients (20% vs. 11%, P = .006).2 Individualized risk prediction for adverse COVID-19 outcomes (all-cause mortality or discharge to hospice) among patients with cancer will help inform evidence-based clinical management, and this is of even more heightened importance amongst patients undergoing active cancer treatment.3 Risk stratification based on clinical and demographic factors can also facilitate more efficient utilization of limited resources in a pandemic setting through proper patient triaging.4 Although COVID-19 mortality prediction models have been published for the general population, patients with cancer remain understudied and are limited to a small sample size of under 1,000.4,5 In this study, we analyzed a large national cohort of cancer patients and developed a COVID-19 mortality prediction model using classic machine learning algorithms.

Methods
We constructed our study cohort from 3.8 million patients included in the National COVID Cohort Collaborative (N3C) electronic health record (EHR) data repository. As of February 25, 2021, 45,511 patients had a diagnosis of cancer preceding a COVID positive status. We excluded patients without records of medication or lab tests at the first COVID positive date. Our final cohort consisted of 8,336 patients. We extracted 91 predictors including demographics (8), medications (46), Charlson Comorbidity Index7 (1), comorbidities (18), lab test results (18) at the time of first COVID positive diagnosis (allowing for early intervention), as well as mortality outcomes (death or discharge to hospice). Choices of predictor variables were based on clinical oncologist expert opinion as well as previous studies on mortality prediction for general population8 and patients with cancer4,5. All the N3C data were transformed into a harmonized Observational Medical Outcomes Partnership (OMOP) common data model, and our cohort and concept definitions are based on the Observational Health Data Sciences and Informatics (OHDSI) standard concept sets. Patients were randomly selected for a 70-30 training-test split. We trained predictive models using two commonly used classic machine learning algorithms, random forest (RF) and logistic regression (LR), because they were easily interpretable. The GridSearch strategy with 10-fold cross validation was used for hyperparameter optimization. To address the data imbalance issue, cost-sensitive9 approaches, which put more penalties on prediction errors from the minority class (patients with mortality outcomes), were explored during model training. Permutation importance scores were calculated on the test data to assess predictors’ contribution to model decisions.

Results
Among our cohort of 8,336 COVID patients with cancer, 18% (n=1503) either died or were

Figure 1. Receiver operating characteristic (ROC) curve (left) and precision recall curve (right) for RF and LR on the test data.
discharged to hospice. The RF model outperformed LR model for mortality prediction, yielding an area under the receiver operating characteristic curve (AUROC) of 0.847 (95% confidence interval [CI]: 0.826-0.867) vs. 0.833 (95% CI: 0.810-0.854) for LR. The area under the precision recall curve (PR_AUC) was 0.613 (95% CI: 0.563-0.663) for RF vs. 0.574 (95% CI: 0.521-0.626) for LR. ROC and PR curves for both models are shown in Figure 1. RF obtained a better precision of 74.4% (95% CI: 68.3%-79.8%) vs. 46.3% (95% CI: 41.9%-50.4%) for LR, while LR yielded a better recall of 60.8% (95% CI: 56%-65.6%) vs. 40.6% (95% CI: 35.6%-45.3%) for RF. The performance differences between two models on the aforementioned four metrics were all statistically significant based on the Student's t-test (p<0.05). Among the top 30 predictors identified by each model, 23 were shared between the two models, which included components of complete blood counts (hemoglobin, platelets, white blood cells, lymphocytes, neutrophils), labs related to nutritional status and hepatic/renal function (albumin, aspartate aminotransferase, bilirubin, blood urea nitrogen), chemistry labs (sodium, potassium, glucose), steroids, antiarrhythmic medication (amiodarone), antiviral medication (remdesivir), pressors (norepinephrine, vasopressin), anti-hypertensive medications (angiotensin converting enzyme inhibitor, angiotensin receptor blocker), age, Charlson Comorbidity Index, and some individual comorbidities (dementia, paralysis, metastatic solid tumor). LR model also identified “not_Hispanic_or_Latino” as one of the top 30 predictors. Figure 2 shows the top 10 predictors identified by RF and LR respectively.

**Discussion**

We demonstrated that EHR data from a large national cohort can be leveraged for predicting severe COVID outcomes (death or discharge to hospice within one year from the first COVID positive diagnosis) in patients with cancer. We found that random forest performed slightly better than logistic regression on this task, but the latter achieved a better sensitivity. It is possible that ensemble methods combining different machine learning models can further improve prediction performance.

Complete blood count parameters, albumin and age were among the top 10 shared predictors using both models highlighting the utility of commonly used, inexpensive lab tests in predicting overall mortality in patients with COVID-19 and cancer. Lab tests related to liver/kidney functions are also important predictors. The current study did not take into consideration longitudinal features and only included a limited set of commonly used OMOP concepts for feature extraction. Our study focused on one-year mortality - further studies with other lengths of follow-up might also be informative. Future studies will address the above limitations, assess potential model biases, and explore additional machine learning algorithms including deep neural networks.

Leveraging Transfer Learning to Analyze Opinions, Attitudes, and Behavioral Intentions Toward COVID-19 Vaccines

Sirus Liu, PhD1, Jialin Liu, MD2
1Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, Tennessee; 2Department of Medical Informatics, West China Hospital, Chengdu, China

Introduction
As a significant global health threat, long-term control of COVID-19 relies on the development and acceptance of a preventive vaccine.1,2 However, according to a recent survey, only 51% of the 10,093 adults in the United States indicated that they would be willing to receive the COVID-19 vaccine when it becomes available3, hardly achieving the recommended threshold of 70% to reach herd immunity.4 While previous studies have explored knowledge in other vaccines using deep learning methods,5 questions related to COVID-19 vaccines remain unknown: What is the prevalence of opinions on the social media platform? How many tweets express attitudes or behavioral intention to take vaccines? Which topics are mostly associated with these contents? To answer these questions, we developed transfer learning models to detect content expressed user opinions, attitudes and behavioral intentions toward COVID-19 vaccines. We then conducted a temporal analysis to explore trends and developed probabilistic topic models to obtain the most important topics. We believe this study will be of great benefit to the timely rollout of the vaccines by extracting the latest public opinions, attitudes, and behavioral intentions to tailor promotion programs.

Methods
We used a combination of keywords and hashtags related to COVID-19 vaccines: “(#covid OR covid OR #covid19 OR covid19) AND (#vaccine OR vaccine OR #vaccine OR vaccine OR vaccinate OR immunization OR immune OR vax)” to collect tweets in English published from November 1, 2020 to January 31, 2021. We randomly selected 5,000 tweets, annotated by two independent reviewers (SL and JL). For each tweet, we labeled whether it included an opinion (yes/no), attitude (positive/negative/unknown), or a behavioral intention (yes/no/unknown).

After the data preprocessing, we split the annotated dataset into three parts: training (60%), validation (20%), and testing (20%). We applied traditional machine learning algorithms (logistic regression, random forest, and support vector machine) with Text Frequency Inverse Document Frequency (TF-IDF). We used the BERT-base-cased as the pretrained language model, the “BERT for sequence classification” model as the pretrained classification model, and the Adam algorithm with weight decay (AdamW) as the optimizer. The BERT models were generated using the huggingface package in Python 3 and developed with the Google Colab platform with a high-RAM GPU. We reported outcomes with 1,000 rounds of bootstrapping. The primary outcome was macro F1. We performed the Nemenyi test to compare the F1 values.

We applied the optimal models to predict the unlabeled data. We calculated the daily proportion of tweets classified as containing opinions to the total number of tweets and the percentage of the tweets predicted to exhibit a particular attitude or behavioral intention to all tweets indicating attitudes or behavioral intentions. To test the variability of this ratio over time, we performed the Augmented Dickey-Fuller (ADF) test with a significant threshold of \(p<0.05\). We conducted the latent Dirichlet allocation (LDA) analysis to extract the main topics.

Results
We annotated 5,000 tweets from 4,796 unique users (\(\kappa=0.76\)). The prediction performances of models are presented in Table 1. The transfer learning model significantly outperformed the machine learning models (\(p<0.05\)), which achieved F1 values of 0.792, 0.578, and 0.614 for three tasks.

We collected 2,678,372 tweets related to COVID-19 vaccines posted by 841,978 unique users. The prevalence of tweets expressing opinions was 0.222 [0.202, 0.245] and was significantly stable over time (ADF=-4.341, \(p<0.001\)). The rates of negative attitudes and positive attitudes were 0.754 [0.707, 0.795] and 0.246 [0.204, 0.293], respectively, and varied over time (ADF=-1.137, \(p=0.700\)). The rates of tweets indicating that users would not vaccinate and would vaccinate were 0.342 [0.229, 0.461] and 0.652 [0.539, 0.771], respectively, and also varied over time (ADF=-0.980, \(p=0.761\)). In addition, we observed a substantial increase in the prevalence of tweets expressing positive behavioral intention starting from mid-December 2020.
We extracted ten topics for each category. For negative attitudes, dominant topics included the concerns about the safety issues for children and pregnant women; unknown side effects; rushing the development process; the virus mutation; and trust in the government or scientists. Positive attitudes came primarily from news of effective trial results and users hoped that COVID-19 vaccines could end the pandemic as well as the desire to return to a normal life. Negative behavioral intentions came from the concerns of long-term and unknown side effects; non-acceptance of forced vaccination; and the lack of need for vaccination against a disease with a low lethality rate. For positive behavioral intentions, the dominant topic was that users would like to become immune to the virus and stay healthy.

**Discussion**

While previous studies have classified sentiment in COVID-19 related tweets, in our study, the task of classifying attitudes towards COVID-19 vaccines is more difficult than the common sentimental analysis. We not only focused on the sentiment of tweets, but also considered simultaneously whether the object of the sentiment was the COVID-19 vaccine. During annotation, we noticed that some tweets contained positive words used to describe what would happen after the vaccine rollout, but also stated negative attitudes toward the vaccine itself, such as lack of trust.

This study has several limitations. First, users of the Twitter platform are not representative of the entire public. The Twitter platform is usually considered to gather more anti-vaccinators and spread misinformation. Understanding their perceptions is a necessary step to tailor vaccine promotion education materials, to have a better chance of effectively changing their behavior. Second, some terms extracted from the topic modeling were difficult to infer. Given the complex situation of behavioral intentions toward the COVID-19 vaccines, our next step is to conduct a theory-based content analysis to understand psychological aspects of why some people will not get the vaccines.

In this study, we presented an annotated corpus of 5,000 tweets and demonstrated the capability to use transfer learning to identify public opinions, behavioral intentions, and attitudes towards COVID-19 vaccines from social media. In addition, we explored temporal trends in attitudes and behavioral intentions on a larger dataset with 2,678,372 tweets from 2020.11.01-2021.01.31. We found that the LDA technique is useful to extract topics. Overall, we provided a method to analyze the perceptions of COVID-19 vaccines from the real-time data, which could be used to tailor the education programs and other interventions to promote COVID-19 vaccine acceptance urgently.

A Longitudinal Study of Burnout and Clinical Workload Measured With Electronic Health Record Audit Logs

Sunny S. Lou MD PhD, Daphne Lew PhD MPH, Derek R. Harford BA, Chenyang Lu PhD, Bradley A. Evanoff MD MPH, Jennifer G. Duncan MD, Thomas Kannampallil PhD

Washington University School of Medicine, St Louis, MO.

Introduction: Burnout is primarily a work-related phenomenon that affects nearly 50% of physicians across the United States, with consequences for the health of both physicians and their patients (1). The causal contributors to this high rate of burnout and potential mitigating steps are not well understood (1). Previous cross-sectional surveys paired with electronic health record (EHR) measurements have shown that increased inbox message use and afterhours work are associated with burnout among outpatient primary care physicians (2–4). However, the workload-related factors that contribute to burnout among inpatient clinicians, who make up a large fraction of the workforce, are less explored. Furthermore, the longitudinal evolution of burnout with varying workloads has not been characterized. Resident physicians are an ideal population to explore both of these issues; residents rotate between inpatient and outpatient settings and experience large shifts in workload and workflow that can be thought of as natural experiments. The goal of this study was to measure resident workload across varying clinical rotations using EHR audit log data and investigate whether specific types of workload are more associated with burnout.

Methods: We conducted a six-month prospective longitudinal observational study of intern physicians from Medicine, Pediatrics and Anesthesiology at a large academic medical center. These interns rotated between inpatient medicine, intensive care, ambulatory, and elective months. Enrollment occurred during 9/2020-10/2020. Consented participants were asked to complete monthly burnout surveys at the end of each rotation for six months. Burnout was measured using the Stanford Professional Fulfillment Index (PFI); this instrument was chosen because it is validated to assess burnout over short time scales (5). PFI scores range from 0 to 4, and scores > 1.33 were considered to have met criteria for burnout.

Workload was measured from the participants’ EHR audit logs (Epic Systems, Verona, WI). Data for the month prior to survey completion was associated with each survey response. EHR audit logs record timestamps and patient identifiers each time a clinician views or modifies elements of the patient record. Although designed to monitor security access, they are also a fingerprint of a clinician’s work habits and have been broadly adopted by the informatics community to measure clinician workload and behavior (6). We measured time spent on each EHR-based action as the time interval between that action and the subsequent action, ignoring time differences greater than five minutes which were assumed to represent inactivity (7). Actions were categorized to orders, notes, and data review by a physician member of the study team. We computed the following monthly workload metrics: total EHR time, total afterhours EHR time (time spent between 6pm and 6am), and total time spent on inbox messages. We also computed the following normalized monthly metrics: average time spent reviewing data per patient per day, average time spent on notes per patient per day, average number of orders placed per patient per day, and average number of patients per day for whom the participant placed either a note or order, used as a proxy for patient load.

A linear mixed effect model was used to assess the relationship between workload metrics and the participants’ monthly burnout scores. Workload metrics were included as fixed effects with a random intercept for each participant. Specialty was included as a fixed effect to adjust for potential confounding. All workload metrics were initially included in the model and stepwise model selection was used. P-values were computed with Satterthwaite’s method. Workload measurements were made with custom python code. Analysis was conducted in Python and R.

Results: 75 of 104 eligible participants elected to enroll in the study (72.1%). The completion rate for subsequent surveys was 76.0% across all participants. Demographic characteristics and average EHR workload metrics for the study population are shown in Table 1. 42.7% of the participants were burned out upon enrollment into the study. Of the participants who completed at least two surveys, 42.0% (29/69) experienced at least one transition between burned out and not burned out or vice versa, and 24.6% (17 / 69) demonstrated at least two transitions.

Results from the multivariable linear mixed effect model are shown in Table 2. Total EHR time, average number of patients seen per day, and average time spent reviewing data per patient per day were significantly associated with burnout. For example, after adjusting for other factors, every additional hour per patient per day spent reviewing data was associated with an increase in burnout score by 0.48 (95% CI 0.08 – 0.89) points. Afterhours EHR time, average number of orders per patient per day, and average time spent on notes per patient per day were not significantly associated with burnout. No statistically significant difference in burnout between specialties was observed.
**Discussion:** We conducted a prospective longitudinal observational study of the time course of burnout among interns engaging in both inpatient and outpatient medicine, and measured the association between their burnout and objective measures of workload as captured by EHR audit logs. We demonstrate that burnout is not static and often varies over time, likely as a function of recent workload and related personal factors. We found that increased patient load, increased EHR time, and increased time spent reviewing EHR data per patient are associated with increased burnout. It is possible that these variables are proxies for other contributors such as total work hours or patient complexity. In contrast to previous findings among primary care physicians (2–4), inbox message volume and afterhours time were not associated with burnout.

This study is one of the first to associate objective EHR-based measures of workload to burnout among clinicians working across both inpatient and outpatient settings, and also is one of the first longitudinal studies of burnout. Our findings might help inform EHR usability and design, and suggest that interventions targeted to improve the efficiency of data review might be highest yield to reduce EHR-related burnout. In addition, workplace interventions to reduce patient load or work hours may be worth considering where feasible. This study was limited to a single institution with incomplete participation that could contribute to response bias, although our participation rate was high. Also, we were unable to measure non-EHR work and our EHR workload measures were imperfect; nonetheless, they likely correlated with true workload.

Feasibility of using machine learning on insurance claims to identify correlates of lower extremity amputation in insured adults with type 2 diabetes who initiate treatment with sodium-glucose co-transporter 2 (SGLT-2) inhibitors

Yuan Luo1, Andrew Cooper1, Raymond Kang1, Ronald T Ackermann1
1Feinberg School of Medicine, Northwestern University, Chicago, IL, US

Introduction

Patients with type 2 diabetes (T2D) are at increased risk for foot ulcer and amputation. Risk is increased in the setting of poorly controlled blood pressure, peripheral arterial disease (PAD), or distal polyneuropathies that limit protective sensation and predispose to low tissue perfusion, foot injury, and infection. In 2016, FDA issued a safety alert regarding amputations associated with canagliflozin, one of 4 currently FDA-approved diabetes medications in the class known as sodium-glucose co-transporter 2 (SGLT-2) inhibitors. The alert was based on a 2-fold increase in risk observed over 2.4 years of median follow up in the Canagliflozin Cardiovascular Assessment Study (CANVAS).

Results from trials of SGLT2 agents have observed elevated amputation risk with unknown mechanism, and it is possible that other patient characteristics or exposures explain the incremental risk observed in CANVAS1. The purpose of our study is to identify both known and new risk factor combinations from insurance claims data that can be integrated in a single model to predict excess amputation risk in individuals being considered for initiation of a SGLT-2 for their diabetes. Note that the focus of this study is on models that are easy to interpret and features broadly applicable and obtainable from an administrative database.

Methods

Study Population: The SGLT-2 new user cohort included all adults (age 18+), who had evidence of type 2 diabetes (T2D), had a first pharmacy fill for a SGLT-2 between 1/1/2013 and 6/30/2018, and covered by a large health insurer for at least 6 months before and 6 months after the first fill date (index date). Figure 1 presents additional requirements and timing for the cohort. All diagnosis codes and pharmacy fills from claims in the 6 months prior to new SGLT-2 start were used. To reduce the high dimensions of diagnoses and pharmacy fills to an amenable size for machine learning algorithms, we grouped the diagnoses using the Hierarchical Chronic Conditions (HCCs, used by Medicare for risk adjusting total costs), and grouped the medications using AHFS Pharmacologic-Therapeutic Classifications (both dichotomous and total fills). Patients in the cohort were classified as cases (n=1237) based on having one or more diagnostic or procedural codes identifying one or more non-traumatic, lower extremity amputation following the SGLT-2 first fill date. From the universe of the eligible control cohort, we sampled 9 control patients for each case patient, matching on age, gender and race, yielding 11,133 total control patients. Bigger control size was kept to retain control heterogeneity. Table 1 shows the well-matched summary statistics of the case and control cohorts. Although the race variable in our dataset is imputed based on probability conditioned on last name and geography and is likely prone to error2, they are only used to match case and control cohorts.

1451
Thus, the imputation error will not disproportionately affect case/control cohort, mitigating concerns over such errors.

**Machine learning:** We experimented with the following machine learning models that allow read off of linear coefficients for easy interpretation: penalized logistic regression (i.e., ridge regression), support vector machine (SVM) with l1, and l2 regularizations respectively. Many HCC and American Hospital Formulary Service (AHFS) features are sparse. Following common machine learning practice, we retained features that are non-zero in at least 1% of the training patients, which yields 136 features. We split the combined case and control dataset into a training set, validation set, and test set by stratified splitting the samples using a 6:2:2 ratio. We trained the model using the training set and tuned the parameters using the validation set.

**Experiments and Results**

The validation set favors the l2 regularized ridge regression as the classification algorithm. **Figure 2** shows that this algorithm achieves a competitive AUC of 0.853 on the held-out test set, indicating strong predictive power of current features on lower extremity amputation risks. **Table 2** shows the top features associated with amputation risks in T2D patients taking SGLT2. The results suggest that recent skin, bone, neurological, vascular conditions, and chronic complications from diabetes are predictive of risk of amputation. Medications such as basal insulins, and platelet-aggregation inhibitors are associated with risks of amputation, possibly by identifying high risk individuals (i.e. those with more advanced diabetes and those with atherosclerotic vascular diseases). Lincomycins are used to treat resistant bacterial infections, which may identify patients with poorly healing diabetic foot ulcerations. It is also not surprising that evidence for prior amputation is a strong predictor of later amputation.

**Discussions and Conclusions**

In this work, we demonstrated the feasibility of using machine learning models on insurance claims data to predict amputation for T2D patients starting an SGLT-2 medication. To this end, we focused on models that are easy to interpret and features broadly applicable and obtainable from an administrative database. While many known factors greatly contribute to the predictions, the inclusion and testing of other factors such as skin, bone and neurologic conditions can help improve risk prediction and be used by clinicians to make informed decisions for prescribing medications for their diabetic patients. Although the safety alert warns against prescribing of SGLT-2s for high risk patients, there may be group of high risk patients who can benefit from SGLT-2 use but show minimal increased risk of amputation. The initial prediction only used broad diagnosis and medication categories and testing of specific codes and medications could improve the predictive power and inform more targeted interventions.

Patient Preferences for Accessing, Communicating, and Sharing Health Information using Visualized Patient-Reported Outcomes

Sabrina Mangal, PhD, RN1, Leslie Park, BS1, Meghan Reading Turchioe, PhD, MPH, RN1, Lisa Grossman Liu, PhD2, Annie C. Myers, MA1, Brittany Taylor, BS, RN3, Parag Goyal, MD, MSc4, Lydia Dugdale, MD, MAR5, Ruth M. Masterson Creber, PhD, MSc, RN1

Introduction
Patient-reported outcomes (PROs) are a common and growing method to collect symptom information that help to inform patients’ health statuses and support their self-management. Recent research has integrated the collection and analysis of PROs to inform the development of interventions and frame patients’ clinical pictures. Moreover, with an increasing emphasis on patient engagement in care and patient-centeredness, it is also important that collected PRO information is returned to patients in an understandable format to facilitate patient-provider communication. However, there is a dearth of research as to the most effective way to deliver PRO information back to patients. To fully understand the utility and implications of returning PRO information to patients, we interviewed participants with heart failure about their experiences with a visualized symptom report and explored implications for future use.

Methods
Patients with heart failure were included in this study (diagnosis confirmed via the patient’s electronic health record) which began in February 2020. Interviews were conducted at the completion of the study where heart failure patients were periodically shown a visually enhanced symptom report webpage after each completion of symptom surveys bi-weekly for 8 weeks (Figure 1). Symptom reports were previously developed using user-centered design methods and integrate visual analogies into the information display. The reports summarized overall physical and mental health, as well as specific symptoms: depression, anxiety, pain, sleep trouble, fatigue, anger, and brain fog. After completing the study, we spoke to patients to determine the usefulness of this data, suggestions for improvement, and explored their levels of trust and preferences for sharing and receiving health information for future research studies. Three trained researchers conducted interviews with participants using a semi-structured qualitative interview guide. Interviews were audio-recorded and transcribed. Researchers used Dedoose to organize coding and content analysis of the transcripts and established inter-rater reliability across three researchers. Two researchers met weekly to compare coding progress, consulting a third researcher if consensus was needed.

Results
To date, 16 participants were interviewed, and 50 participants completed at least one symptom survey. Data collection will continue until data saturation is reached. Qualitative participants (n = 16) had an average age of 63.6 years and were 81% male, 75% White, and 19% Hispanic/Latino. A majority of the participants (94%) reported having an associate degree or higher.

<tr>
<th>Overall, participants found the symptom information to be useful for understanding their physical and mental health symptoms.</th>
<th>I still have the survey and it would be like ‘your mental health is poor’. …I hadn’t really thought about it enough until I took the survey. I was grateful they included more than just cardiac symptoms. It forced me to look at that and think maybe I should de-stress. –P25</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants enjoyed seeing a visual analogy to indicate their progress.</td>
<td>You look at the smiley face. If it’s smiling…hopefully it’s smiling…some days when I have an off week, it lets me know how far I am off… So, it’s good feedback. It keeps me positive and lets me know what I need to work on. –P24</td>
</tr>
</tbody>
</table>

Suggestions for improvement:

| Participants wanted a mechanism for further explaining mental health symptoms based on external circumstances. | Sometimes the depression area I would look at a little more because it was also right before COVID. I think there was a lot of anxiety going on, too. –P14 |

Data sharing implications and preferences:

| Most participants would primarily use the symptom reports for themselves and would share with a clinician if needed. | If there was something significant, I would share it with my physician, but mostly it would be to inform my own choices and my own decisions. –P25 |
| Transparency was critical for patients when considering sharing their health information with different groups such as health-tech companies. | I’d have to look into it to make sure it was all randomized and private… I would be comfortable with it if I looked into it more. –P25 |

Conclusions

Overall, visualized symptom reports using visual analogies were useful to heart failure patients, which is notably different from prior research that encourages the use of line graphs. These symptom reports provided a way to prompt conversations with clinicians and help patients further understand their health status independently. Future research should consider returning health information to patients in a comprehensible format using visual aids, and should allow patients with opportunities to provide additional context to their symptom reports to communicate to clinicians.

Introduction

Alzheimer’s disease (AD) is a progressive neurological disorder that begins with an early symptomatic pre-dementia stage called mild cognitive impairment (MCI). Predicting the risk of MCI-to-AD progression is important for clinical prognostication, risk stratification and early intervention. Few studies have used Electronic Health Records (EHRs) for MCI-to-AD progression prediction. Compared to the previous approaches based on biomarkers like cerebrospinal fluid (CSF) and MRI, routinely collected clinical data from EHRs will reflect real-world evidence and will be a less invasive source. In general, clinical notes in EHRs contain rich information, such as family history, laboratory values, Mini-Mental State Examination (MMSE) scores, among many other details, which may suggest disease progression. On the other hand, the Bidirectional Encoder Representations from Transformers (BERT) model has shown promising results in many NLP tasks, and has been extended to BioBERT2 and Bio+Clinical BERT3 (BC-BERT) for biomedical text and clinical narratives, respectively. However, clinical notes related to MCI and AD usually have some differences from general clinical texts in linguistic characteristics, motivating the need for specific BERT models for MCI-to-AD prediction. In this study, we developed a deep learning framework based on BERT for MCI-to-AD risk prediction using clinical notes from EHRs, and validated it on an independent dataset from a different institute. In addition, we designed a stratified batch sampler to address the class imbalance issue between case and control.

Methods

Study cohort. We identified a cohort of patients with MCI from the Northwestern Medicine Enterprise Data Warehouse (NMEDW) and Weill Cornell Medicine (WCM) using ICD-9 (331.83) and ICD-10 (G31.84) codes. Those who progressed to AD (identified by ICD-9 (331.0) and ICD-10 (G30.9)) are considered as the case group, and the control group is MCI patients who have not yet been diagnosed with AD. We identified 396 cases (average age 76.76, 58.8% females) and 3261 controls (average age 71.62, 51.5% females) from NMEDW and 435 cases and 1632 controls from WCM. Besides the above no-restrict prediction, we also considered the time windows of 6-month, 1-year, and 2-year to predict the MCI-to-AD progression in each time window, respectively. All progress notes before the first encounter when a patient was diagnosed with MCI were collected for the risk prediction model.

Framework. We first pretrained the MCI-BERT from BC-BERT on a corpus of 37K clinical progress notes with an average length of 6250 characters for MCI patients from NMEDW. We then fine-tuned MCI-BERT for the MCI-to-AD prediction task using the training patients with their notes, and evaluated it on an independent test set. In our framework depicted in Figure 1, the clinical notes of a patient were input to the pretrained MCI-BERT to generate a vector representation for the patient, then a linear layer appended with a sigmoid activation was employed to predict the probability of MCI-to-AD progression. We applied the MaxPooling strategy to generate the representation of a patient with multiple notes.

Settings. We used the default settings of BERT in pytorch transformers for MCI-BERT pretraining on MCI-related notes. For fine-tuning, the study cohort from NMEDW was randomly stratified into training and test sets by 8:2, 1/5 of the training set was set aside as a validation set used for model selection. Since the number of cases and controls was imbalanced, a small batch usually contained no case samples, making the model biased to the control class, while a large batch usually caused the out-of-memory issue for long notes. To address this issue, we designed a stratified batch sampler to ensure the same case/control ratio in all batches. In our study, the batch size was set to 4 and the max sequence length was set to 128. We used a weighted cross-entropy loss with the class weights inversely proportional to the corresponding number in a batch. In the training process, the model with the best validation performance was selected. WCM data was used to validate our framework on an independent data source.

![Figure 1 The overview of our framework](image-url)
Results and Discussion

The prediction results of our model in terms of F1 score and AUC on the test set compared to the baseline models are shown in Table 1. On NMEDW data, we observed that deep learning models (e.g., BERT-based models, LSTM and CNN) achieve higher performance than bag-of-word (BOW) model that can only achieve AUC around 0.5, indicating that only word counts in the notes cannot provide any information for MCI-to-AD prediction. Our framework (MCI-BERT) is pretrained on MCI-related notes, it could be more effective for MCI-related tasks such as MCI-to-AD prediction. MCI-BERT pretrained on NMEDW (i.e., MCI-BERT(NM)) cannot perform as well as MCI-BERT(WCM) on WCM dataset, which is due to the different note language styles between the two institutes, suggesting the importance and difficulty of developing a cross-institute pretrained language model. The significant performance difference between NMEDW and WCM by the same model also indicates the discrepancy between the two datasets. In the previous reports, Young et al.4 and Davatzikos et al.5 achieved an AUC of 0.795 and 0.734, respectively, using biomarkers in their risk prediction models. In comparison to these studies, besides clinical notes are more routinely available from large samples of patients than previous biomarkers, our performances also validate the effectiveness of using clinical notes for MCI-to-AD prediction. Figure 2 shows the attention of each word that MCI-BERT relies on to make the prediction, where MCI-BERT pays more attention to the term “memory loss” than others, which is reasonable as serious memory loss is a symptom of AD.

Conclusion

Clinical notes contain rich information that may suggest disease progression. However, it is challenging to extract predictive information from unstructured notes. The deep learning framework using BERT models in this study may provide a solution for clinical note analysis for MCI-to-AD prediction. Our study also demonstrates the discrepancy of clinical note styles between different institutes.

Integrating Evaluations of Predictive Algorithm-Driven Interventions into Clinical Workflows with the Dynamic Discontinuity Deployment Design

Ben J. Marafino, BS¹, Alejandro Schuler, PhD¹,², Vincent X. Liu, MD, MS³, Art B. Owen, PhD¹, Gabriel J. Escobar, MD³, Mike Baiocchi, PhD¹

¹Stanford University, Stanford, CA, USA; ²unlearn.ai, San Francisco, CA, USA; ³Division of Research, Kaiser Permanente, Oakland, CA, USA

Introduction

Electronic health record (EHR) systems now increasingly incorporate predictive algorithms and display their output at the point of care as a form of clinical decision support. This output often takes on the form of an outcome risk score and in some cases, can be used to initiate an intervention or care pathway with the goal of improving a certain clinical outcome. For example, if a patient’s predicted risk of 30-day readmission exceeds a certain threshold value at hospital discharge, then they are automatically enrolled in a care coordination pathway designed to reduce their readmission risk—a process which occurs entirely within the EHR. However, in the absence of some type of formal evaluation, it is unclear whether deployments of these predictive algorithm-driven interventions (or “prediction-action dyads”) actually improve clinical outcomes.¹

Randomized clinical trials (RCTs) represent an ideal choice with which to evaluate the impacts of these deployments on outcomes. However, such RCTs are uncommon, in large part due to the burdens that conducting these trials may impose on existing clinical workflows. In addition, randomization schemes must be carefully designed to avoid unintentional bias, which can be infeasible—for example, if randomizing at the unit of the care team rather than the individual patient encounter.² Moreover, in the context of institutional oversight, many deployments of these algorithms are classed as quality improvement projects, which often precludes the use of randomization. As a result, stakeholders often must resort to uncontrolled before-after studies, which rarely yield robust evidence regarding the impacts of these interventions.

In recognizing the disadvantages of RCTs in this setting, we propose an alternative in the form of a new type of cluster-randomized trial design, which we refer to as the dynamic discontinuity deployment design, or the D3 design. Using the regression discontinuity design as a building block, the D3 design dynamically varies, across clusters, the risk score threshold used to assign a predictive algorithm-driven intervention to characterize its impact in a deployment. The D3 design more closely emulates real-world practice conditions, alleviating many of the training and workflow burdens imposed by RCTs, while also providing valuable direct evidence regarding treatment effect heterogeneity.

Methods

As proposed, the D3 design assumes the existence of a predictive model, and an intervention associated with it, wherein the intervention is assigned based on a patient’s estimated risk score relative to a predetermined score cutoff. Furthermore, the D3 design assumes I subjects, J clusters, K score cutoffs, and L time points. The J clusters may correspond to regions, hospitals, clinical units (e.g., a floor or a ward), or any type of organizational unit. The K score cutoffs, \{c₁, c₂, ..., cₖ\}, are chosen in advance and are assumed to lie on [0, 1]. The central idea of the D3 design is that at each time point 1, 2, ..., L, each cluster uses a different value of the cutoff to assign the intervention. For example, for the month of February, a hospital uses the risk score cutoff of c₃ = 25% to assign the intervention, whereas in March it uses the cutoff c₇ = 30%, and so on. This process is summarized in the left panel of Figure 1.

Thus, as time progresses, each cluster cycles between all risk score cutoffs, if L = K—or necessarily some subset of them if L < K. At the conclusion of the experiment, the data across all clusters for each of the K cutoffs is pooled and a regression discontinuity (RD) estimator is applied to estimate the local average treatment effect (LATE) \( \hat{\tau}_k \) at each cutoff k. Notably, to reduce bias, the RD estimators implicitly take advantage of the balancing property of the risk score under its interpretation as a prognostic score.³ Using these LATE estimates \( \hat{\tau}_1, ..., \hat{\tau}_K \), one can estimate and infer a pooled global treatment effect, which resembles the average treatment effect from a RCT, as well as gain insight into treatment effect heterogeneity implied by the \( \hat{\tau}_k \), as shown in the right panel of Figure 1.
To characterize the statistical properties of the D3 design, we undertake a series of simulation experiments. Our experimental approach primarily assesses the bias and consistency properties of the global and cutoff-specific (LATE) estimators, and also compares the LATE estimators to the analogous post-hoc analysis of a RCT with $K$ interaction terms on the risk scale. The heterogeneous treatment effects (HTE) are parameterized by a scaled beta density, and we assume varying extents of intra-cluster correlation (ICC).

**Results**

For both the global treatment effect, as well as the LATEs, the D3 estimator appears to be unbiased and $\sqrt{n}$-consistent, with somewhat slower convergence in the tails of the risk score distribution. These results appeared robust to various choices of the simulation parameters, including the choice of the HTE parameterization as well as when the ICC was varied. Moreover, compared to the post-hoc analysis of the analogous RCT using risk $\times$ treatment interaction terms, the D3 estimates of the LATEs were 10% to 30% more efficient than the interaction estimates (i.e., $\hat{V}_{\text{D3},k}/\hat{V}_{\text{RCT},k} \approx 0.7$ to 0.9, where $\hat{V}_{\cdot,k}$ represents the variance of either method at or around the cutoff $k$.)

**Discussion**

As verified in simulation experiments, the D3 design appears to have desirable statistical properties. In particular, when compared to the analogous randomized controlled trial, the D3 design incurred a lower cost in terms of variance in its HTE estimates when comparing the cutoff-wise treatment effects to the corresponding interaction estimates. Moreover, the D3 design has another advantage over a RCT in that it may reduce the “friction” that evaluation processes often introduce into clinical workflows. Altogether, the D3 design may be a feasible choice for organizations and health systems considering methodologies to evaluate deployments of predictive algorithm-driven interventions. Further work remains, including fully characterizing the qualitative and process aspects of the D3 design, determining which cutoff schedules may be optimal, and whether the design could be made more efficient, either via borrowing data from other cutoffs or by introducing adaptivity.

Managing Health Care Knowledge in Predictive Modeling, Clinical Decision Support and Metric Reporting – eXecutable Library Architecture (XLA)

Susana B. Martins, MD MSc, Cora L. Bernard, PhD MS, Suzanne Tamang, Jodie A. Trafton, Ph.D., M.S.
VA Program Evaluation and Resource Center, VA Office of Mental Health and Suicide Prevention (OMHSP), Menlo Park, CA; Department of Biomedical Data Science, Stanford University, Stanford, CA, USA; Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, USA.

Introduction
Face-validity, consistency and accuracy of clinical concepts utilized in Clinical Decision Support Systems (CDSS) are paramount for effective use and acceptance. While standard vocabularies have been developed to support knowledge translation, in reality, capture of health care information is locally nuanced and shaped by, for example, Electronic Health Record (EHR) design features such as clinical prompts and documentation tools (e.g., pick lists, note templates, etc.), clinical workflow, and local culture and practice in coding. For use in CDSS, data definitions for clinical concepts must be maintained in alignment not only with an evolving medical knowledge base, but also with local practice patterns and EHR systems. For each clinical concept within each unique EHR implementation, this requires understanding both what to look for and where to find it in downstream databases. Accurate identification of clinical concepts requires not only specification of value sets of clinical vocabulary, but also of the data locations and logic for combining data elements, information that is rarely captured in clinical data libraries. This information is typically captured only in code, limiting transparency and reusability of validated data definitions.

Here, we provide a solution for integration of clinical concept libraries directly within deployed data systems. The eXecutable Library Architecture (XLA) provides a data-driven approach to integrate value set and clinical concept metadata along with best practices in data extraction, enabling maintenance of a library of validated clinical concepts that can be flexibly applied and directly executed to produce datasets required for predictive modeling, CDSS functions or quality and performance measurement, at national, facility or clinician level.

Methods
We created a standard querying language (SQL)-based architecture that seamlessly integrates metadata with code, eliminating the implementation gap between defining and computing complex clinical concepts. The architecture contains two schemas: a portable and Protected Health Information (PHI)-naïve Library and a data-driven Dataset.

The Library has a modular design for transparency and efficiency. The value set functions as the building block and can be grouped into supersets and logically attached (e.g., AND, OR, NOT) or temporarily related (e.g., WITHIN 8 Days) to other sets to create arbitrarily complex concepts. Implementation instructions at each level of aggregation are encoded with exportable and visualizable metadata (Figure 1). The Library definition of a concept is the sole source of instructions for its computation. The system allows end-users to enter requests for concepts and associated time frames of interest (e.g., 1 year prior to selection date) and the architecture automatically generates the dataset. Specifically, the Dataset schema will populate and execute dynamic SQL code to extract the necessary value sets over the desired time frames from the appropriate data sources, seamlessly combining multiple sources such as VistA and Cerner-Millennium sourced tables while tracking the originating context, such as outpatient or inpatient diagnoses. Following value set extraction, the Dataset construction code rolls up the raw data into the requested concepts according to the Library instructions, exposing its computations at each step. Code and data output are exposed to support validation. Version control is embedded in the architecture.

Results
For an initial proof of concept, we recreated the dataset underpinning the VA Stratification Tool for Opioid Risk Mitigation (STORM1), a predictive model that is used to update patient risk estimates nightly for CDS. STORM value sets include VA Office of Mental Health and Suicide Prevention national operational definitions: 360,483,480 variables for 6,675,620 patients were calculated faster (< 1 hour) and with an accuracy of 99.95% when compared to
current standard computational practice. The domains included CPT (1), ICD10 (48), Drug (6), outpatient visit types (2), and inpatient specialty (2). Metadata is seamlessly displayed in a Report (Figure 1).

**Figure 1.** XLA generates a Report on dataset metadata automatically based on data-driven computation.

**Discussion**

EHRs are a living system whose outputs are unique to their design and environment. There is a tradeoff between systems that standardize clinical data and those that support the best institutional-specific practices in extracting clinical concepts from biased data, which change rapidly and locally. To ensure accuracy, XLA pairs customizable knowledge management tools to define variables with the generation of SQL code that searches the VA’s data warehouse to retrieve relevant items that belong to each variable’s value set. Other knowledge engineering frameworks relevant to the deployment of predictive analytics in healthcare that build on open standards include SOLOR and OMOP Common Data Model. However, they focus on the knowledge engineering aspect and do not easily facilitate the execution of CDSS. Although they can be customized to exploit an institution’s data assets and information systems, these tools are designed to support generalizable frameworks for data sharing and interoperability across disparate health systems. XLA is transparent and intuitive to use for SMEs. In addition, it generates and executes code specific to an institutional data warehouse for the purpose of real-world risk prediction as well as CDSS functions.

**XLA Advantages:**

- Provides standardization of clinical concept definitions & methods for computing from source databases.
- Enables reuse of clinical concepts across analytic endeavors: CDSS, predictive modeling, metrics, etc.
- Organizes and documents data definitions in a clear format for knowledge management.
- Transparently computes clinical concepts, making them usable to a wide variety of stakeholders.

Future work will focus on optimization for increased computational efficiency, strengthening the validation and embedded version control features, and expanding the metadata report.

**Conclusion**

The XLA architecture successfully computed a clinically relevant dataset with a high level of accuracy and performance. Integrated metadata for this dataset were displayed in a report. We are currently implementing this architecture to support predictive modeling, CDSS and metric reporting.

Longitudinal Performance of a Machine Learning NICU Sepsis Predictor

Aaron J. Masino, PhD\(^1\)\(^2\), Mary Catherine Harris, MD\(^1\)\(^2\), Lakshmi Srinivasan, MD\(^1\)\(^2\), Robert W. Grundmeier, MD\(^1\)\(^2\)

\(^1\)Children’s Hospital of Philadelphia, Philadelphia, PA; \(^2\)University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

Introduction

Despite the importance of early treatment, timely recognition of sepsis remains difficult among infants hospitalized in neonatal intensive care units (NICUs) due to heterogeneous and often indolent presentation. A number of predictive models have been proposed to automate early sepsis recognition in both adult and pediatric settings using a variety of methods including machine learning\(^1\). Nearly all of these studies present model performance results for a single point in time, typically the time of blood culture order. However, an operational sepsis early warning system (EWS) will necessarily make multiple predictions over time during which variation in data availability and clinical status will affect model performance. For example, the median length of stay of infants hospitalized in the Children’s Hospital of Philadelphia (CHOP) NICU is 12 days (IQR [5, 34]). Here, we examine the longitudinal performance of a machine learning sepsis prediction model over a 24-hour period for a NICU setting.

Methods

This study was approved by the CHOP IRB. We conducted a retrospective analysis of infants hospitalized in the CHOP NICU between January 2013 and September 2019. We obtained electronic health record (EHR) data for all infants with at least one sepsis evaluation. The 922 infants in our dataset had 847 positive sepsis evaluations. We obtained case data from the 48-hour period ending at the time of clinical sepsis evaluation, defined as the time of blood-draw for culture or initiation of antibiotic treatment, whichever was earlier, for evaluations resulting in positive cultures for bacteremia or negative cultures with ≥120 hours of antibiotic treatment (commonly described as “clinical sepsis”). We obtained 1,412 control samples by randomly selecting 48-hour observation periods from all individuals in our NICU sepsis registry during periods for which there was no evidence of sepsis for ≥10 days before or after the observation period. For model development, we used 35 features including vital signs, demographics, lab measurements, chronic conditions, and clinical observations. We also used threshold and vital sign difference features, where we computed the difference between the current value and the mean over the previous 24 hours. We binned the data into 48 one-hour windows such that the final bin, denoted bin 1, ends at the time of sepsis evaluation for cases with data bin assignment based on its EHR timestamp. Due to high missingness rates, lab values were treated as indicator variables (i.e., the lab feature was set to 1 if the lab result was available in the bin hour, 0 otherwise). All other features were carried forward in time if there was an observation earlier in 48-hour time period to address missing values. Otherwise, we used mean imputation. We used the first 24 hours, bins [48, 25], of the 48-hour period to populate the vital sign difference features and carry forward values into the final 24 hours, bins [24, 1]. We trained an XGBoost\(^2\) classification model to predict sepsis probability using a leave-one-out cross validation (LOO-CV) approach using only the data available in bin 1 (the hour ending with sepsis evaluation). For each LOO-CV iteration, the model was used to predict sepsis for each hour in the last 24 hours of the held-out episode, bins [24, 1]. We selected the decision threshold to achieve 80% sensitivity in the last hour, the end of which corresponds to the sepsis evaluation time for cases. We assessed model performance by calculating sensitivity, positive predictive value (PPV), and area under the curve (AUC) of the receiver operating characteristic over all predications in each of the last 24 hours.

Results

We found that model performance was nearly constant over the first 20 hours, followed by rapid improvement in all performance metrics during the final 4 hours (left, Figure 1). We also found that the mean probability of sepsis for cases was more than double that of controls at each hour (right, Figure 1). Furthermore, while the mean probability remained constant over the entire 24-hour period for the controls, there is an apparent linear increase over the first 20 hours followed by a more rapid, non-linear increase in the final 4 hours for sepsis cases. To gain further insight into potential influences on model performance, we examined the update frequency of each of the model input features (Figure 2). Nearly half of the input features, including all lab values, were updated less than once per day, implying most information available to the model does not change during the 24-hour period. Kernel density estimates (not shown), suggest however, that in the case samples there is a bias toward lab value observation in the 4 hours prior to sepsis evaluation, whereas the distribution of hour of observation is approximately uniform for controls.
Figure 1: (Left) Model performance metrics at each hour. (Right) The mean probability of sepsis at each hour across all cases (blue, squares) and controls (red, circles). The shaded regions indicate standard deviation.

Figure 2: Mean updates per hour for longitudinal varying input features (excludes chronic conditions which we considered to be a baseline input for the entire period and derived vital sign difference variables). Error bars indicate standard deviation. The dashed line corresponds to an update frequency of once per day. MAP: mean arterial pressure. CVL: central venous line. UAC: umbilical arterial catheter. ITRATIO: neutrophil immaturity ratio.

Discussion

The consistent model performance observed over time suggests the model is stable and may be useful in screening for sepsis in a NICU setting. However, we note that at about 80% sensitivity, the model sustained about 60% PPV which may lead to an unacceptable number of sepsis evaluations per infant depending on resource availability. The difference in mean probability of sepsis between cases and controls over the entire evaluation period suggests the difference in baseline sepsis risk is discernable at least 24-hours prior to clinical recognition. The observation that the mean probability of sepsis for controls is constant over the entire period is suggestive that a combination of relatively static features (i.e., gestational age, comorbidities, presence of central lines) establishes the baseline risk. Noting that we used a carry forward approach for missing values, most episodes have a complete set of recent observations during the final hours of the window. Thus, if the dynamic variables establish baseline risk, we would expect a change in sepsis probability for controls toward the end of the 24-hour period. The increase in mean sepsis probability for cases and improved model performance at the end of the 24-hour period indicate some change in input features that improves classification. It is likely that evolving sepsis produces changes in many, or all, of the variables that improve classification only a few hours prior to clinician recognition. However, we noted there was a bias toward updated lab observations in the final 4 hours for cases. Since we treated labs as indicator variables (i.e., the model does not use the actual lab result only the fact that the lab was observed), it may be that the observation of a lab value is a proxy for clinician suspicion of deterioration. We are continuing to investigate these questions through our ongoing research.

“There for You Every Day”:
Pilot Study of an Automated Conversational Health Coach

Elliot G Mitchell, MA, MPhil, Lena Mamykina, PhD

1Columbia University, Department of Biomedical Informatics, New York, NY

Introduction

In-person self-management education and coaching are among the most successful interventions for managing chronic conditions. In particular, health and lifestyle coaching aims to help individuals meet personal health goals through interaction with a health coach, with an emphasis on developing essential skills and knowledge, cultivating motivation, and personalizing support for each individual. Unfortunately, many individuals, especially those from disadvantaged communities, face barriers to accessing coaching support, and there are not enough coaching practitioners to reach the growing population living with chronic diseases. Because coaching takes the form of a conversation between a coach and a client, conversational agents are well-positioned to deliver coaching interventions, and can reach broader and more diverse populations than their in-person counterparts. However, key questions remain in designing effective conversational agents for health coaching.

A common approach to designing conversational agents in health is structuring dialogs to follow clinical protocols for specific coaching strategies, like Cognitive Behavioral Therapy. In this approach, designers create a scripted dialog structure that anticipates the possible interactions between an individual and the agent and specifies appropriate responses. While less flexible than dynamic conversational agents, which are based on dialog models trained from a large corpus, fully-scripted agents have been successful in domains where corpora are not available or feasible to create, and also offer designers more precise control over how the agent will respond, which is important when delivering health-related information. Despite their potential to serve the role of a health coach, conversational agents have not been widely studied in their ability to support chronic disease self-management.

Methods

We designed t2.coach through an iterative, user-centered design process. Following the dominant approach for designing conversational agents in health, t2.coach was implemented as a scripted chatbot following an established protocol for goal-setting, Brief Action Planning (BAP), which lays out a series of steps and scripted prompts for practitioners to facilitate goal setting conversations. Inspired by BAP, interactions with t2.coach start by guiding the user through a series of prompts to choose a health goal related to nutrition or physical activity and plan specific actions to achieve that goal. Every day, t2.coach initiates a check-in conversation to inquire whether the user met their goal, and if they didn’t, what barriers they encountered and how they might overcome them; users can choose a new plan each day. See Figure 1 for an example exchange.

t2.coach was implemented as a text message (sms) based chatbot with a botkit backend and twilio integration for sms messaging. Similar to Woebot and other health chatbots, users could reply with a mix of multi-response, yes/no, and free-text prompts, though the free text responses did not impact the overall flow of the conversation.

We sought to examine the feasibility of automated conversational approaches like t2.coach to serve as a health coach and support individuals with type 2 diabetes (T2D). In particular, we assessed the extent to which individuals engaged with t2.coach, and captured qualitative perceptions from individuals after using t2.coach for 2-3 weeks.
To examine these questions, we recruited individuals with T2D from community health centers in the New York City metro area as well as from Columbia University’s online RecruitMe portal to participate in a series of focus groups and pilot studies. In the first phase, participants messaged with an early “wizard-of-oz” (woz) prototype, where messages were sent by a member of the research team. We updated the t2.coach script based on feedback from the woz pilot, and in the second phase, participants interacted with a functioning prototype of t2.coach. Both pilot studies ran for 2-3 weeks, followed by semi-structured interviews with participants. We calculated descriptive usage statistics of interactions from both pilots. Interview transcripts were analyzed with inductive thematic analysis.

Results

20 individuals with T2D participated in the pilot. Of those, 13 were enrolled in the woz pilot, while 7 were enrolled in the pilot with the functioning chatbot.

Iterative Design. There were several findings from the woz pilot that led to updates in the t2.coach script. For example, we found that the full BAP script, which was designed for an in-person session, was sometimes prohibitively long for text messaging, and shortened it to make it more concise. We also updated and expanded the available content – goals and action plans to choose from based on focus group feedback.

Engagement. Participants responded to daily messages 50% of the time with the woz prototype, and 70% of the time with the fully implemented t2.coach chatbot. This difference was statistically significant with an unpaired t-test ($t < 0.05$), and suggests that the modifications made through the iterative design process improved the user experience for participants. When users did respond, users took an average of 16.9 minutes to reply suggesting a substantial delay compared to synchronous human-human conversations.

Qualitative Perceptions. Thematic analysis across both pilot studies identified several main themes, summarized here:

- **Working with a coach.** Overall, participants described experiences as consistent with working with a health coach. Participants used words like “coach” or “teacher” to describe the system. Through setting and following goals, participants described increased motivation, and a sense of accountability to achieve their chosen goals. Participants also commented that their exchanges with the coach felt like a conversation, and that they felt they were building a relationship with t2.coach through their messaging.

- **Annoying, but helpful.** Some participants described the frequency of messages as “annoying,” especially when messages would arrive at inopportune times. This was particularly the case for participants who used text messaging infrequently prior to the study. At the same time, participants often found t2.coach’s persistence to be helpful, as it provided necessary encouragement for following through on behavioral intentions.

- **There for you every day.** Many participants had prior experience with a health coach, like a dietitian, who they saw every few months, and whose recommendations often took the form of a meal plan. Participants contrasted t2.coach with these prior experiences, and appreciated the flexibility and autonomy of setting goals with t2.coach, as opposed to the prescriptive and rigid nature of meal plans. Furthermore, the daily messaging from t2.coach helped to keep up motivation, and the ability to adjust their daily plans to meet goals helped to avoid monotony.

Discussion and Conclusion

We presented the iterative design and a multi-stage pilot trial of t2.coach, a conversational agent health coach designed to support individuals with T2D. We refined t2.coach with a wizard-of-oz trial, followed by a pilot deployment of the functional chatbot. Qualitative results suggested that a scripted, rule-based chatbot can lead to engagement and cultivate a coach-like relationship in the context of self-management. Future work should explore the potential of more advanced computational approaches to facilitate improved automated coaching conversations.

Pragmatic Patient Reported Outcomes via EHR Patient Portal vs. Telephone: A Pilot Randomized Controlled Trial among Adults with Epilepsy and Anxiety or Depression Symptoms

Heidi M. Munger Clary, MD, MPH, Beverly M. Snively, PhD, Umit Topaloglu, PhD, FAMIA, Pamela Duncan, PhD, James Kimball, MD, Halley Alexander, MD, Gretchen A. Brenes, PhD

1Wake Forest School of Medicine, Winston-Salem, North Carolina

Abstract

This pragmatic pilot randomized trial was designed to assess feasibility of patient reported outcome collection at 6-months via the electronic health record (EHR) patient portal versus telephone among adults with epilepsy and anxiety or depression symptoms. While retention was lower in the EHR arm than telephone (67% vs. 100%), EHR collection required significantly less staff time. A hybrid of these two approaches may be optimal in future studies.

Introduction

To advance pragmatic trials and other research in routine care settings, study recruitment at the point of care using integrated EHR functionality may help identify and recruit more generalizable study samples. In addition, EHR portals may help facilitate rigorous outcome collection with low participant burden. Studying EHR-based clinical research methods among people with comorbid anxiety or depression and epilepsy may have high impact1, notwithstanding these comorbidities are understudied. Despite patient interest in research participation, even a single in-person research visit can be a significant deterrent to treatment study enrollment2-3. Thus, the objective was to assess feasibility of 6-month patient reported outcome collection and examine process measures in a randomized study of EHR patient portal versus telephone interview outcome methods among adults with epilepsy and anxiety or depression symptoms.

Methods

Recruitment began at a tertiary epilepsy clinic visit, with initial EHR-embedded screening consent and automated EHR eligibility assessment (Figure 1). Quality measure-satisfying anxiety and depression screening was conducted at clinic visits using EHR-based Generalized Anxiety Disorder-7 (GAD-7) and Neurological Disorders Depression Inventory-Epilepsy (NDDI-E) questionnaires. Individuals with borderline or high scores (GAD-7 ≥8 or NDDI-E ≥14) immediately received a brief research screening consent within the EHR, and automated rules in the Epic® EHR were utilized to assess other eligibility criteria (age≥18, negative suicidality screen on the NDDI-E passive suicidality question). A silent Best Practice Advisory (BPA) message to the study team inbasket pool was activated for patients who were potentially eligible and interested based on the screening consent. The study team then manually assessed the EHR for the final eligibility criterion (diagnosis of epilepsy). Fully eligible and interested individuals then completed full consent, enrollment, and randomization via telephone.

Figure 1. Recruitment process and role of the EHR

Participants (N=30) were randomized 1:1 to patient portal versus telephone outcome assessment (stratified by patient portal account status at enrollment: activated vs. not), and outcomes were collected at 3- and 6-months (patient-reported outcomes: anxiety, depression, quality of life along with process outcomes). The primary outcome was 6-month retention in the patient portal arm, defined as outcomes returned via EHR portal by one week after five
electronic portal reminders (sent every 2-3 days if no outcome returned). Process outcomes included research staff time, number of reminders required, and timing of outcome collection relative to target date for outcome assessment. Staff time included time to send portal message reminders manually, conduct telephone reminder calls, and collect and enter outcome data in the study database. This initial report focuses on the retention and process outcomes.

**Results**

The study sample had a mean age of 42.5 years and was composed of mostly non-seizure free individuals (67%) with focal epilepsy (80%). Among the 15 individuals randomized to patient portal outcome assessment, 10 (67%, 95% CI 41.7-84.8%) completed 6-month outcomes by this modality, compared with 100% (95% CI 79.6%-100%) of those randomized to the telephone interview (p=0.042). Following ascertainment of the primary retention measure, the five EHR arm participants who did not complete the outcome measures were contacted by telephone, and four completed the measures via telephone interview, while the fifth eventually returned outcome measure responses via the patient portal. Patient-portal based outcome assessment required significantly less research staff time, especially when outcome collection was successful using the EHR modality (Table 1).

*Count (column %), mean ± SD; data are complete unless otherwise noted. **P values are for comparison of EHR and telephone groups, based on Fisher’s exact and Wilcoxon rank sum tests.

**Discussion**

In this randomized pilot study, EHR portal outcome assessment had lower retention than telephone interview, but it saved significant research staff time. Patient reported measures were ultimately collected from all participants using a hybrid approach following primary outcome assessment. Future pragmatic studies may benefit from a hybrid of these approaches, should examine the relation between factors such as baseline EHR portal activity with completed EHR outcomes, and consider comparison with in-person methods. Future directions could include using automated methods to further reduce staff time for reminders. The small sample size of this study may limit its generalizability.

Predicting Level of Care for Emergency Hospital Admissions to Optimize Triage

Minh Nguyen1 M.A, Nicolai P. Ostberg2 M.S, Conor K. Corbin1 B.S, Tiffany Eulalio1 B.S, Gautam Machiraju1 B.A, Ben J. Marafino1 B.S, Michael Baiocchi3 Ph.D, Christian Rose4 M.D, Jonathan H. Chen5 M.D, Ph.D

Department of Epidemiology and Population Health, Stanford University School of Medicine, Stanford, CA 4. Department of Emergency Medicine, Stanford University School of Medicine, Stanford, CA 5. Department of Hospital Medicine, Center for Biomedical Informatics Research, Stanford University School of Medicine, Stanford, CA

Introduction:
Due to the dynamic and high acuity nature of patients in the Emergency Department (ED), determining an accurate level-of-care assignment for admission is difficult. Delays in ICU admission due to under-triaging contribute significantly to mortality and increases nursing care demand [1]. Conversely, over-triaging patients may misallocate scarce ICU resources [2], which can be particularly poignant during times of high critical care stress, like during the COVID-19 pandemic.

Evidence suggests that physicians frequently make level-of-care assignments based on qualitative clinical judgment, as opposed to written guidelines [3]. As a result, these decisions may be prone to unintentional biases and other errors in judgment. Therefore, triaging patient admission assignments from the ED represents an opportunity for computer-aided clinical decision support to manage difficult triage decisions that otherwise place undue pressure on decision-makers, with potentially dire consequences for both under- or over-triaging.

In this study, we sought to develop a model to predict the level of care needed (ICU vs. non-ICU) following inpatient admission for ED patients using EHR data. Specifically, we aim to predict a patient's highest level of care within 24 hours and level of care at the 24th hours following inpatient admission, using only data available prior to the time when the admission order was written.

Methods:
We used de-identified electronic health record data for patient encounters at a tertiary academic hospital (Stanford hospital and Stanford Valley Care community hospital) and Level I trauma center between 2015 and 2019. All adult patients 18 years or older admitted to the hospital as inpatients from the ED were included. Patients who were not full code status were excluded. The primary outcome was the patient’s highest level of care within 24 hours following their initial inpatient admission. The secondary outcome was a patient’s level of care at the 24th hour since inpatient admission.

To account for feature drift, the data were split by time, with the training dataset including all patient admissions from 2015 to 2017, whereas the validation dataset included all 2018 admissions, and the test dataset included all 2019 admissions. Prediction models were trained under two regimes, corresponding to different feature sets. In Regime I, a model was constructed that used all relevant structured electronic health record data, including demographics, Emergency Severity Index (ESI), vital signs, lab results, historical diagnosis codes, and imaging, procedure, and medication orders (99,667 features). This model served as an upper bound on model performance, assuming that most structured data can be easily queried to feed the model pipeline when deployed. In Regime II, a simpler model was trained using only patient demographics and vital signs (97 features) from the current admission.

We applied four machine learning algorithms: elastic net regularized logistic regression, random forest, gradient-boosted trees, and feed-forward neural networks. Additionally, because the ESI is the triage score assigned when a patient is first assessed by triage nurses to guide treatment priority in the ED, we included a univariate logistic regression with ESI as the only predictor as a benchmark method. Predictive performance was quantified using areas under the receiver operator characteristic curve (AUROC) as well as under the precision-recall curve (AUPRC), sensitivity, specificity, positive and negative predictive values. Feature ablation studies were performed to determine importance of feature types. Furthermore, we reviewed the most erroneous predictions (such as ICU admissions with predicted probability of admission less than 0.2) for the primary outcome.

Results:
Our cohort consisted of 41,654 distinct admissions, of which 28,985 (70% of the cohort) were unique patients. In the holdout test set of 10,096 admissions, 75% of patients were not in the training and validation sets. We identified 5,568 (13.4%) admissions who were admitted to the ICUs at some point within 24 hours following their initial admission, and 3,892 (9.3%) in the ICUs at the 24th hour after admission.

Gradient-boosted trees consistently performed better, or just as well as, other algorithm types. Results are summarized in the below table and figure. The full-feature model outperformed the simple-feature model and the ESI-only model. For the
primary outcome, using a threshold such as 0.6, our best model achieved 85% positive predictive value, 89% negative predictive value, 30% sensitivity, and 99% specificity.

<table>

</tr>
<tr>
<td>ESI-only regression</td>
<td>0.67 (0.65 - 0.70) 0.37 (0.35 - 0.40)</td>
<td>0.67 (0.65 - 0.70) 0.28 (0.26 - 0.31)</td>
</tr>
</tbody>
</table>

Feature ablation analysis revealed that vital signs were the only stand-alone feature type that significantly impacted the predictive performance of our models. Among patients whose first inpatient admitting physicians were not critical care services, the most erroneous predicted values were for patients from neurosurgery, pulmonary hypertension, and trauma services, accounting for 10 to 18% of all errors.

**Discussion and Conclusion:**

Our model appeared to accurately discriminate patients requiring ICU care against those who did not, which could help identify higher-risk patients and improve clinical decision-making. While the Regime I model outperformed that trained under Regime II (AUROC 0.88 vs 0.82 for primary outcome), the relative ease of feature availability in Regime II makes it an attractive option for robust prediction without complicated data pipelines. Analysis of cases of prediction error indicated greater uncertainty amongst patients initially admitted to certain specialty services, likely due to admission protocols which supersede clinical decision making based on specific disease severity measures.

**Clinical implementation:** We propose a 3-tier alarm system to identify: very low, very high, and uncertain acuity levels depending on case mix and hospital bed capacity. Mid-range patients are those with predicted probability is in the mid-range and would require further assessment and interventions for admission triage.

**Limitations:** Guidelines for admission changes and thresholds for level of care assignments depend on case mix and overall patient acuity. Our models cannot be applied as-is but need to be adapted to specific hospital settings for implementation. Our study is observational, using electronic health record data which has issues such as missing data, entry errors, and inconsistent coding practice.

In conclusion, our proposed prediction models demonstrated good discrimination for ICU vs non-ICU level of care within 24 hours and at the 24th hour after initial admission, substantially better than existing standards of care in patient risk assessment such as the Emergency Severity Index system. Outputs of such models could be used as priority scores to aid triage decision-making, improving the efficiency and quality of emergency hospital care.

**Attendees’ Take-away Tools:**

Our approach and algorithm using electronic health record data for machine learning prediction and proposed three-tier alarm system can be reproduced, adapted, and may be implemented in another practice setting.

Developing an Automated Recipient Risk Prediction Tool for Life-long Mortality After Pediatric Heart Transplantation

Yizhao Ni, PhD, Farhan Zafar, MD, Alia Dani, PhD, David Morales, MD
Cincinnati Children’s Hospital Medical Center, Cincinnati, OH

Introduction
Pediatric heart transplantation is a life-saving procedure for children with end-stage heart failure. The procedure has a high early mortality (18%) and the rate remains constant (4% per year) for the next 20 years. The existing studies have focused on models predicting short-term (e.g., 1-year) survival with pre-operative and sometimes operative data. We aim at using state-of-the-art machine learning technologies to analyze patients’ life-long mortality with continual data feeds. Our objective is to develop an automated approach to identify risk factors continually with time period data and predict life-long mortality for pediatric recipients of heart transplantation.

Methods
We utilized heart transplantation data collected by the Organ Procurement and Transplantation Network (OPTN) as of March 1st, 2020. The study was performed in accordance with the regulations of the institutional review board of Cincinnati Children’s Hospital Medical Center. The study population included all pediatric patients aging ≤18 at the time of transplantation. Patient mortality outcome (alive/deceased) was calculated at one month, six months, and then at 6-month increment till ten years to simulate their status during postoperative follow ups. If an alive patient’s record was less than ten years in the dataset, he/she would be excluded from outcome prediction one year after his/her last record. To capture potential risk factors, we extracted patients’ preoperative, operative, and follow-up information from the OPTN data. Descriptive statistics of the extracted variables is presented in Table 1. The numerical variables were standardized using z-score normalization. The categorical variable was binarized with a dummy variable to avoid linear dependencies. To deal with missing data, we implemented grand mean and model imputation for numerical variables and unique-value imputation for categorical variables. If a variable was missing for all patients at a time point (e.g., all follow-up variables were not available at the first month), it was removed from the predictive models.

We aimed to predict mortality outcome for a patient at each time point (time of a follow-up visit) using information up to the patient’s last visit. We developed two approaches to analyze patient information. The first approach was a binary-class classification using a snapshot of latest features till a patient’s last visit. Four traditional machine learning classifiers were implemented including logistic regression (LR) with L1 and L2 normalization, linear support vector machines (SVMs), random forests (RFs), and gradient boosting machines (GBMs). The other was a sequence labeling setting that aggregated information till a patient’s last visit to predict his/her current mortality. We implemented a one direction long-short term memory (LSTM) network to aggregate information and make sequence predictions.

We performed a stratified random sampling based on individual patients to split the dataset into two parts, 70% for training and 30% for evaluation. Ten-fold cross-validation was utilized in training the machine learning and deep learning algorithms, where model parameters were optimized with grid search parameterization. For model evaluation, we used the area under the receiver operating characteristic curve (AUC) as the primary measure. To understand risk factors contributing to patient mortality, we performed an iterative step-forward feature selection (LR with L2 normalization) with best first search to identify key predictors at each time point.

Results
The distribution of patient mortality outcome over time is visualized in Figure 1. The sample size ranged from 10,213 at one-month with a mortality rate of 10% to 6,004 at ten-year with a mortality rate of 48%. The sample size decreased due to alive patients excluded from analysis as described above. Performance of the predictive models is presented in Figure 2. All machine learning models achieved similar performances, and the differences in performance were not statistically significant. The best-performing model (GBM) achieved 0.802 AUC at one-month and over 0.9 AUCs after one year. Figure 3 presents the importance of selected variables over time based on their reciprocal of ranks.

Discussion and Conclusion
The machine learning models showed good capacity for predicting risk of life-long mortality. The best-performing GBM achieved decent AUCs in predicting early mortality and the performance improved over time when more information was available. The LSTM model did not show improved performance, suggesting that mortality outcome was dependent more on recipients’ short-term status. The findings from feature selection suggested shift of importance in risk factors over time. Recipients’ clinical status during transplantation such as ECMO use, stroke and serum total bilirubin were important for early mortality. In the medium and long terms, recipients’ chronic conditions (e.g., renal dysfunction), healthcare utilization and quality (e.g., follow-up care by transplant center, specialty physician, primary care provider, or unknown) and organ matching factors (e.g., recipient age/height, donor weight) were more dominant.
By analyzing time period data, the developed approach provides continual updates of mortality outcome and risk factors. The approach has potential to assist with postoperative care after heart transplantation by informing healthcare providers if a patient requires additional attention, and if so, what are the actionable items.

Experiences of Discrimination and Withholding Information from Providers
Paige M. Nong, BA¹, Alicia K. Williamson, BA¹, Jody E. Platt, MPH PhD¹, Denise L. Anthony, PhD¹
¹University of Michigan, Ann Arbor, Michigan, USA

Introduction
Patient-centered care depends on provider patient relationships that facilitate information exchange and patient involvement.¹ ² Health information technology (HIT) that promotes the utilization and sharing of patient information, care coordination and quality of care³ ⁴ relies on communication between patients and providers. Patient concerns about what will be done with the information they share, and who has access to it, may inhibit information exchange with providers.⁵ ⁶ For example, patients may withhold information from a provider based on concerns about stigmatized health conditions, security, privacy, or trustworthiness.⁶ ⁷ Incomplete patient data introduces bias, which can negatively impact quality of care.

Some dimensions of trust have been identified as important to disclosure, such as patient trust that a provider will use their personal information appropriately (confidentiality), and will disclose conflicts of interest.⁶ ⁸ Prior work also demonstrates that patients face interpersonal discrimination while seeking medical care⁹ ¹⁰ and that experiences of discrimination are associated with low trust.¹¹ Our study contributes important evidence about the associations between disclosing information to healthcare providers, experiences of discrimination in healthcare, and trust in providers.

Methods
In order to identify the relationships between trust, discrimination, and withholding we fielded a national survey of US adults. A total of 2,157 US adults who speak English from the National Opinion Research Center’s (NORC) AmeriSpeak panel responded to the survey in May 2019 (66% response rate). The final analytic sample included 2,144 respondents and analyses used post-stratification weights based on the Current Population Survey. A more complete description of the survey development and implementation is available elsewhere.⁹

Withholding information was measured as a binary yes/no response to the question “have you ever kept information from your healthcare provider because you were concerned about privacy or security?”. We asked respondents whether they had ever been discriminated against, hassled or made to feel inferior while getting medical care (yes/no). To measure dimensions of trust, respondents indicated their agreement with four statements about providers: 1) “health care providers care most about making money for themselves”, 2) “health care providers disclose their conflicts of interest”, 3) “I trust health care providers to use my health information responsibly”, and 4) “All things considered, health care providers in this country can be trusted”. Responses were coded so that low trust in a given dimension was equal to one and higher trust was equal to zero.

We conducted weighted bivariable and multivariable logistic regressions of withholding information on experiences of discrimination and four dimensions of low trust. Multivariable logistic regressions controlled for demographic, health, and access to care factors: sex, age, race/ethnicity, education, income, self-reported health status, health insurance status, having a regular healthcare provider, high satisfaction with care, and time of most recent visit to a healthcare provider.

Results
In weighted analyses, 27.5% of respondents reported having withheld information from providers because of concerns about privacy or security. Using weighted percentages, approximately half the sample were men (51.8%). The racial and ethnic composition of the sample was 63.8% white (non-Hispanic), 16.8% Hispanic, 11.9% Black (non-Hispanic), 4.7% other and multiple racial/ethnic identities (self-selected), and 3.8% Asian (non-Hispanic). Approximately 19.1% of respondents reported experiencing discrimination while seeking medical care. In weighted bivariable logistic regressions, having experienced discrimination and each dimension of trust are significantly associated with a greater likelihood of withholding information from a provider.

In the multivariable weighted logistic regression, we observe a statistically significant greater likelihood of withholding information from providers for those who report experiencing discrimination in the healthcare system (OR 3.67 [CI 2.6-5.2], p<0.001). Those reporting low trust in providers using health information responsibly (OR
Low trust in providers generally.

a Covariates in the multivariable model include sex, age, race/ethnicity, education, income, self-reported health status, health insurance status, having a regular healthcare provider, high satisfaction with care, and time of most recent visit to a healthcare provider.

**Discussion**

Patients who have experienced discrimination in the healthcare system are significantly more likely to withhold information from their provider. Those with low trust in providers using health information responsibly and disclosing conflicts of interest are also significantly more likely to withhold information. These findings underscore the importance of addressing interpersonal discrimination in the healthcare system and facilitating trustworthy provider relationships in order to ensure patient information sharing necessary for quality patient-centered care.

Incomplete information can result in poorer care, exacerbating existing disparities and compounding the harm of a discriminatory experience. Future work should engage qualitative methods to identify and understand causal relationships and mechanisms, as well as clarify the roles of each type of trust analyzed here. As we improve our understanding of data bias in healthcare and work to minimize it, we must also recognize and address the role of patient trust in providers, confidentiality, and discrimination in healthcare that undermine the quality of care and of healthcare data.

**PHenotype Observed Entity Baseline Endorsements (PHOEBE)** - recommender system for concept selection in phenotype algorithm development

Anna Ostropolets, MD, MA¹, Patrick Ryan, PhD², George Hripcsak, MD¹,³
¹Columbia University, New York, NY, USA; ²Janssen Research and Development, Titusville, NJ; ³New York-Presbyterian Hospital, New York, NY

**Introduction**

Large-scale observational studies in distributed networks allow leveraging large patient populations to produce reliable evidence, but they require a recognition and reconciliation of differences in patient data capture. While single-center studies can use phenotypic algorithms that were developed and validated on that data source, such algorithms may not be applicable to other data sources. As we have shown before, data sources are highly heterogeneous with respect to ontologies, with most of the concepts being unique to a data source [1]. This challenges conventional approaches to phenotyping [2,3] such as using administrative claims concepts, concepts from existing literature or exploring concepts at a local patient data instance. Due to the large ontological space, patient phenotyping in network studies becomes time-consuming and oftentimes leads to disparate phenotypes representing one clinical idea. Such lack of consistency results in potential patient loss and biased results.

Recent Observational Medical Outcomes Partnership (OMOP) studies [4] enable leveraging a shared knowledge base of concepts allowing the construction of comprehensive phenotypes. We created a recommender system that uses lexical and ontology features to select recommendations and prioritize them based on the prevalence of concepts in the network of 21 US and international data sources. In this work, we will describe its principles and validation experiment.

**Methods**

The details of the Concept Prevalence study that was used to generate the concept knowledge base are described elsewhere [1]. The initial set used by PHOEBE consisted of 11 million unique concepts appearing in at least one source within the network, with 272 billion records summarized to provide verbatim and descendant concept frequency estimates. Aggregated frequencies of concepts across participating data sources were used to pre-compute a set of recommended terms for all standard concepts in the OMOP Standardized Vocabularies. Recommended terms were selected based on string matching and filtered based on the aggregated frequency to remove unused concepts.

First, the recommender system provided the most prevalent starting concept based on the user text input. After the initial concept was selected the OMOP Standardized Vocabulary hierarchy was used to provide ancestor and descendant terms as well as potentially relevant terms not included in the concept set (orphan codes). The output was prioritized based on the aggregated frequency to focus decision-making on the concepts largest gain in number of patients. The recommender system was made publicly available (https://data.ohdsi.org/PHOEBE).

For validation, we used an electronic health record data source (Columbia University Medical Center EHR) and two administrative claims data sources (IBM MarketScan® Multi-State Medicaid Database and IBM MarketScan® Medicare Supplemental Database) translated to OMOP Common Data Model. We selected diabetes mellitus type II and diabetes mellitus type I - two common conditions that were extensively studied in the observational literature and for which specific drug treatment exists. For each of the conditions, PHOEBE was used to create concept sets following the steps outlined above. As a reference, we selected two eMERGE network phenotypes representing the same clinical ideas [5]. For each phenotype, we extracted ICD9-CM concept sets and translated to SNOMED-CT concept [6]. We then created patient cohorts by selecting patients with at least one occurrence of a diagnosis code from corresponding concept sets and with at least 365 days of prior observation to ensure data coverage. For each cohort, we followed patients to look for a specific treatment, which included any occurrence of insulin products for type I diabetes mellitus and oral antidiabetic drugs (metformin, sulfonylureas, thiazolidinediones, dipeptidyl peptidase IV inhibitors and glucagon-like peptide-1 agonists) for type II diabetes mellitus.

We computed the positive predictive value (PPV) of each phenotype, which was defined as a proportion of people with diagnostic code who also had subsequent treatment with corresponding drugs. Additionally, for patients with subsequent treatment identified by both PHOEBE and eMERGE algorithms, disorder start dates were extracted and compared.
Results
We found that for both disorders, the PHOEBE algorithm identified significantly more patients (Table 1).

</tbody>
</table>

While there was no significant difference in PPV for diabetes mellitus type I, PHOEBE algorithm identified more patients with subsequent treatment for diabetes mellitus type II on MDCR and MDCD. As expected, since eMERGE phenotypes were developed on CUMC data, PHOEBE did not show significant patient gain on that data source for both conditions. For patients identified by both algorithms, PHOEBE identified such patients earlier in the course of the disorder on all data sources. In CUMC, patients on average presented with diabetes mellitus type II and diabetes mellitus type I more than two years earlier when using the PHOEBE algorithm (median difference 688 days (IQR 179 – 1,533) and 1532 days (538 – 3,070) respectively). This can be explained by multiple patients having unspecified diabetes mellitus codes prior to being treated by endocrinologists. MDCD and MDCR displayed smaller difference with median difference 374 days (139 - 806) and 407 days (176 - 894) for diabetes mellitus type I and 820 days (377 – 1,431) and 122 days (13 - 417) for diabetes mellitus type II.

One of the limitations of this work is using only US data sources. As PHOEBE leverages data from a large network, it may show better performance on non-US data sources, which is yet to be shown. We used specific treatment as a proxy for patients being true positive. While imperfect, it allows assessing algorithm performance in absence of methods to validate phenotypes in administrative claims data.

Conclusion
Patient phenotyping in network studies in time-consuming and oftentimes produces inconsistent results due to different patient representations in disparate data sources. We developed a recommender system that facilitates phenotype development standardization and comprehensive concept set creation. We examined its performance against eMERGE concept sets and found better performance for some conditions and early detection of patients of interest.

Introduction and Objective

Sophisticated natural language processing (NLP) pipelines, such as cTAKES¹ and MetaMap², and simpler rule-based approaches combining regular expressions (RegEx) and logic have been increasingly leveraged in the electronic health record (EHR)-based phenotyping process³. A one-year pilot study was conducted by the electronic Medical Records and Genomics (eMERGE) Network to test the feasibility of deploying portable phenotype algorithms that are enriched by information from NLP, with the goal of improving the performance of existing algorithms. We report our results including lessons learned, and recommendations of best practices for incorporating portable NLP algorithm components in computable phenotypes.

Materials and Methods

Based on scientific merit and predicted difficulty, eMERGE selected 6 existing phenotypes to enrich with NLP. The eMERGE Phenotyping workgroup restricted NLP pipelines to cTAKES, MetaMap, and/or regular expressions to assist in algorithm portability, and used 2 commonly adopted negation detection modules: NegEx⁴ and ConText⁵. Algorithms were developed, then validated by at least one other site, before dissemination to up to 8 other sites for implementation, similar to our existing validation workflow⁶. We retrospectively compared the NLP methods and tools to assess performance, portability, and ease of use. Sites reported lessons learned for creating and sharing NLP algorithms via a brief informal survey designed to collect both quantitative and qualitative data. Quantitatively, sites reported changes in performance, and estimated the amount of resources and elapsed time it took to complete.

Using grounded theory⁷, a thematic analysis was conducted by two authors (JAP, LVR) via independent review of the qualitative feedback. First, open and axial coding on categories of issues or concerns was completed to identify phrases and loosely categorize them. The coders used selective coding to refine axial codes into a comprehensive hierarchical codebook, independently re-coded the feedback, and reviewed to achieve consensus. Emergent themes were identified through iterative review of the codes. Finally, we summarized lessons learned for review by all authors, including a) challenges for each theme; b) corresponding best practices to address those challenges based on existing published evidence and/or eMERGE experience; and c) opportunities for future research.

Results

In all but one case (where precision decreased), the precision and recall stayed the same or improved. Of note, the time it took to develop and validate phenotype algorithms at secondary sites was considerably longer when NLP was
incorporated (1-2 years). Figure 1 shows the three major themes identified from the qualitative analysis: portability, phenotyping, workflow/process, and technology, along with sub-themes. The technology theme was used as a modifier for the other two primary themes - that is, all technologies were associated with another theme.

Figure 1. Themes of lessons learned

Discussion and Conclusion

Our study shows that an NLP component brings extra benefits to an existing phenotyping algorithm. This study also demonstrates NLP performance may vary between primary and validation sites, due to heterogeneity in clinical document names and the basic structure of clinical notes. Implementing standard terminologies to categorize all document types is impractical due to the absence of clear document types at this stage. Thus, we suggest starting with semi-structured clinical notes and imposing minimal reform or costs at the institutional level, such as comprehensive documentation and customization needed at each site. The generalizability of a negation module remains an open NLP challenge; thus, local tailoring on negation may be necessary, such as adding correction rules to the code for negating language. It is also important to understand that to successfully share and implement a computable phenotype using NLP is not just about the NLP technology or the algorithm itself. Critical factors to ensure project success include privacy protection and attention to regulations; intellectual property agreement; and technical infrastructure setup and efficient communication as previously reported.

Limitations to this study include that we preselected pipelines for each task as the comparison of the performance using other pipelines was beyond our resources and timeline. Finally, no formal, standardized measurement of time and effort was used, leading to reliance on estimates which could lead to inconsistent reporting and inaccuracies.

Our results show that NLP continues to make a positive impact on phenotype performance. While portable phenotype definitions are possible, careful planning and architecture of the algorithms is essential to support local customizations that are expected to be needed for the foreseeable future.

Statistical Modeling of Multiple Vital Sign Trajectories to Assess Risk of Postoperative Complications and Predict Readmission

Rema Padman, PhD1; Sameera Kodi, MS1; Urmila Ravichandran, MS2; Nirav Shah, MD, MPH2,3
1Carnegie Mellon University, Pittsburgh, PA; 2NorthShore University HealthSystem, Chicago, IL; 3University of Chicago, Chicago, IL

Introduction
Early identification of patients at risk for postoperative complications can facilitate timely workups and treatments and improve health outcomes. Current risk prediction approaches mostly use only preoperative predictors to assess the risk of postoperative complications. They lack dynamic, real-time capabilities to include postoperative information, such as postoperative vital signs, that are collected as part of routine care during the entire inpatient stay. Studies have shown that postoperative fevers, for example, result in increased diagnostic testing, antibiotic usage and length of stay. These may, in turn, result in decreased patient safety, increased antimicrobial resistance and readmission, higher healthcare utilization, and increased morbidity and mortality. With millions of inpatient surgeries completed per year in the United States, improving clinicians’ ability to target only those patients at highest risk of complications has the potential to improve patient safety, quality of care and value on a large scale. In this study, we apply multi-trajectory modeling and evaluation of elective colectomy patients using multiple postoperative vital signs to analyze post-surgery complications and predict risk of readmission.

Methods
Data were extracted for all patients who underwent elective colectomy between January 1, 2007 and December 31, 2013 at NorthShore University HealthSystem. For each surgical episode, information regarding the index hospitalization and any subsequent patient encounters within 30 post-operative days were extracted from the electronic data warehouse (EDW). These included demographics, comorbidities, vitals, laboratory results, medications, length of surgery, start and end time of surgery, length of hospital stay (LOS), readmissions and death. Complications data was extracted initially from the EDW, and then confirmed by manual chart review by a physician, using criteria of symptoms and objective data from diagnostic testing. Missing data was handled using imputation, when feasible, such as missing body mass index (BMI) using the average for the age group and gender of the patient. Group-based multi-trajectory modeling was applied to study the joint developmental course of patient temperature, mean arterial pressure, pulse and WBC readings during inpatient stay up to 9 days (mean LOS < 15% inpatients after 9 days) and readmission risk was predicted for each group. Analyses include: (1) Trajectories of temperature, mean arterial pressure, pulse and WBC measurements taken every four hours, using a censored normal distribution, with important patient characteristics including age, gender, BMI, the actual surgery procedure time, and comorbidities that were considered potentially relevant for the surgical condition such as diabetes, hypertension, chronic obstructive pulmonary disease, rheumatoid arthritis, congestive heart failure, and metastatic cancer, and (2) Comparison of complication rates by trajectory group (3) Comparison of readmission prediction from the multi-trajectory model against five standard machine learning models, with SMOTE for handling imbalance in the data, and five-fold cross validation to obtain readmission probabilities.

Results
Postoperative vital sign trajectories from 584 patients who underwent elective colectomy were evaluated for risk of postoperative complications. A group-based multi-trajectory model with 5 distinct trajectory groups was generated using temperature, mean arterial pressure, pulse and WBC measurements over a period of 9 days as shown in Figure 1. Number of groups was determined using Bayesian Information Criterion. Groups 1 (18.5%) and 2 (30.6%) include low risk patients whereas group 4 (20.2%) contains medium risk patients. Groups 3 (19.9%) and 5 (10.8%) include high-risk and very high-risk patients, respectively. Table 1 shows the profiling of groups according to patient demographics and comorbidities. We see that high-risk groups 3 and 5 had longer procedure hours and more patients with diabetes and pulmonary disease. Low risk groups 1 and 2 had younger patients, more females and fewer rheumatoid arthritis patients. Group 4 had highest percentage of congestive heart failure patients. Also, the post-operative fever percentages are higher in the higher risk groups who also experience more readmissions. Table 2 summarizes the complications, showing a general trend in increasing complications with increasing risk. In particular, we note that deep vein thrombosis, surgical site infection and bacteremia are more prevalent in high-risk groups. For readmission prediction, we observe the predicted probabilities from the prognostication model increasing from low to high-risk groups in Table 3. The group-based prognostication model also exhibits a better AUC score in Table 4 compared to the standard machine learning models evaluated in this study.
The multi-trajectory model stratifies colectomy patients into distinct risk groups, based on a combination of postoperative vital signs and baseline covariates, that are correlated with multiple postoperative complications. The prediction model for readmission risk, in particular, modestly outperforms some widely used machine learning models and provides a more interpretable solution with better insights. These results demonstrate significant promise for developing a more accurate, robust and interpretable postoperative complication and readmission risk approach which can be deployed, similar to NSQIP, to benefit the millions of annual surgeries in the US to potentially lower adverse events and healthcare costs and improve surgical outcomes. This study is limited by its retrospective nature and the inherent limitations of obtaining data from an EDW.

Addressing Disparities in Diabetes Using Temporal Fairness Models

Introduction

Diabetes is an important global public health burden. In the U.S., 10.5% of the population or 34.2 million individuals have diabetes, and 34.5% of the adults or 88 million people aged 18 years or older have prediabetes1. Health disparities in diabetes and its complications (or/and co-morbidities) exist worldwide2-3. Biological, behavioral, social, environmental, and health system contributors (e.g., social determinants of health) to diabetes disparities rely on sensitivity and specificity and are subject to clinical intervention and insurance product development. With the adoption of machine learning in healthcare, the potential to increase knowledge of this condition illuminates the differences in how diabetes presents, its variable prevalence, and how best treatment practices vary between subpopulations4. Simply training a learning model to minimize prediction error has been criticized for its potential to exacerbate unintended discrimination based on sensitive characteristics. A cause of criticism is that machine learning applications often consider static objectives defined on a snapshot of the population at one instant in time, resulting in static data bias being captured5. Temporal fairness models via fairness criteria evaluate the trend of long-term outcomes and impose selected fairness constraints. In this talk, we discuss how temporal fairness models might reduce the disparities in diabetes care or at least avoid perpetuating discriminatory practices.

Methods

We retrieved 420,979 unique patients with diabetes seen between July 1st, 2017, and June 30th, 2018, gathered from the research patient data registry at Mass General Brigham (MGB), a large integrated healthcare delivery network based in Boston, MA. Our dataset’s population characteristics show that most patients are Caucasian (69.5%) but that sizeable subpopulations of minorities (i.e., African American (5.72%), Hispanic (5.293%), Asian (3.03%), Other/Not Recorded (16.51%)) exist. We extracted patient demographics, insurance plan data, and diagnostic information corresponding to the fields of [principal diagnosis], [admitting diagnosis], and [diagnosis 1...n] that are coded as International Classification of Disease (ICD10) codes. This study was approved by the MGB IRB.

We used a three-step, pipeline approach to: (1) conduct a hypothetical diabetes scenario to approximate the intended relation between input and output values; (2) extract the outcome curves using an optimized version of Liu et al.’s delay model6; and (3) analyze each fairness criteria (and their possible optimizations) over time. Fairness criteria include utility-maximizing criterion (MU), demographic parity (DP), equal opportunity (EO). MU ensures the institution is free to focus solely on utility. DP results in equal selection rates between both groups. EO gives the conditional probability of selection to patients who can be successfully independent of the population, resulting in equal true positive rates between both groups. We assume that the institution is utility-maximizing but may impose certain constraints to ensure that the decision is fair. In many cases, it may be unrealistic for an institution to ensure that fairness constraints are met exactly. Liu et al.’s model is a one-step feedback model that considers temporal indicators; it was first introduced in a hypothetical lending scenario. When we experimented with Liu et al.’s model, we found that it required tuning of too many parameters, and thus we could not apply it directly to our diabetes scenario. We optimized the input layer of Liu et al.’s model to only utilize the source, success, buff, and utility parameters. We consider a total population that is comprised of two groups A and B, and an institution (i.e., hospital) that makes a binary decision for each diabetes patient in each group (the source parameter). Diabetes patients in each group are assigned scores and the score for this group follows a type of probability distribution. The success parameter is defined as any diabetes patient with a diabetes-related ICD10 code (“E1”). The buff parameter measures whether a patient is fortunate or not, associated with success and could be affected by multiple factors such as racial or ethnic difference.
in selecting an insurance product. The utility parameter represents decreased disease management expenses. The model output is a visualization depicting an outcome curve showing the average score change.

Results

Figure 1 displays outcome curves corresponding to four ethnic groups and the three fairness criteria. This output can be interpreted, for example, in MU, when enough diabetes patients in a group are successfully given an accurate diagnosis and appropriate management plan, the average score in that group is likely to decrease (MU results in a negative average score change in the population in this case); as we deviate from profit maximization to give out diagnoses to more patients, the average score change decreases up to a certain point, where it is minimized (the altruistic optimum). The MU is primarily in a state of relative harm, consistent with our assumption of “no active harm.” DP and EO are much better (both residing in a state of “relative improvement”). Interestingly, the curves for African American and Hispanic are similar to each other, but different from the Asian and Caucasian curves (which also have a similar topology).

Figure 1 Disparities across ethnic groups when placed under fairness criteria constraints (compared with a schematic diagram of the outcome curve). Note that the horizontal axis represents the selection rate for patients related to the distributions of both score and fairness criterion; the vertical axis represents the mean change in source.

Discussion

We present an adaptation of an innovation from the economics domain, an optimized version of Liu et al.’s temporal fairness model, to simulate and understand how the fairness of algorithms might mitigate or perpetuate undesirable societal impacts in healthcare. Our main finding is that disparities exist as MU results in relative harm but that this might be mitigated with an unconstrained utility objective (DP & EO). A temporally dynamic model fairness paradigm should be adopted to assess how fair the model is when treating pre-existing biases in the data distribution while simultaneously accounting for the impact decisions have on the underlying population over time. This solution might help to mitigate malpractice risk, improve insurance product offerings, or optimize population health management.

Acknowledgments: We thank Sharmitha Yerneni and Carlos Ortega for help drafting the IRB protocol.

Consequences of Rapid Telehealth Expansion in US Nursing Homes: Exploring Stakeholder Perspectives

Kimberly R. Powell, PhD, RN1 & Gregory L. Alexander, PhD, RN, FAAN, FACMI, FIAHSI2
1Sinclair School of Nursing, University of Missouri, Columbia, MO; 2Columbia University School of Nursing, New York, NY

Introduction: The COVID-19 pandemic has thrust telehealth, the provision of health care resources, tools, and consultation via mobile digital technologies1, from a convenience to an imperative. Before the COVID-19 crisis, telehealth uptake in nursing homes (NH) was slow and understudied.2-4 While expectations regarding use and potential benefits of telehealth in NH is high, experience shows unplanned and unexpected consequences can occur as a result of major policy and technological changes.5 In March 2020, Medicare rules and regulations were relaxed to broaden access to telehealth services in NH settings so that beneficiaries receive the care they need virtually, avoiding risky travel and possible exposure.6 Augmented clinical work resulting from telehealth expansion during the COVID-19 pandemic warrants urgent and deliberate investigation exploring the experience of NH staff and providers interfacing with these mobile systems. Using the AMIA Input-Output model of unintended consequences5 as our theoretical framework, our aim was to describe perceived anticipated and unanticipated consequences of rapid telehealth expansion in NH.

Methods: Using a mixed sequential explanatory design, we drew a sample based on findings from an analysis of telehealth expansion in a national study examining trends in NH IT maturity.7 IT maturity describes IT capabilities, use and degree of integration in a NH setting. We used maximum variation sampling to purposively select participants who: 1) were affiliated with a NH who participated in our IT maturity survey for two consecutive years 2) completed year 1 of the IT maturity survey prior to telehealth expansion (before March 6, 2020) and year 2 after telehealth expansion (after March 6, 2020) 3) represented a broad range of facility characteristics (e.g., location, bed size) 4) were identified as an end-user of telehealth or responsible for telehealth implementation at the NH. Using six questions from the IT maturity survey, we created a total telehealth score (THS) for each facility. We selected participants from NHs with change in THS ranging from year 1 -year 2 in the bottom 20% (low THS), middle 60% (middle THS), and upper 20% (high THS) to enhance variability. An interview guide was used to ensure consistency among participants and all interviews were conducted using Zoom video conferencing. Each interview was transcribed verbatim by members of the research team with prior transcription experience. A second reviewer verified the transcripts with the audio recording to ensure accuracy. Data were analyzed using directed content analysis. The coding process began by highlighting exact words from the text that appeared to capture key thoughts or concepts. The preliminary codebook was iteratively refined as additional transcripts were analyzed. Preliminary codes were sorted into categories by identifying relationships between codes and groupings of codes. Dedoose qualitative software was used to help organize and visualize data. Processes to ensure trustworthiness were maintained by ensuring credibility, dependability, confirmability, and transferability.8 This study was approved by the University of Missouri institutional review board project number 2009109.

Results: Interviews were conducted with (n=20) NH administrators and clinicians from 16 facilities. Participant demographics are reported in Table 1. Participants represented NHs with change in THS ranging from -22 to +17 (median 3) from year 1 to year 2. Over the course of the analysis, 42 open codes were developed. These were grouped by theme and organized according to the domains of the Input-Output model (See Figure 1). Desirable/anticipated consequences included benefits of avoiding travel for NH residents (e.g., avoiding exposure to infectious disease, avoiding stress associated with leaving the NH, residents more comfortable with NH staff) and saving NH resources (e.g., not sending staff out, avoiding transportation). Desirable/unanticipated consequences included improved access to care and enhanced communication. Undesirable/unanticipated consequences were worsening social isolation, difficulty for residents with cognitive impairments and workflow/technology usability challenges. We found similarities and differences in perceptions of TH expansion by participants from NHs with low, middle, and high THS. Highlighted cells (see Figure 1) indicate the top code(s) for each theme according to THS group.

Discussion: Identifying unintended consequences of rapid TH implementation in NHs is a necessary prerequisite for developing strategies to mitigate undesirable consequences and providing data needed for developing best practices
based on desirable consequences. Mitigation strategies for undesirable consequences could include better standardization, use of secure data exchange, workforce development, identifying types of visits (initial vs. follow up) and types of residents best suited for TH, workflow (using NH staff vs. provider medical assistant in the facility) and measures to ensure resident privacy. Identifying unanticipated/desirable consequences, such as opportunities for early intervention and improved communication should be considered when evaluating factors contributing to the success of TH use in NHs. The qualitative methods used in this study are well-suited to studying the complexity and contingencies that emerge when technological tools, like TH, are rapidly implemented in real-world environments. Further research is needed into the unintended consequences of TH implementation in NH and the widespread dissemination of these findings is even more pressing now as federal initiatives to enhance safety and care requirements incentives, like those set forth in the Nursing Home Reform Modernization Act of 2020, are being considered.

References
Among service members transitioning from military to civilian life, two adverse outcomes indicative of poor reintegration are homelessness and criminal justice involvement. Veterans have historically experienced homelessness at a higher rate compared to non-veterans \(^1\) though the rate of veteran homelessness has dropped substantially in the past five years in large part due to interventions by the Department of Veterans Affairs (VA).\(^2,3\) Risk factors for homelessness in veterans include posttraumatic stress disorder (PTSD),\(^4\) severe mental illness (SMI; psychotic, bipolar, and major depressive disorders), misconduct, substance abuse, and traumatic brain injury (TBI).\(^2\) With respect to criminal justice involvement (CJI), risk factors in veterans include younger age, male sex,\(^5\) military experience,\(^6,7\) substance abuse,\(^5,6\) PTSD,\(^6,7\) and SMI.\(^8\) While existing programs within VA can use health system data to help identify individuals at risk of adverse outcomes this is not possible for those transitioning from the Department of Defense (DoD) because linked data are not currently available.

To address this we conducted a longitudinal cohort study that used data from the DoD health system to identify risk factors for homelessness and criminal justice involvement within 2 years of separation from the military for Post-9/11 era Veterans in VA care. Variables from DoD data included demographics (age, sex, race/ethnicity, marital status), military characteristics (branch of service, highest rank and indicator for deployment to a combat zone) and health status documented in DoD care using ICD-9/ICD-10 codes (TBI, substance use disorder (SUD), PTSD and other mental and physical health conditions). Homelessness and criminal justice involvement were identified in VA health system data using ICD-9/ICD-10 codes and VA clinic stop codes for homelessness and criminal justice clinics. To examine the association of neighborhood deprivation of initial post-discharge location we included the Area Deprivation Index (ADI) from the Neighborhood Atlas developed by the University of Wisconsin. We used Fine and Gray competing events models to identify characteristics associated with time to homelessness or criminal justice involvement within two years of military discharge. We present data below for variables with an adjusted hazard ratio \( \geq 1.5 \) or \( \leq 0.67 \).

Among the 418,624 veterans who met inclusion criteria, the two-year incidence of homelessness and criminal justice involvement was 4.7% and 0.8%, respectively. Homelessness was most strongly related to being Black (2.24 [2.16-2.31]) or Native American/Pacific Islander (1.54 [1.51-1.61]), being unmarried (1.56 [1.51-1.61]), being 30 or younger (vs. 40-49 (0.43 [0.40-0.46]) or \( \geq 50 \) years (0.26 [0.21-0.32]), being enlisted (2.38 [2.13-2.63]), SUD (2.08 [2.01-2.14]), severe mental illness (SMI 1.93 [1.85-2.00]), and personality disorder (1.71 [1.60-1.82]). Criminal justice involvement was most strongly associated with male sex (2.94 [2.50-3.45]),
being unmarried (1.84 [1.70-1.99]), being 30 or younger (vs. 40-49 (0.12 [0.04-0.32]) or ≥50 years (0.34 [0.29-0.40]), being enlisted (1.96 [1.52-2.56]), SUD (3.53 [3.27-3.81]), SMI (1.96 [1.80-2.15]), TBI (1.58 [1.40-1.78]), and military deployment (1.85 [1.66-2.06]). Veterans with co-occurring SUD, SMI, and posttraumatic stress disorder had 4 times the incidence of homelessness and 10 times the incidence of criminal justice involvement vs. veterans with none of these diagnoses. Moreover, while the impact of the ADI was not significant by itself, the incidence of homelessness and criminal justice involvement was highest among veterans with co-occurring mental health and SUDs residing in disadvantaged neighborhoods.

These findings identify the importance of using informatics tools to assist in identifying risk factors for adverse outcomes for service members as they transition to civilian life. Programs beginning before transition are needed to provide additional, targeted assistance to Black and Native American/Pacific Islander Veterans and those with complex mental health comorbidity. Further research may be warranted to better understand how existing or new programs/policies may help address needs of Veterans with combat deployment, TBI and complex mental health comorbidity regarding criminal justice involvement.

Planning Equitable Clinical Trial Enrollment using Integer Programming

Miao Qi, BS1, Amar K. Das, MD, PhD2, Kristin P. Bennett, PhD1
1Rensselaer Polytechnic Institute, Troy, New York, USA; 2Center for Computational Health, IBM Research, Cambridge, Massachusetts, USA

Introduction

Ensuring equity in randomized clinical trial (RCT) participation is an important societal goal. Prior informatics work has focused on identifying potential underrepresentation of minorities and other groups in RCT recruitment. For example, in GIST 2.01, the rates of subgroups in the target population and those meeting eligibility criteria are estimated from electronic health records (EHRs), and the difference between actual and target rates may reveal potential inequities. We propose an alternative approach assessing target subgroup rates that is focused instead on designing and achieving RCT enrollment plans that meet equity targets. We show that we can derive the equity targets for multiple subgroups specified over the superset of protected attributes in a patient population. These attributes can include demographic, clinical, laboratory, or risk factors. We use an integer programming (IP) model, integrated with the equity targets and total recruitment goal, to create an equitable enrollment plan. For this presentation, we discuss our approach and demonstrate its application to a previously conducted RCT study of hypertension.

Methods

Given data from clinical patient population (e.g., a health system’s EHR) or a nationally representative population of disease prevalence (e.g., one based on the National Health and Nutrition Examination Survey, or NHANES), we have developed an approach to define rates for all possible subgroups in disease-specific set (S). We use these rates to produce an equitable enrollment plan for the desired number of participants (n_j) across all subgroups j ∈ S. Specifically, we formulate an IP model that informs, for a given trial size, whether it is feasible to meet target enrollments (n_j,ideal) estimated from the patient population, and, if not, creates an enrollment plan that is equitable as maximally possible. The IP model takes into account desired constraints in the RCT design such as minimum subgroup sizes (n_j,min). The model can also determine trial sizes that are likely to meet equity targets for all subgroups of interest.

\[
\begin{align*}
\min_{N,z,d} & \quad \sum_{j \in \hat{S}} (\delta_j z_j + \lambda_j d_j) \\
\text{s.t.} & \quad l_j - z_j \leq n_j \leq u_j + z_j \\
& \quad n_j,ideal - n_j \leq d_j \\
& \quad n_j - n_j,ideal \leq d_j \\
& \quad \sum_{j} n_j \leq N \\
& \quad z_j, d_j \geq 0 \text{ are integer} \\
\forall j \in \hat{S}, & \quad n_j \geq n_j,\text{min} \geq 0 \text{ are integer} \\
\forall j \in \hat{S} \setminus S, & \quad n_j = \sum_{k \leq j} (n_k)
\end{align*}
\]

The IP minimizes the difference between RCT and target subgroup distributions using at most N participants. Let x be a set of patient attributes, S be the set of all lowest-level subgroups defined over x (i.e. every attribute takes unique value) and \( \hat{S} \) be the set of all possible non-empty subgroups defined over x. For each subgroup \( j \in \hat{S} \), we use 95% CI based on equity measures to define an equity target range \( (l_j, u_j)^2 \). Subgroup \( j \)'s enrollment size, outside of its range, generates the equity violation \( z_j \).

The absolute difference between the plan and real RCT subgroup size, \( d_j \), ensures the model does not stop at boundary values when better choices are available. The first model constraint computes the equity violation to be minimized; the next two constraints make sure the subgroup size is as close to the target size as possible; then, we assure enrollment numbers are reasonable in real world; finally, the summation of subgroups are required to equal its parent group. Since patient subgroups are hierarchical based on the attributes, computation of lowest-level subgroup assignments is sufficient; higher-level subgroup assignments can be derived from their children. Penalty coefficients \( \delta_j \) and \( \lambda_j \) can be adjusted based on different needs. For example, if overrepresentation is considered less harmful than underrepresentation, we set penalty coefficients for underrepresented groups larger. These coefficients provide flexibility to model to real-world requirements.

To demonstrate our approach, we calculate survey-weighted prevalence rate estimates for each subgroup within the U.S. population of individuals with hypertension using NHANES 2015-2016\(^3\). These estimates form equity targets, which could alternatively be derived from a local clinical population or a global population. We assess our IP model...
results against the participant-level data from the Systolic Blood Pressure Intervention Trial (SPRINT)\(^4\), available from the Biologic Specimen and Data Repositories Information Coordinating Center (BioLINCC). The difference between subgroup equity targets and RCT enrollment can be measured using metrics\(^{1,2,5}\) such as GIST 2.0 (difference in rates of RCT and target), or a machine learning-based fairness metric (difference in log odds of RCT versus those of target). We have implemented the latter metric in an R Shiny-based tool. For categorization and visualization purposes, our tool shows for any planned, ongoing, or completed trial the absence (red), high underrepresentation (orange), underrepresentation (light orange), equitable (teal), overrepresentation (light blue), and high overrepresentation (blue) based on a user-defined metric with lower and upper thresholds \((\tau_l,\tau_u)\) and associated statistical test\(^2\).

**Results**

The following table shows enrollment targets for subgroups using the same trial size \(N = 9361\) as the original SPRINT study with \(x = \{\text{race/ethnicity, age}\}\). The table indicates the actual trial enrollment and the equity measure for each subgroup in the SPRINT trial and an enrollment target and range that would be equitable. Equity = subgroup \(\log((\text{odds in trial})/(\text{odds in equitable plan})).\(^1\)

**Discussion**

Our approach helps clinical researchers incorporate equity considerations into enrollment plans by identifying optimal numbers of participants in each subgroup for a given study size. The equity targets can be used to specify enrollment of race/ethnicity and gender subgroups for the NIH-required Planned Enrollment form. Our tool allows researchers to review and visualize how close the equity of an ongoing RCT recruitment effort is to the target. The tool is adaptable to meet other trial-specific goals. Future work includes developing a variant of the IP model to address multi-site trial planning, in which the number of participants that are enrolled at each site should meet overall equity targets.

COVID19 Hospital Length of Stay, Readmission Rate, and Hospital Death Tied to Socioeconomic Area of Deprivation Index

Priya Ramaswamy, MD MEng1, Phoebe Lu, MPH1, Jen J Gong, MS PhD1, Travis Porco, PhD MPH1, Priya B. Shete, MD MPH1, Seth Blumberg, MD PhD1, Xinran Liu, MD MS FAMIA1
1University of California, San Francisco, California, USA

Abstract

Higher Area of Deprivation Index (ADI), a socioeconomic measure based on US census data, is often associated with worse health outcomes. For 822 COVID-19-positive inpatient encounters at a California hospital system, we found evidence of relationships between ADI and 30-day readmission (p<0.001), in-hospital death (p<0.001), and hospital length of stay (p<0.001). Thus, disparities in the acute care of COVID patients should be addressed.

Introduction

There has been increased national interest in reducing healthcare disparities based on socioeconomic background, especially with the onset of the COVID-19 pandemic which has disproportionately impacted minorities and poorer neighborhoods.1

Area of Deprivation Index (ADI), a socioeconomic measure whose granularity is at the neighborhood (9-digit zip code) level, is derived from US census data aggregating factors like education, employment, income, poverty, and housing. There have been several studies focusing on aggregate COVID-19 positivity rates based on ADI, but less attention has been given to in-hospital outcomes. If such outcome disparities exist at the inpatient encounter level, then measures should be taken by health systems to improve COVID-health equity. We address this gap by measuring the relationship between Area of Deprivation Index (ADI) and inpatient outcomes such as hospital length-of-stay (LOS), all-cause readmission rate, and in-hospital death at a tertiary academic center.

Methods

After obtaining IRB approval at University of California, San Francisco, we identified hospitalization encounters for adult (age >=18) COVID-19-positive patients between February 2020 and April 2021. We used a third-party hospital-licensed API to identify the 9-digit zip-code for each patient encounter. We mapped these zip codes to the California ADI database (latest version 2018) from the Neighborhood Atlas2,3, resulting in ADI state-level decile scores of 1 (least disadvantaged) to 10 (most disadvantaged). We excluded patients with zip codes that were out-of-state and/or did not have an associated ADI from the 2018 census-derived ADI scores (i.e. new neighborhoods established after 2018).

To test the significance of the relationship between ADI and LOS, readmission, death, we fit a regression model for each outcome using ADI and covariates listed in Table 1 as regressors. For LOS, we used the log LOS as the outcome variable based on its empirical distribution. For binary outcomes readmission and death, we used a logit link in a binomial regression. We used a semiparametric GAM to model the effects of age and of ADI in each case. Data analysis was performed using Python (3.8.1) and statistical analysis was performed using R (R package mgcv).

Results

Based on our exclusion criteria, we analyzed data from 822 COVID-19-positive admissions (79% of all hospitalized COVID-19 patients). The average age was 60.2 years (SD = 19.5), and 51.6% of patients were male. The average LOS was 12.6 days (SEM = 0.61). The all-cause readmission rate was 13.6% and in-hospital death was 8.8%. Figure 1 shows the distribution of patients within each ADI decile, with most patients in ADI 1-3 (60.1%). Figure 2A shows the average LOS per ADI. Figure 2B shows all-cause readmission rates among the study population’s ADI scores. Notably, ADI of 10 had a 28% readmission rate, which was greater than 2.5-times that of ADI of 1. We found evidence of a relationship between ADI and in-hospital-death (p < 0.001), readmission (p < 0.001), and LOS (p < 0.001).

*Main outcome of interest

Figure 1. Inpatient Encounter Distribution of ADI

Figure 2. Inpatient Encounters (A) LOS per ADI (B) Readmission Rate per ADI

Conclusion

Our findings suggest a relationship between socioeconomic background and in-hospital outcomes related to COVID-19. Specifically, we find evidence of a relationship between ADI and 30-day readmission, in-hospital death, and hospital LOS in one metropolitan tertiary-care center. Further studies should investigate other confounding factors including specific comorbidities and severity of disease on admission. In the future, Area of Deprivation Index could be incorporated into the electronic health record to help risk-stratify a patient at time of admission, and hospital systems can develop measures to address COVID health inequity related to hospital readmission and death.

CovRNN: predicting outcomes of COVID-19 patients on admission using their electronic health records with minimal data processing

Laila Rasmy, MSc1, Masayuki Nigo, M.D2, Bijun Sai Kannadath, M.B.B.S, M.S3, Ziqian Xie, Ph.D1, Bingyu Mao, MA1, Khush Patel, MD1, Yujia Zhou, MSc1, Wanheng Zhang, M.S4, Angela Ross, PhD1, Hua Xu, PhD1, Degui Zhi, PhD1

1School of Biomedical Informatics, UTHealth, Houston, TX; 2McGovern Medical School, UTHealth, Houston, TX; 3College of Medicine, University of Arizona – Phoenix, AZ; 4School of Public Health, UTHealth, Houston, TX.

Introduction

Coronavirus disease (COVID-19) is an infectious disease that emerged in December 2019 and it leads to the death of more than four million patients worldwide by the mid of July 2021. During the peaks of the pandemic waves, many places have reported near-capacity hospital and intensive care unit (ICU) utilization. Accurate prediction of the future clinical trajectories of COVID-19 patients at the time of admission is crucial for clinical decision-making and enables efficient allocation of resources. A survey of the literature till the end of April 2021 showed only two studies1,2 trained their proposed models on more than 20,000 patients. Both of which are based on specific features and needed laborious data preprocessing and feature engineering processes that limit the transferability, reliability, and sustainability of such models.

We developed CovRNN, a collection of deep learning based predictive models for the clinical outcomes of COVID-19 patients including: in-hospital mortality (iMort), need for mechanical ventilation during the stay (mVent), and hospital stay longer than one week (pLOS). CovRNN models were trained on more than 200,000 hospitalized COVID-19 patients to accurately predict patients’ outcomes on admission using readily available structured electronic health records data (EHR) without the need for specific feature selection, feature engineering, or missing values imputation.

Methods

CovRNN utilized a gated recurrent neural networks (RNN) architecture namely gated recurrent unit (GRU) that encodes the temporal nature of patient history including the most recent COVID-19 visit as well as distant events that happened years ago. For iMort and mVent prediction tasks, CovRNN was trained to predict both time-to-event risk scores (survival prediction) as well as the all-time risk scores (binary prediction), to fit different clinical needs for healthcare workers confronting COVID-19.

We kept our data processing to the minimum to facilitate the transferability of our trained models among different datasets. We extracted all patient information on or before the date of their first hospital admission with COVID-19, including demographics, diagnosis, medication, procedures, laboratory results, and observations. We utilized standard terminologies that are readily available in the majority of EHR systems to facilitate interoperability: ICD 9, ICD10, and SNOMED-CT for diagnosis; LOINC and SNOMED-CT for laboratory tests and observations; Multum drug identifiers and categories for medications; and CPT-4, HCPCS, ICD-9 PCs, and ICD-10 PCs for procedures. In cases where a coding system is not used such as Multum codes for medication, pre-existing mapping tools are available that can be used to convert NDC medication codes to corresponding Multum information. For laboratory results, we used clinical interpretations such as “below normal low”, “normal”, or "above normal high", instead of using the actual numerical value. By doing so all our input data became in a categorical format so we can further convert our input into trainable embedding matrices which will learn the features representation that mediates our model robustness to input errors and generalizability.

CovRNN was trained on a large heterogeneous dataset of 243,785 de-identified patients data derived from 85 different health systems and available through the Cerner® Real-World Dataset (CRWD) hosted on the Cerner HealthDataLab. We reported our prediction accuracy and model calibration results on a large heterogeneous held-out test set of 48,781 patients. For external validation, we evaluated the CovRNN on two held-out hospitals' data and compared the model performance against traditional machine learning models logistic regression (LR) and light gradient boosting machine (LGBM) for baseline comparison. We reported the results of subgroup analysis to understand CovRNN performance in different populations and utilized the integrated gradient technique to explain the model predictions.
Results

CovRNN achieved AUC of around 93% for both in-hospital mortality and need for mechanical ventilation binary predictions (vs. around 91.5% and 90% for LGBM and LR respectively) and 86.5% for prediction of LOS > 7 days (vs. 81.7% and 80% for LGBM and LR respectively. For survival prediction, CovRNN achieved a C-index of 86% for mortality and 92.6% for mechanical ventilation. External validation, showed a consistently high prediction accuracy for CovRNN models, as shown in Table 1 and Table 2. Subgroup analysis showed consistent results among different populations based on race, geographical region, and comorbidities as appear in figure 2, while a slight decrease in the model prediction accuracy was observed for older age (65 years or older).

Discussion and Conclusion

To the best of our knowledge, CovRNN is the first RNN based model that can accurately predict different COVID-19 patient’s outcomes on admission, using readily available structured EHR in its raw categorical format without any need for specific feature selection, or missing values imputation.

Our trained COVID-19 outcomes prediction models achieve high prediction accuracy comparable to the state-of-the-art in the literature as well as good calibration and lower risk of bias as it was trained and evaluated on large heterogeneous datasets collected from different health systems. Moving forward, our models can be fine-tuned on new data for continuous improvement as recommended by the FDA's good machine learning practice. Furthermore, our framework includes a utility for model predictions explanation to facilitate clinical judgment on the model predictions. For clinicians fighting COVID-19 in the frontline, there are two potential actionable contributions of our work: (i) They can fine-tune our pre-trained model on their local data regardless of the size; (ii) Use our comprehensive model development framework to train a predictive model using their own data. In our work we considered the major factors to establish the feasibility of our model, however, further clinical validation is required.

Differential Presentation and Delays in Treatment for Acute Myocardial Infarction Associated with Sex and Race/Ethnicity

Harry Reyes Nieva, MAS; ¹ Tony Y. Sun, MA; ¹ Sharon R. Gorman, MA; ¹ Grace Mao; ¹
Noémie Elhadad, PhD
¹ Columbia University, New York, NY;

Introduction

Prior studies concerning disparities in medical intervention following acute myocardial infarction (AMI) have focused mainly on in-hospital mortality and long-term outcomes.¹ ² Given that prior research has shown the importance of early intervention at time of AMI, ideally within 90 minutes of arrival to the emergency department (ED), assessing differences in care practices during ED visits has the potential to produce actionable insights for mitigating disparities in care. Large data networks, such as the Observational Health Data Sciences and Informatics (OHDSI) collaborative, have the potential to support investigation of these epidemiological questions.³ In particular, the electronic health record (EHR), with its highly granular temporal information regarding clinician orders, can provide meaningful data for analysis. Moreover, informatics-based approaches, such as natural language processing of the clinical narrative, can help elucidate differences in disease presentation across patient groups. The aim of this study was to leverage the OHDSI data network to examine differences in presentation of AMI across sex and race/ethnicity, and identify potential disparities in timeliness of treatment.

Methods

We performed a retrospective observational cohort study of ED visits at the Columbia University Irving Medical Center in New York between January 2010 and June 2019 for patients presenting with AMI. We standardized data extracted from the EHR using the OHDSI Observational Medical Outcomes Partnership (OMOP) Common Data Model and identified patients with AMI-related ED visits using a combination of billing codes, EKG findings, laboratory measurements, and coded clinical observations. We excluded any patients with prior history of myocardial infarction. Detailed specifications are available online as an OHDSI ATLAS Cohort Definition.⁴ For each patient, we extracted administrative and EHR data, including ED visit notes. This study was approved by the Institutional Review Board at Columbia University.

Using named entity recognition,⁴ we extracted sign and symptom mentions from clinical narratives. We restricted our search to SNOMED clinical terms associated with the Unified Medical Language System (UMLS) disorder semantic group and the Clinical Observations Recordings and Encoding (CORE) Problem List Subset. We assessed differences in presentation of signs and symptoms among patients using Chi-squared tests with false discovery rate (FDR) correction for multiple comparisons. Using EHR timestamp data, we calculated length of stay and length of time from visit start to orders for first measurement, first medication, and first procedure. Based on these intervals, we fit multivariable Cox proportional-hazards models for in-hospital survival and time to first measurement, medication, and procedure.

Results

We identified 2,286 patients who presented to the ED during the review period with their first diagnosis of AMI. Patients were 54% male and 46% female with a mean age of 66 years (standard deviation [SD], 16) and 72 years (SD, 16), respectively. Among those with available data on race/ethnicity, 30% were Hispanic/Latinx, 16% were Caucasian/White, 11% were African American/Black, and 1% were Asian or Pacific Islander. A larger proportion of women had hypertension (91% vs 88%, p=0.02), were overweight or obese (24% of women vs 17% of men, p<0.001), and had depression (35% vs 31%, p=0.04), while a greater percentage of men had a history of alcohol or substance abuse (3% of women vs 8% of men, p<0.001 and 6% vs 9%, p=0.004, respectively).

Differences in in-hospital survival were not statistically significant for sex (p=0.84) or race/ethnicity (p=0.18). Analysis of clinical documentation reveals that, compared to male patients, female patients were less likely to exhibit diaphoresis and more likely to present with generalized pain, head pain, dyspepsia, epigastric pain, leg pain, esophageal reflux, musculoskeletal pain, malaise/fatigue, neck pain, and impaired cognition (Table 1).

*Ordered from largest to smallest odds ratio.

The analysis of time to different orders in the EHR yielded the following insights. Mean time to first measurement was 0.3 hours (SD, 1.0), first medication was 2.4 hours (SD, 3.1), and first procedure was 11.26 hours (SD, 5.9). We note that the average wait time until first medication and procedure are well beyond the golden response time since onset of symptoms (as they occur more than 2 hours after admission to the ED). Significant differences were found among women who presented with symptoms generally considered atypical for AMI. For example, women presenting with leg pain had longer waits for their first medication compared to men (adjusted Hazard Ratio [aHR]: 0.80; 95% CI: 0.71-0.92; p=0.04), even after correcting for FDR and adjusting for patient age, race/ethnicity, and comorbid conditions. African American and Latinx patients with AMI had longer wait times, on average, than other patients for their first medication (mean difference of 0.39 hours; p=0.04) and first procedure (mean difference of 0.89 hours; p=0.02). They also experienced longer lengths of stay with higher variability (195 hours [SD, 238] vs 194 hours [SD, 191]; p=0.03). Cox proportional-hazards models adjusted for age, sex, and comorbidities indicate that African American and Latinx patients experienced longer time-to-first-measurement (aHR: 0.88; 95% CI: 0.78-0.99; p=0.04) and time-to-first-procedure (aHR: 0.83; 95% CI: 0.73-0.94; p=0.003) compared to all other patients.

Conclusion
The granular data contained in ED documentation (temporality, detailed clinical narratives) enables investigation of differences in outcomes across different patient groups. Our analysis supports consideration of sex-based differences when diagnosing AMI and suggest disparities in time-to-treatment based on sex, racial/ethnic origin, and symptom presentation. The natural language processing analysis of clinical notes confirms that female patients are more likely to experience gastrointestinal symptoms, malaise/fatigue, impaired cognition and types of pain not typically associated with AMI compared to male patients and our analysis suggest that atypical presentation may lead to delays in care. The time-to-event analysis indicates that African American and Latinx patients with AMI have longer wait times and lengths of stay compared to other patients. By leveraging the OHDSI common data model, our analysis is reproducible. Our next steps are to carry out a network study across OHDSI sites with access to EHR documentation. Further work will also build on our analysis to identify patients with atypical presentation who were originally misdiagnosed. Extrapolating from our findings, we hypothesize that atypical presentations would lead to greater misdiagnosis and care delays, particularly among women.

Challenges to Public Health Reporting Experienced by Hospitals

Chelsea Richwine, PhD1, Carmelita Marshall, MS, PMP1, Christian Johnson, MPH1, Vaishali Patel PhD MPH1

1Office of the National Coordinator for Health Information Technology, Washington, D.C.

Introduction

Amidst a global pandemic, the need for efficient exchange of public health information between hospitals and public health agencies (PHAs) has never been stronger. To strengthen PHAs’ ability to monitor and respond to disease outbreaks, the Centers for Medicare and Medicaid Services (CMS) require hospitals to report health information to local, state, and federal PHAs as a condition for meeting Promoting Interoperability (PI) program requirements. Understanding challenges hospitals faced related to public health reporting just prior to the pandemic provides insights into their readiness to support PHAs’ abilities to monitor and address the pandemic. This abstract uses nationally representative survey data from the 2019 American Hospital Association (AHA) Information Technology (IT) supplement to describe the number and types of challenges hospitals experienced when submitting health information to public health agencies and how these challenges varied by state and hospital characteristics.

Data Source and Methods

Data come from the 2019 AHA IT Supplement Survey. The survey was administered via mail or a secure online website and was in the field from early January 2020 through the end of June 2020. Target respondents were hospital chief information officers reporting on hospitals’ health IT capabilities and experiences. In this study we analyzed data from a sub-population of 2,645 non-federal acute care hospitals, whose survey response rate was 59%. The sample was further restricted to hospitals that answered the question about challenges experienced when submitting health information to PHAs, resulting in a sample of 2,606 hospitals. Responses were weighted to account for non-response. To understand the extent of public health reporting challenges experienced by hospitals, we assessed the number and types of challenges reported. We also examined whether the types of challenges experienced varied significantly by hospital characteristics (i.e., hospital size, rurality, critical access status, system affiliation) or geographic location.

Results

Number of Challenges Experienced by Hospitals

A majority of hospitals reported experiencing at least one challenge reporting health information to PHAs. Among those who experienced one or more challenges, more than half experienced one or two challenges and less than a quarter experienced three or more challenges (Figure 1).

Figure 1. Number Challenges Experienced by Hospitals, 2019

1 Challenge, 28%
2 Challenges, 23%
3 Challenges, 16%
4 or more challenges, 3%

Types of Challenges Experienced by Hospitals

Interface-related issues and a lack of capacity to electronically exchange information were the most common challenges experienced by hospitals (Table 1). About one in five hospitals also reported difficulty extracting relevant information from electronic health records (EHR) or issues exchanging information due to differing vocabulary standards. Approximately 6 percent of hospitals experienced other challenges not listed in Table 1 below.
No HIE participation 4% 51% 15% 38% 17%

| Issues with capacity (e.g., technical, staffing) to electronically exchange information | 50% |
| Interface-related issues (e.g., costs, complexity) make it difficult to send the information | 40% |
| We use different vocabulary standards than the PHA, making it difficult to exchange | 19% |
| Difficulty extracting relevant information from EHR | 17% |
| We don’t know which PHAs our hospital should send info to meet CMS reporting requirements | 4% |

Source: 2019 AHA IT Supplement Survey. ‘Refers to hospitals’ lack of capacity to electronically send information or PHAs’ lack of capacity to electronically receive the information.

Variation in Challenges Experienced by Hospitals

Examine the different types of challenges reported at the state-level reveals substantial variation in public health reporting challenges experienced by hospitals. For instance, half of all hospitals nationally reported issues with the capacity to electronically exchange information. However, the prevalence of the challenge ranges from as low as 17 percent of hospitals in Michigan to as high as 100 percent of hospitals in Rhode Island (Figure 2).

</tr>
</tbody>
</table>

In addition to geographic variation, the overall number and types of challenges experienced varied by hospital characteristics (Table 2). Small and rural hospitals were more likely to report interface-related issues, difficulty extracting relevant information, and confusion about where to send information. Similar patterns held for independent and critical access hospitals (CAH). Hospitals participating in a health information organization (HIO) were less likely to experience difficulties extracting relevant information compared to non-participating hospitals.

Discussion

Understanding the number and types of challenges experienced by hospitals is critical to developing solutions aimed at improving hospital and PHA capacity to effectively exchange health information. This study shows that just prior to the pandemic a majority of hospitals experienced public health reporting challenges that would impact PHAs’ ability to monitor and address disease outbreaks. These findings are consistent with 2018 survey findings, suggesting these were not emergent issues. Challenges reported by hospitals suggest the need to improve the methods used to exchange information with PHAs. Our findings indicate a potential role for HIOs to support public health by facilitating this exchange. Increased data standardization and bulk reporting could also improve hospitals’ capacity to exchange data with PHAs. Further, variation in challenges by state indicate potential differences in PHA exchange capacity that need to be addressed to support key public health activities related to COVID-19 and future public health emergencies.

Signal from the Noise: Quantitative Measures of Conformity and Variability From Process Mining Graphs

Christian C. Rose∗,1, Morteza Noshad∗,2, Jonathan H. Chen2,3

Introduction

Many life-threatening emergent medical conditions require time-sensitive progression through multiple points of evaluation and management to deliver definitive life-saving interventions. In the case of an acute stroke, blood samples must be collected by a nurse, evaluation must be performed by a physician, the CT scanner must be prepared by a technician and a pharmacist must prepare medications as soon as a stroke has been identified by a radiologist. Studying and improving care processes for these conditions underlies the vision of a learning healthcare system.

Given that these conditions are often complex, requiring multiple providers with differing responsibilities in multiple care settings, it can be difficult to obtain granular detail about how they occur in practice. However, understanding the current process is critical for determining how much variation there is in the process across the organization, where performance problems exist, and where to invest in improvements. Defining current state of processes has hitherto often relied on expert opinion and recall instead of direct observation which can be time-consuming and lack generalizability. Process mining, the method of determining the order of events from an event log, may address these issues.† Process mining can help organizations easily capture workflow information from enterprise systems and provides detailed, data-driven insights about how key processes are being performed. ‡ These logs may illuminate how computer-mediated work, where most of the clinical time may be spent, is really happening - including who did it, how long it takes, and how it deviates from best practice guidelines.

However, a graphical representation alone may not be useful for continuous quality improvement. Hospitals may want to know how much an individual case differed from the standard of care or how variable the process is across their institutions so that they can intervene with educational or decision support initiatives. Here, we utilize process mining of the event log from a common EHR vendor, Epic, at our academic medical center to build a model for tPA management of stroke care. We then utilize the process map to identify the most common pathway (MCP) at our institution. Individual pathways are then compared to the MCP to determine their conformity and the variability of conformity scores across all cases is used to determine variability - comparable to a standard deviation score. It is hoped that the robust mapping and quantitative assessment of critical pathways can then be used to identify and maintain the highest possible quality of care.

Methods

Process mining is based on a set of simple rules to create a graph. In this graph the nodes represent the clinical events, edges represent the subsequent events, edge labels show the relative lag between the events. The graph nodes are time-ordered from beginning to end. For our stroke patients, these nodes began with the emergency department admission and ended with tPA-administration. The edges of the process mining graph connect the pairs of nodes that happen sequentially in the event-log data. They are then given a weight based on the probability that the two events will occur in series over the entire set of possibilities. The most common path is thus the series of edges from beginning to end with the greatest weights.

While the primary application of the proposed process mining graph is to represent the scope of common pathways for a process of interest, it may also be helpful to measure the conformance of the pathways across patients or encounters. Many factors may affect the conformity to a particular pathway. Patients may present for evaluation with different symptoms, from different locations (near or far from the hospital), or the ED may be busy at the time of presentation. A particular encounter can be compared against the rest to better understand how it compares.

We propose the following conformity score using the probability weights of the edges:

\[
C_P = \frac{1}{|E_P|} \sum_{e \in E_P} p_e
\]
where \( P \) represents a path for a patient, \( E_P \) is the set of all of the edges for the patient \( P \), and \( p_e \) are the probability weights for the edge \( e \). A higher conformity score means the patient’s path closer to the expected pathway from the probability of each edge in that pathway, whereas lower conformity scores are associated with encounters that proceeded through a much less probable series of events. The variability score represents the average differences in conformity scores across all cases, which is normalized for all the possible edges.

**Results**

We were able to automatically create a workflow model for the care of acute stroke patients receiving tPA in our hospital by utilizing the event log data captured in our EHR. Our analysis resulted in a graphical representation of the most common pathway (a process map which we could not include here due to space limitations), which progressed according to the series of events anticipated by our hospitals “Code Stroke” guidelines. We were also able to calculate conformity and variability scores for our pathway from our process mapping data, which were a conformity of 0.64 for the MCP and a variance of 0.36 for the entire graph. We identified specific subsets of care which had minimal variability to each other, but poor conformance to the average pathway - which may represent out of hospital code strokes or other practice deviations and settings.

**Discussion**

Simple process measures like “time-to-tPA” have been used to confer the totality of the experience and to set a benchmark for the quality of care despite the complexity of decisions and actions that take place in the setting of emergent conditions. Process mining offers a unique opportunity to unveil the totality of actions taking place from the moment the patient presents by utilizing event log data. Even simple “spaghetti” graphs which result from process mining might help clinicians identify bottlenecks or areas of high variability. They can be used to identify patient or provider clusters (like out of hospital stroke activations) which result in particular outcomes of interest (like faster time to tPA) or to predict the set of future nodes from the current state allowing for streamlined care.

However, such graphs face some limitations. They traditionally weight all pathways equally, limiting their use in identifying the most common pathway or to provide measures for pathway conformity or variability. Such measures could be used to trend the consistency of interventions within an institution and to identify the effect of process or quality improvement initiatives on practice. They can also be used to identify those pathways which result in the highest quality outcome of interest and thus coordinate care accordingly.

This exploratory work represents the first step in utilizing this graphical process to create reproducible measures which may then be used for quality improvement initiatives. Individual cases may be reviewed based on the outcome of the patient to understand if the care provided was close to that which was expected or ”standard” for that institution. Case review committees might review the pathway of those with negative outcomes to understand if they had the expected sequence of events but simply represent an unfortunate, perhaps inevitable outcome. On the other hand, cases with good outcomes but with low conformity scores may represent ”near misses” - an opportunity to intervene for education or training. Furthermore department directors may want to compare variability across sites. High variability may represent an opportunity to intervene to streamline workflows - much like development of code-stroke pathways - which can be compared before and after those interventions.

It is hoped that with a clearer understanding of how care is actually provided, and a reproducible, measurable way to evaluate it we can then begin to describe and thus improve these processes and the patient care associated with them.

Cyberchondria: Does mHealth Technology Reassure Patients or Promote Hypervigilance? An Observational Cohort Study Following Total Joint Arthroplasty

Benjamin I. Rosner, MD, PhD
1University of California San Francisco, San Francisco, CA

Introduction
Historically, the hypervigilant patient was one who presented for care, sometimes unnecessarily, with heightened concerns about minor signs or symptoms. As the internet democratized the availability of both good and questionable health information, the term “cyberchondria” described a new internet-informed (or misinformation) version of hypervigilance. As mobile health (mHealth) and digital patient engagement (DPE) platforms that asynchronously guide patients through episodes of care over time and offer them regular reminders to watch for red flag symptoms pervade more deeply throughout healthcare, the question is whether such platforms decrease potentially avoidable healthcare encounters as intended, or increase utilization through heightened patient awareness and vigilance.

We describe a two-site study in which a DPE platform guided patients remotely pre and post total joint arthroplasty (TJA) via automated serial push notifications, and examine the impact on 30-day post-discharge emergency department (ED) visit rates. Such platforms have been shown to decrease hospital readmission rates, but we sought to understand whether ED visit rates decrease when patients are guided through longitudinal care plans remotely, or whether reminders about red flag symptoms may lead to unintended excess ED utilization.

Methods
We carried out a retrospective observational cohort study at two clinical sites in Maryland using a DPE platform (HealthLoop) for patients undergoing TJA between April 6, 2017 and October 13, 2018. As the platform was being used for routine clinical care for all patients, the only eligibility requirements were that patients had email or a smartphone and internet or cellular data access. Through the platform, patients received automated pre-operative education, and a 4-week tapering schedule of automated post-operative education, symptom assessments, and reminders of the signs and symptoms of complications including deep vein thrombosis, pulmonary embolism, surgical site infection, hemorrhage, dislocation, and narcotic induced constipation. Patient engagement was measured longitudinally as the ratio of patient interactions with the platform relative to automated, scheduled interactions that patients were prompted to complete. The primary outcome was the rate of 30-day ED visits ascertained by patient self-report. Self-report of this metric through the platform has been validated against claims data and described elsewhere, characterized by an agreement of 0.96 and a kappa statistic of 0.45, and free of non-response bias. We compared these ED visit rates to both a national set of orthopedic practices using the same platform, and to a regional all-Maryland benchmark from the Healthcare Cost and Utilization Project (HCUP) state emergency department database (SEDD) and state inpatient database (SID). Maryland data were selected for this analysis because Maryland is one of a few states for which the SEDD is linked with the SID, enabling patient-specific tracking of healthcare utilization following an index encounter. Fisher’s exact test was used to compare outcomes with \( P<0.05 \) considered significant.

Results
Summary statistics of the available demographics are shown in Table 1. We found that Maryland patients on a DPE platform had 60.7% and 13.4% relative reductions in 30-day ED visit rates after hip (61/149 vs. 884/8662, \( P<0.01 \)), and knee arthroplasty (14/167 vs. 1287/13302, \( P=0.69 \)) respectively, compared to a state HCUP benchmark. (Figure 1) To better understand the drivers of these reductions, we segmented the 30-day ED visits by patients who were treated and admitted and those who were treated and released. For hip and knee arthroplasty, there were greater relative reductions for treat and admit (84.4% relative reduction, \( P<0.02 \); and 78.6% relative reduction, \( P=0.10 \), respectively) than for treat and release (41.1% relative reduction, \( P=0.28 \); and 14.7% relative increase, \( P=0.64 \), respectively), with treat and admit for hip arthroplasty being the only one to reach significance. However, an accentuated effect, with significant reductions in both ED visit types for knee and hip arthroplasty \( (P<0.001) \) was seen in the larger sample sizes associated with the national DPE cohort, although a matching national HCUP
benchmark (with linked SID and SEDD datasets) was not available for a direct geographically matched comparison.

**Conclusion**

The findings from this study suggest that for hip arthroplasty in the two site Maryland cohort, overall ED visits and those ED visits resulting in admissions decreased significantly, without significant change in ED treat and release rates. Furthermore, there were no significant changes for ED visit rates in this cohort following knee arthroplasty. The reason for the differential effect between the two procedure types (i.e. significance for hip metrics but not for knee metrics) is not clear, but could be due to the relatively smaller sample sizes of the Maryland cohort, particularly since consistent trends become more evident with the larger cohort of the national DPE sample. In both cases, hip and knee arthroplasty, ED utilization showed no significant increases. These findings imply that mHealth technologies that increase patient awareness of red flag symptoms, don’t necessarily significantly increase hypervigilance as measured through ED visit rates, and that they may, in some circumstances, decrease these rates as intended. Reduced rates of ED visits may be explained, in part, by better adherence to aftercare instructions resulting in greater complication avoidance.

As mHealth technologies are put into the hands of patients, they have the potential to educate or to exacerbate. Our study demonstrates that it is possible to leverage these systems to elevate patient awareness about red flag symptoms, without increasing cyberchondria that results in significant excess 30-day emergency department utilization.

**References**

**Abstract**

Mobile health technologies are powerful tools for educating patients, but a side effect is their potential to create hypervigilance and increased healthcare utilization. We conducted a retrospective observational study of two clinical sites in Maryland using a digital patient engagement platform, and compared 30-day emergency department visit rates post-arthroplasty against an all Maryland HCUP benchmark. We found no significant increase in 30-day emergency department utilization, and following hip arthroplasty, there was a significant decrease.
The Efficient Inpatient Provider
Wh-EHR to Find Best Practices

Benjamin I. Rosner, MD, PhD¹, Robert Thombley, Wendi Zhao, MD, MHI¹
¹University of California San Francisco, San Francisco, CA

Introduction
Efficient delivery of care is an important prognostic marker of physician well-being and resilience, while the inverse has been associated with burnout and turnover. In recent years, proprietary provider efficiency profiles (PEPs) have been developed by Epic Systems (Verona, WI) that leverage the audit logs (timestamped records of digital actions taken) of the electronic health record (EHR) to describe the relative efficiency of ambulatory care providers, including measures of time spent in the EHR during clinic hours and after hours (“pajama time”). However, little is known about the provider efficiency in the inpatient setting, and the digital factors that distinguish higher efficiency providers from those with lower efficiency. If it is possible to identify high efficiency providers and to understand the behaviors and factors that are associated with efficiency, then best practices could be shared across care settings.

We describe an evaluation of inpatient adult Hospital Medicine providers at a large academic medical center to (1): Identify those with higher and lower levels of average daily work time (a surrogate of efficiency), and (2) Understand intrinsic or extrinsic factors that distinguish between these two groups.

Methods
We performed a 6-month cross-sectional study of adult Hospital Medicine attending physicians on primary inpatient non-teaching services at the University of California San Francisco between January 1, 2019 and June 30, 2019. We used the audit logs of the EHR to characterize physician daily work time, segregating it into the portion carried out locally at the hospital, and the portion carried out remotely (“pajama time”). We then identified the quartiles of physicians with the lowest and highest average daily work times to study factors associated with observed differences.

We developed an ordinary least squares (OLS) regression model with standard errors clustered by provider to examine the degree to which a number of explanatory variables, both intrinsic and extrinsic to the provider explain the differences observed in average daily work time between the highest and lowest provider quartiles. Variables extrinsic to the provider, including daily patient census, daily patient APR-DRG distribution (an encounter level metric of patient illness severity), number of daily discharges to the community and to post-acute care facilities, number of daily minutes of electronic translation services used, and number of daily pages received, were derived from the EHR audit log, translation service logs, and pager logs. Variables intrinsic to the provider included gender and number of years in practice. Student’s two-sided t-test and Fisher’s exact tests were used to compare continuous and categorical variables respectively. P < .05 was considered significant.

Results
Fifty six physicians were captured in our study period, with 58.9% (33/56) female, and an average (SD) of 7.91 (± 2.85) years of practice experience. On this specific non-teaching, attending only service (one of several services on which these

Figure 1. Average daily worktime for all physicians in the study cohort.
hospitalists at our institution practice), they provided care across 1,595 unique patients, totaling 1,073 physician-days. We found that the average daily work time (Figure 1) for physicians ranged from 7.27 to 14.54 hours, representing a 2-fold difference between the extremes ($P < 0.001$). 89.3% of physicians (50/56) logged some remote work time. In comparing the quartile of physicians with lowest and highest average daily work times, we found a significant difference (8.43 vs. 12.24 hours, $P < 0.001$), and no difference in the proportion of physicians between the two quartiles (12/14 in each) who had logged remote work time ($P = 1.0$).

Overall, the OLS model had an adjusted $R^2$ of 0.274, suggesting that the factors considered describe about 27% of the variability in daily work time observed. (Table 1) By way of reference, when studying human behavior, $R^2$ values greater than 0.25 have been characterized by some as large.\(^1\) Residuals were normally distributed and there was no correlation among predictors (maximum absolute value of Pearson correlation coefficient of 0.188, and maximum variance inflation factor of 1.9). The model demonstrated that neither of the intrinsic variables (gender or years in practice) significantly explained variability in worktime between the lowest and highest quartiles. Of the extrinsic variables, neither patient census, APR-DRG, nor the number of community or post-acute care facility discharges done per day reached a level of significance. However, the average number of minutes spent using translation services and the number of pages received were significant ($P = .015$, and $P < .001$ respectively).

### Conclusion

As in the ambulatory setting, efficiency in the inpatient setting may be an important factor associated with physician resilience, clinical outcomes, and quality of care. If we wish to discover and disseminate best practices of highly efficient inpatient providers, we must first identify who they are, and then we must understand the differences between the factors characterizing their practice of care - including total daily work hours - and those of providers who are less efficient.

In our identification of inpatient hospital medicine providers with lower and higher average daily work times, it is noteworthy that many extrinsic factors such as patient census, patient illness severity, and the volume of discharges daily do not significantly explain differences in work time, suggesting that providers are similarly equipped to manage these factors. It is also noteworthy that neither of the intrinsic factors examined, provider gender and years of practice, were significantly associated with differences in work time. Two extrinsic factors, time spent with translation services, and the number of pages received were significant in explaining work time variability. In total, the factors considered explained about 27% of the variability observed in work time, leaving a variety of other potential intrinsic factors to be examined in ongoing research, including, for example, how providers leverage efficiency tools within the EHR (e.g. text shortcuts, order sets, etc.), as well as the daily path navigated through the EHR itself.

Pre- and Intra-COVID-19 Comparison of Nursing Flowsheet Documentation Burden in Acute and Critical Care Units

Introduction
At the outset of the COVID-19 pandemic the need to decrease any burdens on clinicians that took time away from direct patient care or unnecessarily increase risk of exposure was recognized. Decreasing documentation burden was a large focus of these efforts at the local level1 and through a Center for Medicare and Medicaid Services (CMS) waiver.2 These changes to minimum documentation requirements provides a unique natural experiment to study EHR burden. We aimed to study year over year changes in documentation rates and hypothesized that they would decrease in 2020. Our team replicated our methods and compared prior findings quantifying nursing flowsheet documentation from 2017 data3 with additional pre-COVID-19 years (2018 and 2019) and an intra-COVID-19 pandemic year (2020).

Methods
We replicated queries and analytical methods from our prior publication analyzing nursing flowsheet documentation burden of 2017 data.3 We extended our 2017 data set to include two more years of pre-COVID-19 data (2018 and 2019) which allowed for analysis of year over year trends, and included 2020 as the intra-COVID-19 data set for the same 4 acute care units (ACU) (specialty: general medicine) and 2 intensive care units (ICU) (specialty: medical) at a large academic medical center as in our prior study.3 Please see our prior publication for specific methods and rationales that were replicated to extract and calculate rates of documentation per nurse, per patient for 12 hour shifts on our study units, including separating out manually entered data from auto-populated device integrated data entries.3

Prior to the COVID-19 pandemic there was a minimum data set of required data elements, such as vital signs and pain assessment. Our study site activated the hospital’s “disaster documentation” mode (changes in EHR configuration and policy) due to the surge in patient demand from 4/1/2020–7/13/2020. The intent of this “disaster documentation” mode was to reduce the extent and frequency of the data elements required for documentation based on CMS COVID-19 waivers. Our site also provided newly configured EHR “navigator” functionality to streamline the new documentation workflows.1 Two changes had implications for flowsheet documentation: 1) documentation by exception, and 2) reassessment required only once per shift in the ICU and required only as appropriate in the ACU.4 Notably, these are minimum requirements. Nurses may (and should) document as appropriate per patient condition, but that is up to the nurse’s judgement rather than dictated by a universal policy for all patients. Another important study-wide impact during our analysis period was the deferral of all elective procedures and ambulatory appointments beginning 3/16/2020 with a phased recovery period through 7/6/2020 in order to preserve inpatient resources for COVID-19 patients. In order to account for these fluctuating rates of patient admissions, we controlled for census in our documentation rates by calculating per nurse per patient. We calculated a time-series 14 day moving average of nurse flowsheet documentation rates per patient per shift in order to compare year over year changes. We also calculated T-Tests to identify any statistically significant changes in documentation rates year over year. Finally, we calculated data entry sessions and plotted sessions in a histogram to understand when the largest (by percent) documentation period occurred in a shift (figure excluded due to space constraints). Our team is currently performing analyses to also control for patient acuity and these data will be presented at the Annual Symposium. Study IRB approval was obtained.

Results
Our time series analyses indicated overall stable trends of manual flowsheet documentation rates per nurse per patient year over year from 2017 to 2019 (Figure 1), and we found significant changes in flowsheet documentation rates during the COVID-19 pandemic in 2020 (e.g., Apr 2019 vs Apr 2020: t(58)=-2.9735, P=0.0043). Most notably, there were steep increases in documentation rates in March-April 2020 across all of our study units (Figure 1). We also looked for emerging patterns in any specific flowsheet measures that contributed to the increase of the documentation rate but did not identify clear clinical categories driving the increase. Device integrated data entries accounted for
2.51%-2.75% of flowsheet data entries across our sample in 2017, 2.14%-2.41% in 2018, 1.85%-2.05% in 2019, 2.31%-2.53% in 2020. Seventy percent of all manual data entries occur in sessions between 8am - 11am and 3pm - 6pm, with approximately 5% more documentation occurring during the 8am-11am session in 2020.

Discussion
We observed an increase in year over year documentation trends for 2020 with a spike in March to April 2020. Our data also indicates that within a month after “disaster documentation” mode (which is intended to decrease documentation burden) was implemented in April 2020 documentation rates were consistent with the year over year rates of prior years, indicating that factors other than EHR configuration and policy were likely driving nurses decisions to document more. There may be several possible explanations for the increase in documentation, and our study design is not intended to identify explanatory data. However, we do point to a similar pattern that our study team has identified and quantified on an individual nurse level—when a nurse is concerned about a patient he/she increases patient surveillance activities (beyond requirements) of specific flowsheet measures.

It is possible that nurses, as they encountered COVID-19 patients, increased their documentation rates due to clinical concern or uncertainty. This would be consistent with early reports of clinical uncertainty in how to treat COVID-19 patients, and that we know in the early months of the pandemic only the sickest patients were hospitalized. Moreover, during the months when “disaster documentation” mode was active after April 2020, documentation rates only decreased to levels similar to prior years, as opposed to lower than prior years (the intent of “disaster documentation” mode). If the increased documentation we observed in this study is due to nurse’s concern about COVID-19 patients that would have important implications for how to address the problem of documentation burden. In other words, the finding that nurses in aggregate increase their documentation (and presumably increase patient surveillance activities) due to a patient state in the absence of requirements would justify efforts for innovative modalities to better support nurses’ data capture, rather than only a focus on reduction of requirements and data elements within the EHR. Self-imposed documentation burden has also been identified as a product of organizational culture. Nurses’ decisions related to documentation require further investigation. In this study we identified no increase in the amount of automated device-integrated data captured from 2017-2020 and data elements that were sometimes captured using automated device data and other times manually entered, indicating immediate room for improvement in the implementation of device integration. Limitations: This study took place at a single academic medical center. We accounted for census changes, but not for case-mix index/acuity which could also impact documentation. Some trends could also be due to EHR configuration changes unrelated to COVID-19.

Conclusion
We found significant changes in manual flowsheet documentation rates during the COVID-19 pandemic in 2020, including steep increases in documentation rates at a time when decreases may have been expected instead. Future work to explore explanations for why documentation rates changed during 2020 should occur to shed light into nursing practice and decision-making amidst uncertain clinical circumstances and patient states, as well as better formulate the specific barriers facing nursing in the effort to reduce documentation burden.

Abstract
The recently launched MMRF CureCloud(R) Direct-to-Patient Registry and Research Study aims to generate longitudinal genomic and clinical data from over 5000 myeloma patients and share this data with the patients and their doctors, empowering them to make informed decisions for the management of the disease. More than 950 patients have screened into the CureCloud study in a year since the launch and biosamples have been collected from over 300 patients

Introduction
In July 2020, the Multiple Myeloma Research Foundation (MMRF) launched the CureCloud(R): Direct-to-Patient Registry (CC-DTP) and Research Study (ClinicalTrials.gov Registration Number: NCT03657251) with the objectives of: a) aggregating Electronic Health Records (EHR), genomic data, patient-reported outcomes, immune profiles, and patient surveys from over 5000 myeloma patients in the next five years and b) making these integrated datasets available to patients and their clinicians, enabling them to use this information to make informed decisions for disease management, including targeted therapy selection and clinical trial enrollment.

Methods
STEP 1: The patient registers at the CC-DTP website and answers screening inclusion/exclusion questions. If entry criteria are met, the patient digitally signs the consent to participate in the study, a release of data request, Health Insurance Portability and Accountability Act (HIPAA) Release of Information (ROI) forms and, in the case of a California resident, a California Patient Bill of Rights. The patient also answers a demographic and medical history survey in addition to providing the names of all medical institutions and clinicians where they have received treatment for myeloma. Lastly, the patient is given a blood draw order form to be signed by their primary hematologist/oncologist. The patient is fully enrolled in the study once the form is signed and returned to the MMRF

STEP 2A: Once fully enrolled, a copy of the digitally signed consent and the HIPAA ROI form are transferred to Cota Healthcare, the Electronic Health Records (EHR) data curation partner to begin the process of making EHR requests at each institution where the patient has received treatment. The records, once obtained, are processed for information abstraction.

STEP 2B: Concurrently with Step 2A, the Broad Institute’s CLIA-certified Assay Team uses the CC-DTP shipping portal to ship a blood draw kit to the patient’s home, to await the phlebotomist’s arrival. STE

STEP 2C: Concurrently with Step 2B, an order is sent via an API (Application Programming Interface) to the phlebotomy partner for the MMRF to set up an in-home blood draw. Patients receive messages through the CC-DTP portal alerting them to expect the kit to arrive at their homes and a call from the phlebotomy partner to schedule the heme biopsy needed for genomic sequencing and biobanking. The phlebotomist arrives at the patient’s residence (with Covid-19 precautions in place) at an arranged date to draw four tubes of blood. One tube is sent to the Broad Institute for the 70-gene myeloma-specific panel; the others are sent to the MMRF CureCloud Biobank, where they are kept in liquid nitrogen for future bioassays including immune profiling.

STEP 3: When the sequencing and the variant calls are completed at Broad, the resulting files are transferred, via secure, encrypted channels to the Dana Farber Cancer Institute Department of Pathology where the somatic variant calls are made and confirmed by staff hematopathologists who sign out the genomics report. The genomic report is
returned to the CureCloud workflow engine in PDF and JSON formats. The PDF file is sent to the patient’s primary hematologist.

STEP 4: After the pathology report is returned, the variant calls are read from the JSON files and transmitted to the genomic counseling partner, who then takes those calls and creates a patient-readable report at the 8th-grade reading level. Secure links to the patient report are posted to the CC-DTP Patient Portal with information about clinical trials the patient may be eligible for. Copies of the reports are stored in MMRF Google Buckets as PDF files and in JSON format in the CureCloud database.

![Figure 1: The workflow of the MMRF CureCloud Direct-to-Patient (CC-DTP) Registry](image)

**Results**
In the year since going live, more than 950 patients have screened into the study, of which 727 patients have completed all the steps for enrollment. Blood samples have been collected from 302 patients, from which genomic reports have been generated and shared with 292 patients and their doctors along with their clinical information; the other 2 were set aside for research purposes only (Table 1)

| Table 1: Counts of multiple myeloma patients in MMRF CureCloud (On: August 6, 2021) |
|---------------------------------|--------|
| Signed up on CureCloud homepage and screened in | 953    |
| Completed paperwork and Consent | 727    |
| Doctor approved Blood Draw      | 582    |
| Blood Biopsies Obtained         | 302    |
| Reports generated and shared    | 292    |

**Discussion**
The patient enrollment numbers for CureCloud project are comparable with the numbers for other contemporary observational studies despite the impact of delays due to Covid-19, coordination issues among multiple partners, biospecimen collection issues, and healthcare centers refusing to release patient records for extramural research.

**Conclusions**
The CureCloud study is well on its way towards collecting and integrating heterogeneous data from 5000 patients. The translational analysis workflows developed against these datasets will drive novel research initiatives, which will significantly improve the quality of life and life expectancies of myeloma patients.
Systematic replication of smoking disease associations in the All of Us Research Program

Introduction
The All of Us Research Program (All of Us)1 is a multi-site, national study with the goal of recruiting at least one million participants to further precision medicine. In this study, we assess the extent to which the currently-available dataset of the All of Us can replicate known findings reported in meta-analyses with a commonly studied environmental exposure, cigarette smoking, as defined in Electronic Health Record (EHR) data and via survey responses completed upon enrollment.

Methods
To assess the association between smoking and phenotypes represented in the All of Us, we implemented three Phenome-Wide Association Studies (PheWAS)2. For the independent variables of interest, we used EHR-defined smoking as well as more granular representations of smoking (ever and current smoking) using participant provided survey results (PPI). We defined ever-smoking exposure from EHR data (‘EHR Ever Smoker’) by identifying all participants with at least two instances on separate calendar days of billing codes related to smoking. Never smokers from EHR data (‘EHR Never Smoker’) were participants with zero occurrences of the billing codes used to define EHR Ever Smokers and at least one other billing code present. For survey-based exposure, we used the All of Us “Lifestyle” survey responses. We used an affirmative response to “Have you smoked at least 100 cigarettes in your entire life” to define “Survey Ever Smoker”, and the branching logic question “Do you now smoke cigarettes every day, some days, or not at all?” with the response “Every day” to designate “Current Smokers.” Participants answering “No” to the 100 cigarettes question were included as “Survey Never Smokers”, and participants skipping the question were excluded. Analyses were adjusted for age at last relevant EHR code, sex at birth, race and ethnicity from survey responses, EHR length as reflected by time between first and last billing code, and number of unique billing codes per record. To benchmark the associations uncovered in the All of Us dataset, we compared phenome-wide significant results to known phenotypic associations assessed in meta-analyses found on PubMed. First, we extracted all smoking and tobacco-related meta-analyses from PubMed (N=1840) using the easyPubMed R package. We excluded studies investigating marijuana, vaping, chewing tobacco etc., which resulted in 538 studies that we matched to known phecodes where possible. We then merged this list to all phenotypes with at least one phenome-wide significant result among the three PheWAS analyses. We ran the analysis using the All of Us Researcher Workbench using Python 3, and will be made available to any approved All of Us researcher.

Results
The PheWAS using EHR smoking, Survey ever, and Survey current smoking returned 657, 489, and 602 phenome-wide significant results, respectively. Figure 1 presents a comparison of all PheWAS effect sizes across the three analyses and crosstabulation of counts for PPI Smoking representation versus EHR smoking among participants who had both. We see that the effect sizes for current smoking are closer to the EHR smoking effect
sizes. For the current-smoking meta-analyses, 63 unique phenotypes were matched to phenome-wide significant results. Of these meta-analytic effects, 53 phenotypes had an effect with a 95% CI excluding zero. Among PheWAS results, 45 phenotypes (84.9%) were concordant (36 of the PPI Current results, 42 of the EHR Smoking results) and 13 phenotypes (24.5%) were discordant (13 of the PPI Current results, 7 of the EHR Smoking results) in the sign of the effect size with at least one meta-analysis effect size (note, several phenotypes had multiple meta-analyses associated with them as can be seen in Figure 2.). For the ever-smoking meta-analyses, 36 unique phenotypes with 32 with CIs excluding zero, were matched to phenome-wide significant results. Of the 32 phenotypes, 28 (87.5%) of the phenotypes in the PheWAS analyses agreed (24 of the PPI Ever results, 25 of the EHR smoking results) with at least one meta-analysis for current smoking. Figure 2 presents forest plots of PheWAS effect sizes compared to their corresponding meta analyses. Here, we can see concordance in the direction of effect size between All of Us and meta-analyses for well-known outcomes such as lung cancer.

Discussion

In this study, we found that the majority of phenome-wide significant phenotypes (that were able to be matched to a meta analysis) found in each of three PheWAS were able to rapidly replicate the direction of at least one previously published meta-analysis effect size. Survey driven smoking provides a more sensitive and detailed measure of smoking behaviour, but both EHR and survey smoking behavior replicated known associations well. Smoking is a well known driver of many human diseases, however, we have shown that such knowledge which has been accumulated over several years of study can be rapidly obtained by a single cohort.

WA Notify, A COVID-19 Exposure Notifications Tool: Modeling Cases Averted in Washington State
Courtney Segal, BA1, Zhehao Zhang, BS1, Bryant T Karras, MD2, Debra Revere, MLIS, MA1, Gregory Zane, MPH2, Janet G Baseman, PhD, MPH1

1University of Washington, Seattle, WA, USA; 2Washington State Department of Health, Olympia, WA, USA

Abstract
Secure and anonymous smartphone-based exposure notification tools are recently developed public health interventions that aim to reduce COVID-19 transmission and supplement traditional public health infection control efforts, including case investigation and contact tracing. We assessed the impact of Washington State’s exposure notification tool, WA Notify, in mitigating the spread of COVID-19 during its first four months of implementation.

Introduction
In May 2020, the Google|Apple protocol GAEN (Google-Apple Exposure Notifications) was released for use by public health authorities (PHAs) within their jurisdictions. A GAEN-based tool is considered “privacy-preserving” in that user’s phones log their exposure history without requiring geospatial location tracking or allowing access to personal data. GAEN-based tools operate as decentralized systems. The Association of Public Health Laboratories (APHL) hosts both a multi-tenant verification (Google) and a key server (Microsoft) supporting interoperable GAEN implementations. Once added to a smartphone, exposure notification tools utilize Bluetooth technology to determine digital proximity between devices and exchange random, ephemeral cryptographic keys when two smartphones are within the physical distance and duration of time specified by a given PHA. A user who tests positive for COVID-19 can anonymously notify others through the tool by voluntarily entering a verification code which then allows them to upload keys to the APHL server. Other users whose proximity and duration of exposure to the index case match specifications set by the PHA are alerted with an exposure notification message. WA Notify1, using the GAEN EN Express solution launched in Washington (WA) State, has been installed on more than two million devices, representing approximately 33% of the adult population. Exposure notification technology represents a potentially disruptive public health informatics strategy for pandemic control. Recent modelling and simulation evaluations have demonstrated the epidemiological value of exposure notification tools in improving contact identification, particularly of contacts unknown to the index case, and slowing secondary transmission of infection2,3. The preliminary evaluation of WA Notify described here seeks to answer the question: To what extent did WA Notify avert new COVID-19 cases in Washington during the first four months of its use?

Methods
Empirical validation of WA Notify’s epidemiological impact and value as a non-pharmaceutical intervention is limited by the anonymity of users and data privacy. Within these constraints, the approach described herein were designed to leverage aggregate metrics across disparate sources, including de-identified WA State DOH contact tracing data, aggregated APHL verification code server metrics, the MITRE Exposure Notifications Private Analytics Dashboard Data, and a survey among exposure notification recipients. To estimate the number of cases averted by WA Notify, a modeling approach developed to evaluate the NHS COVID-19 app was adapted2. This model is essentially a product of five terms: (i) number of notifications generated, (ii) secondary attack rate, i.e., the probability that notified individuals go on to become cases, (iii) expected fraction of transmissions preventable by strict quarantine of an infectious individual after a notification, (iv) actual adherence to quarantine, and (v) expected size of the full transmission chain that would be originated by the contact if they had not been notified.

Results
The mathematical modeling to estimate number of cases averted used variations of the parameter calculations, presented in Figure 1. The chosen parameters used reflect team and WA State DOH congruence regarding most realistic variation in SAR and quarantine behavior within the bounds of the modeling approach. Figure 1 illustrates the estimated number of COVID-19 secondary transmissions averted at varying levels of secondary attack rate and quarantine effectiveness.
Between 11/30/2020 and 03/31/2021 modeling estimates that:

- Assuming 5.1% SAR and 53% quarantine effectiveness, 2636 cases are averted.
- Assuming 6.659% SAR and 53% quarantine effectiveness, 3439 cases are averted.
- Assuming 12.085% SAR and 53% quarantine effectiveness, 6240 cases are averted.
- Assuming 12.085% SAR and 64% quarantine effectiveness, 7536 cases are averted.
- Assuming 13.706% SAR and 64% quarantine effectiveness, 8547 cases are averted.

After conducting a sensitivity analysis, the estimated number of COVID-19 cases averted is 5,500 (central 95% range of sensitivity analysis 2,800-8,200). Applying an estimated case fatality of 1.4% in WA State to the cases averted estimates, WA Notify saved 40-115 lives between November 30, 2020 and March 31, 2021.

Conclusion

GAEN-based exposure notifications are just one public health tool among many (vaccines, contact tracing, masks, hygiene, social distancing, occupancy policies) that should be leveraged to contain the spread of COVID-19. With the expanding evidence-base for their effectiveness, integrating informatics tools like WA Notify into public health practice alongside other established interventions will be helpful for epidemic control in the future. As new variants emerge and non-essential travel bans are lifted, there is uncertainty about the future of the COVID-19 pandemic and a need to maintain effective pandemic control strategies. As we emerge from the COVID-19 pandemic, the application of digital proximity detection and anonymous exposure notifications may shift to other public health emergencies in the future and strengthen community-clinical engagement with added functionality (e.g., requesting a test or reporting vaccination status) and informatics research.

Enhancing Clinical Data Analysis by Explaining Interaction Effects Between Covariates in Deep Neural Network Models

Yijun Shao, PhD1,2, Ali Ahmed, MD, MPH1,2,3, Edward Zamrini, MD4, Yan Cheng, PhD1,2, Qing Zeng-Treitler, PhD1,2

1George Washington University, Washington, DC, USA; 2Washington DC VA Medical Center, Washington, DC, USA; 3Georgetown University, Washington, DC, USA; 4University of Utah, Salt Lake City, UT, USA

Introduction

Deep neural networks (DNNs) have attracted much attention in recent years, and application of DNNs to medicine and healthcare quickly followed and has shown some success.1 Despite their increasing popularity, DNN models are very difficult to explain or understand, which makes them harder to adopt by clinicians and clinical researchers. Current explanation approaches include Attention Mechanism, Local Interpretable Model-Agnostic Explanations (LIME), and Layer-wise Relevance Propagation (LRP).4 However, model-specific approaches are not easily generalizable, and model agnostic approaches like the Shapley value5 can be computationally very expensive. Covariate interactions are commonly observed in healthcare studies. It is natural to ask whether DNN models can capture interaction effects of two variables and how to measure the interaction effects. In this study, we develop a quantitative method called "interaction scores" to measure covariate interactions and apply it to two DNN models trained on two datasets respectively: a simulated dataset and a real-world clinical dataset.

Methods

Consider a DNN with one input layer of n nodes, one output layer with one node, and a number of hidden layers with various number of nodes each. The activation function for the output layer is assumed to be the sigmoid function \( \sigma(x) = 1/(1 + e^{-x}) \) so that the output is a single value between 0 and 1, which is commonly used for predicting binary outcomes such as mortality. Let \( p = F(x_1, ..., x_n) \) denote the final DNN model, where \( x_1, ..., x_n \) are the n predictor variables corresponding to the n nodes of the input layer. Define \( f(x_1, ..., x_n) = \logit(F(x_1, ..., x_n)) \), where \( \logit(x) = \log \frac{x}{1-x} \) is the inverse function of the sigmoid function \( \sigma \). For each variable \( x_i \), we fix a reference value \( x_i^r \).

For two variables \( x_i \) and \( x_j \), we define the individual-level interaction score between them as

\[
\text{Interaction score} = \frac{f(\cdot x_i \cdot x_j \cdot \cdot \cdot) - f(\cdot \cdot \cdot) - f(\cdot x_i \cdot \cdot \cdot) + \cdot f(\cdot \cdot \cdot)}{x_i^r - x_i^r} \text{ for each individual subject with } x_i \neq x_i^r \text{ and } x_j \neq x_j^r.
\]

The population-level interaction score is similarly defined as the mean of all individual-level interaction scores. We apply the interaction scores to two datasets. The first dataset is created from simulation, and the second contains clinical data from the real world.

Simulation Data. The simulation uses 100 variables \( x_1, x_2, ..., x_{100} \) as predictors and a variable \( z \) for binary outcomes 0 and 1 respectively, which satisfies a nonlinear relationship as \( \logit(P(z = 1)) = \beta_0 + \sum_{i=1}^{100} \beta_i x_i + \sum_{m=1}^{20} \gamma_m x_{jm}^2 + \sum_{m=1}^{20} \theta_m x_{jm} x_{km} \), where \( \{i_m\}_{m=1}^{20}, \{j_m\}_{m=1}^{20} \text{ and } \{k_m\}_{m=1}^{20} \) are 3 randomly sampled out of the index set \( \{1, 2, ..., 100\} \) with \( \{j_m\} \cap \{k_m\} = \emptyset \). We generate a set of 50,000 samples, which is the simulation data.

Real-world Data. The dataset is derived from a cohort developed by Cheng et al.6 for the study of Alzheimer’s disease and related dementia (ADRD) and contains 500,000 patients of only two races: black and white. The outcome is the ADRD diagnosis within 10 years of follow-up.

DNN Architectures. The DNN model for the simulation data will be a multiple layer perceptron (MLP) with 10 hidden layers, and the DNN model for the Real-world data will be an MLP with 8 hidden layers.

Results

The DNN model trained on the simulation data achieves a testing AUC of 0.945. The comparison of the interaction scores calculated based on the true model and those based on the true relationship is shown in Table 1. The DNN model trained on the simulation data achieves a testing AUC of 0.945. The comparison of the interaction scores calculated based on the DNN model and those based on the true relationship is shown in Table 1.

Discussion and Conclusion

Significance: DNN model’s ability to capture unknown or undefined interaction present in nonlinear relationships is one of its strengths. Such captured interactions may reveal important underlying relationships (e.g. drug-drug, race-risk factor, gene-environment) in biomedical data. Prior explanation of DNN focused on individual variable’s contribution to outcomes. We proposed a novel method to measure interactions captured by DNN models in this study. Since it is difficult to validate the authenticity of the interactions assessed by our method in clinical data, we first utilized a simulated dataset. The results showed a high level of agreement between the interaction scores and the interaction coefficients underlying the simulation data. We then applied the method to an ADRD dataset, representing real-world data. The interactions between different ADRD risk factors is not well known in general. The DNN model and the interaction score make it possible to study and better understand the interactions of the ADRD risk factors.

Implication: The ability to quantitatively assess interactions allows for an additional means to explain DNN models. This is particularly important because DNN models are often not linear. Assessing individual variable’s importance to or impact on the outcome, of course, is very helpful. Interaction score can complement the explanation provided on individual variables. The assessment of interactions can generate new hypotheses for future exploration. For example, the interaction between race and a number of comorbidities in the context of incident ADRD is not well documented in literature and requires further examination. A better understanding of the race-risk factor interaction could lead to improvement in care of African Americans. It could also support a more personalized medicine approach in ADRD prevention.

Prescribing Pharmacogenomics Testing: Analyzing the Acceptance of Healthcare Providers through a Survey Study
Mohit M. Sharma MPH¹, Yonaka Harris MS¹, Yiye Zhang PhD¹, Jyotishman Pathak PhD¹
¹Weill Cornell Medicine, New York, NY

Introduction
Pharmacogenomics (PGx) is a branch of research that examines the effect of genes on the response of an individual to medications. Considered as a part of precision medicine, it is intended to assist the doctors in choosing the medications which are best suited for patients, thus helping them treat each patient individually (1). Presence of acceptance barriers is causing a significant impediment in the way of harnessing the scientific advancement in this area into clinical practice. To investigate the barriers and opportunities in the adoption of PGx testing for the selection of antidepressant, we conducted a survey of healthcare providers’ current knowledge of and experience with PGx testing and their perception of its utility in routine clinical care (2).

Methods
We distributed electronic cross-sectional surveys using Qualtrics (Qualtrics, Provo, UT) to anonymous primary care providers (N=340) in Weill Cornell Medicine/New-York Presbyterian campus. Participants were offered a gift card of $25 as compensation for their participation in the survey. They were provided with an information sheet which contained details on how the survey answers will be used, the risks/benefits associated with the survey, the confidential nature of the data, and assured that the participation of subjects was voluntary. We adapted the survey present in Haga et al. (3). All the participants provided demographic details at a baseline level. Likert-type questions in assessing their understanding, knowledge, experience, and preferences regarding Pharmacogenomics testing were included in the survey. The response choices include - neither agree nor disagree, somewhat agree, somewhat disagree, strongly agree, and strongly disagree. This study was approved by the WCM internal review board (IRB).

Results
As of August 2020, 158 responses were collected. The response rate is 18% and the completion rate is about 90%. Male healthcare providers constituted 55.4% of the total respondents and females were 44.6%. Likert-type responses were collapsed (for example, strongly disagree and somewhat disagree) to estimate the proportion of providers in agreement or disagreement. In general, 67 out of 134 of the providers agreed to feeling well informed about genetic testing in general while only 37.13% (50 out of 134) expressed their disagreements. Moreover, 60 providers out of 130 (46.15%) did not feel well informed about the role of PGx testing in choosing a psychotropic substance, whereas 55 out of 130 (42.30%) agreed to being well informed.

We observed that younger healthcare providers were less comfortable in ordering a genetic test to diagnose a disease, with 53.2% of them under 30, and 70% of them in the age group 31-40 respectively. Across the specialty, 31 out of 65 (47.69 %) of psychiatry providers were not comfortable in ordering a genetic test, whereas 58.62 % i.e 17 out of 29 Internal Medicine providers answered the same. Seventy six out of 133 healthcare providers (57.14 %) did not feel that their genetic training had sufficiently prepared them to order genetic tests and utilize the results clinically, with 21 of them (15.79%) not being able to decide on a conclusive response.

To evaluate the experience of ordering genetic tests, we asked them how often in the past year had they ordered genetic testing for either disease susceptibility or diagnosis. Seventy out of 133 (52.63%) of the providers never ordered genetic testing for either disease susceptibility or diagnosis whereas 35.54% (47 out of 133) of them had ordered only 1-2 times during the year. Three providers each have ordered for 11-25 times per year and more than 25 times per year respectively. This response reflects about the lack of experience amongst all the providers in ordering genetic tests in general. Across specialty, we observed that the highest number of providers not having any experience in prescribing genetic tests belonged to Psychiatry (31.57%) followed by Internal Medicine (11.27%).

Providers were asked that if a comparable non-genetic test (such as enzyme, plasma level, or protein assay) were also available, would they be more likely to order such a test to predict drug safety or efficacy for an individual patient (as opposed to the genetic test). It was found that although 71 out of 132 (83.53%) were of the opinion to order such non-
genetic tests, 47 out of 132 (35.61%) of the providers were unsure, with only a handful of them i.e 14 (16.47%) prefer not to order such a test.

Majority of the providers (53.04%) believed that PGx testing is or will become a valuable tool to predict risk of adverse events or the likelihood of treatment response for psychotropic medications while 35 responses out of 130 (26.92%) were not sure of their beliefs. Moreover, 56 out of 129 (43.15%) of the providers could not give a conclusive answer when asked if they believe that there is a strong evidence base of PGx testing for psychotropic medications, followed by 42 of them (32.55%) who responded negatively. Only 24% of the responders agreed. Fifty-nine out of 129 (46%) healthcare providers felt that the PGx testing will be beneficial for their patients with Major Depressive Disorder, however there were 42 providers (32.5%) who could not decide about its benefit.

Conclusion

Our findings suggest that despite the healthcare providers having knowledge of the PGx testing and understanding the benefits, there are significant concerns and barriers in the adoption of PGx testing in standard clinical practice. Some of the responses were heterogeneous in nature while in some questions, lack of confidence in expressing clarity of opinion was observed. Our findings are consistent with the ones obtained in previous studies where physicians received sporadic education on the topic of PGx and thus felt underconfident for ordering the tests, even when they expressed almost universal acceptance of the concept of PGx. This underscores the need of having rigorous implementation initiatives and more frequent education programs. The next phase of the analysis includes regression analysis to further investigate the multivariate relationships.

Outpatient Portal Use in Pregnant Women for Blood Glucose Management

Priti Singh¹, PhD, MS; Pallavi Jonnalagadda¹, MBBS, DrPH; Evan Morgan², BA; Naleef Fareed¹,², PhD, MBA

¹The Center for the Advancement of Team Science, Analytics, and Systems Thinking in Health Services and Implementation Science Research (CATALYST), ²The Ohio State University, Columbus, OH; Department of Biomedical Informatics, College of Medicine, The Ohio State University, Columbus, OH

Keywords: patient portals, technology use, health information technology, diabetes in pregnancy

Introduction

Health information technologies (HIT) have transformed the health care industry by reducing the patient-provider communication time, increasing accessibility to health information and providing individuals with tools to manage their health. The integration of Electronic Health Record (EHR) with HIT has established new avenues for care delivery and care co-ordination including patient portals. A patient portal is a patient facing health technology tool that provides secure access to personal health information including medication list, laboratory results, upcoming appointments, encounter summaries, billing and more. Government initiatives, and greater accessibility to the internet and internet-based devices have enhanced portals use in recent past. Preliminary evidence suggests positive outcomes of portal use such as greater patient engagement, improved clinical decision making, higher levels of patient satisfaction and improved health outcomes such as medication adherence ¹. Patients with chronic conditions, who need to manage care across multiple sites and providers, especially benefit from portal use due to reasons such as convenience, patients’ own insight and support of care continuity ². Extant studies have examined portal usage in nonpregnant adults, few have focused on pregnant women. Pregnancy is a time for continuous care with higher demands of patient-provider interaction and health monitoring. Given the potential benefits of portal use and frequent contact with the health care system, it is vital to examine patient portal use during pregnancy. Particularly, among pregnant women with existing comorbidities like diabetes requiring frequent clinical encounters and laboratory tests. Diabetes is among the most commonly encountered conditions in pregnancy, affecting up to 10% of pregnant women in the US. Yet, few studies have examined portal usage and their association with blood glucose levels. Analysis of log files generated from pregnant women’s use of the portal present an opportunity to understand technology engagement in this understudied population. Knowledge of patterns of utilization of patient portal and their association with clinical outcomes can inform the development of better health care delivery strategies. To this end, we examined the association between demographic and clinical covariates, blood glucose levels and outpatient portal use in a sample of pregnant women receiving care in the Obstetrics and Gynecology (OB/GYN) department and the Division of Maternal Fetal Medicine (MFM) at our academic medical center (AMC). We hypothesized that women with elevated blood glucose levels will have higher use of the patient portal, as measured by the number of times all the portal functions are used.

Methods

The study followed a retrospective cohort design, wherein we extracted server audit log files from the outpatient portal, MyChart (MC) in use at our AMC from 2016 – 2020. Women eligible for inclusion must have been 18 years or older, has a pregnancy episode and were cared for by our AMC’s OB/GYN and MFM providers. There were 17,224 patients with active MC accounts, who had a prenatal visit (initial or follow-up) and a pregnancy episode during the study period. Patients were excluded from the study if they did not have a prenatal visit with OSUWMC OB/GYN and MFM providers or were not pregnant during the study period. Our AMC MC offers the following functions: Messaging (links to messaging center, letters to the patient, prescription refill option); Visits (list of past and upcoming visits); My Record (list of medications, allergies; medical history, immunizations; test results and health summary; preventive care and a summary of plan of care); Medical Tools (share medical records with other services; participate in research studies; and connect tracking devices); Billing (account summary, payment); Resources (terms and
conditions; patient education; and frequently asked questions); Proxy (request or renew proxy); Preferences (personal and security settings; notification preferences); and Custom (miscellaneous).

Analysis and Results

We used a negative binomial regression to model the association between portal usage and blood glucose levels adjusting for episode of pregnancy (1st pregnancy, 2nd pregnancy, and so on), age at first clinical encounter, Charlson Comorbidity Index, an area-level measure of deprivation (ADI) based on Zip Code, pregnancy risk (high/normal), race, and BMI at the initial encounter. Geometric mean was obtained for glucose values collected throughout pregnancy. The ADI scores were obtained from freely available Neighborhood Atlas website and measures the neighborhood disadvantage with the public, including educational institutions, health systems, not-for-profit organizations, and government agencies. Those with multiple pregnancy, diabetes, high blood pressure, genetic conditions, history of premature birth, preeclampsia, advanced maternal age, or any condition requiring high-risk care or fetal treatment were classified as high pregnancy risk. Our model included an offset for the duration of portal use. Findings from fully-adjusted models are reported as incidence rate ratios (IRR) and 95% confidence intervals (CI) significant at a p-value <0.05. Overall, patients used the Visits feature the most, followed by My Record. No activity was observed for the Resources feature. For every 10 unit increase in blood glucose, portal usage was 3% higher after adjustment (IRR: 1.003, 95% CI:1.002, 1.004). Women living in areas with the high ADI rank (most deprived) (quantile 5) had lower portal usage as compared to those living in least deprived areas (quantile 1) (IRR: 0.80, 95% CI: 0.73, 0.88). Overall, adjusted portal usage was almost 30% lower in Black women as compared to White (IRR 0.73, 95% CI 0.68, 0.78). Patients with high-risk pregnancy had significantly higher use of the Visits, MyRecord, and Billing features, as well as, the overall portal usage than normal risk patients, as indicated in the figure.

Conclusion

We found differences in outpatient portal use based on disease severity among pregnant women. Further, women living in areas of high opportunity had significantly higher use of the outpatient portal. Future work should focus on examining the association between outpatient portal use and clinical outcomes of diabetes management like glycemic control and medication adherence. Our findings have implications for care providers, who can provide encouragement, training, or navigational assistance to pregnant women to use outpatient portals to better manage their health.

User Evaluation of Interactive Longitudinal PRO Visualizations Designed by Prostate Cancer Survivors with Limited Graph Literacy

Lauren Snyder MPH1, Daniel Phan RN1, Sarah E. Connor MPH2, Sheba George PhD3, Kristen C. Williams MA2, Jefersson Villatoro2, Ayan Sara4, Lorna Kwan MPH2, Nick Reid MHI1, John Gore MD, MPH3, Mark S. Litwin MD, MPH3, Andrea L. Hartzler PhD1

Introduction

Visualizing patient-reported outcomes (PRO) over time has become a common strategy to help patients track their health and engage in healthcare. However, traditional line graphs and bar charts might not be understood by people with limited numeracy and graph literacy. Prostate cancer is the most common solid malignancy in men. Although it causes over 33,000 deaths annually in the United States, many men live for many years with indolent low risk disease.

Prostate cancer survivors with limited graph literacy may also have low socioeconomic status, limited health literacy, and experience other health inequities and resulting poor health outcomes associated with racial/ethnic minority group membership. Although White, college educated prostate cancer survivors prefer PRO visualizations in line graph and bar chart formats, these formats may not be accessible, acceptable or usable to all survivors.

To investigate longitudinal PRO visualizations codesigned with prostate cancer survivors with limited graph literacy, we conducted a series of design studies. We engaged survivors from a state-funded program providing free prostate cancer care to low-income Californians at Martin Luther King Jr. Outpatient Clinic, a safety net community clinic. Our previous work describes our process to understand user needs and to co-design 3 longitudinal PRO visualizations with our Patient Advisory Board of 6 survivors where numerous designs were assessed to identify key features needed for a PRO visualization acceptable to this population. In the present study, we engage prostate cancer survivors who have limited literacy to assess the 3 visualizations (Figure 1) compared with a bar chart that combines emojis (“emoji bar”) as a comparator from the literature. We use virtual methods to engage representative users from this hard to reach, diverse population.

Figure 1. Interactive PRO visualizations that illustrate urinary function scores from the Expanded Prostate Cancer Index Composite over 48 months. The Meter (top left) includes buttons to change the time point; in the Words, (top right) time can be changed on the axis or by arrow; and the Comic (bottom) includes audio of the conversation.
Method

The objectives of our user evaluation were to measure 1) the accessibility, using the metrics of preference, comprehension, and utility of the PRO visualizations, and 2) assess the usability of interactive versions in the subset of participants who are able to use Zoom. To accomplish these objectives, we use mixed-methods to collect data through remote phone/Zoom interviews during the Covid-19 pandemic in February to April 2021. A critical component of this work is engaging prostate cancer survivors who are representative of our target audience, namely prostate cancer survivors with limited graph literacy. We recruited English-speaking survivors with high school education or lower. We characterized literacy with the Newest Vital Sign (NVS) and Short Graph Literacy Scale (GLS). We mailed participants paper versions prior to the interview and afterwards sent them a $50 gift card.

To assess accessibility we measured comprehension (correct/incorrect), utility ratings (1=“not at all helpful” to 4=“extremely helpful”), and rank order preference among the four visualizations (i.e., meter, word, comic, emoji bar). We also collected qualitative feedback to assess acceptability. For participants with access to a computer and Zoom, we assessed the usability of interactive, web-based versions of our three visualizations through task analysis (e.g., participants interacted with the visualization to determine urinary function scores at different time point and the System Usability Scale (SUS). Interviews were audio recorded and transcribed for qualitative analysis.

Results

We conducted 18 interviews with prostate cancer survivors, 4 of whom were willing and able to complete the usability assessment via Zoom. The mean age of participants was 69 (range 61-77), and we purposively sampled for racial/ethnic diversity, including 50% African American and 16.7% Hispanic participants. 89% of participants had a low graph literacy score as measured by the GLS and 78% had low literacy as measured by the NVS. The average comprehension of the Meter was 74%; the Words was 68.5%; the Comic was 61.1%; and the emoji was 79.6%. We used the constructs of helpfulness, satisfaction, and confidence to measure utility. Participants ranked the Meter and Emoji prototypes highest for helpfulness (3.1 and 3.2 out of 4, respectively) and satisfaction (4.3 and 4.5 out of 5, respectively). For confidence, all prototypes received nearly the same score of 3.1 (+/-1) out of 4. Most frequently ranked the Meter and Emoji as their first or second most preferred visualization. In the usability testing with 4 participants, the Meter and Words scored better on the SUS than the Comic; we heard from participants that the Comic made light of a serious health condition and was not relatable or appropriate. This feedback was in stark contrast to the input of our PAB during the design process who highly favored the comic and spent a great deal of time helping us refine and improve the PRO visualization. One participant even audio recorded their voice to provide a narration functionality to the online version. These differences speak to the need to create visualizations that are evaluated by a sample of end users who have not been closely involved in the design.

Conclusion

Findings build on previous research to address the specific needs of prostate cancer survivors with limited graph literacy. We used mixed-methods with standardized instruments that have been adapted for virtual administration. By collaborating directly with our survivors throughout the design process, we increased the likelihood that our visualizations are reflective of and responsive to the needs of our specific population, and ultimately improve accessibility, acceptability and usability of longitudinal PRO visualizations to all survivors.

A Scoping Review of Informatics Research for Clinical Practice Variation

Sunghwan Sohn, PhD1, Sungrim Moon, PhD1, Larry J Prokop, MLS3
Victor M Montori, MD, MS4, Jungwei Fan, PhD1,2*
1Department of Artificial Intelligence & Informatics, 2Kern Center for the Science of Health Care Delivery, 3Mayo Clinic Libraries, 4Department of Internal Medicine
Mayo Clinic, Rochester, Minnesota, USA

Introduction
Clinical practice involves reasoning and decision-making that are affected by interlaced factors from the patient, clinician, and environment – all contributing to potential variation. Clinical practice variation (CPV) stands for a common phenomenon that a specific clinical task is performed differently across providers, regions, or times. For example, inter-provider variation in prescribing prophylactic antibiotics prior to urologic procedures. The issue is becoming ever significant in the face of our aging, multi-morbid population susceptible to disease-disease, drug-drug, and drug-disease interactions, for which credible guidelines are lacking and clinicians frequently need to make autonomous judgment based on their beliefs, instincts, or even incentives. CPV is an established area with decades of scholarly work in health services research, a discipline that has evolved with medical informatics in parallel and shares increasing methodological interests. Without attempting to compare the two disciplines, we believe a dedicated survey of informatics research in CPV will be extremely helpful to facilitate a cross-disciplinary dialogue. Accordingly, we conducted a scoping review of CPV studies published within informatics journals and conferences.

Methods
We targeted on CPV research published in major informatics journals or proceedings. The Ovid integrated database was searched on October 27, 2020, which covered EBM Reviews - Cochrane Central Register of Controlled Trials, EBM Reviews - Cochrane Database of Systematic Reviews, Embase, Ovid MEDLINE and Epub Ahead of Print, In-Process & Other Non-Indexed Citations and Daily. An additional small set of articles were collected by serendipitous browsing or referral from colleagues. Based on the search hits, two annotators (SS and JF) independently reviewed every abstract to determine whether the main topic is about CPV – each was then labeled as include, exclude, or full text needed. The agreed ones, either to include or exclude, were deemed final decision. For those disagreed or marked as full text needed, a second-round screening was performed with another independent reviewer (SM) adjudicating the unresolved ones. All three annotators approved the final set of articles to include for thematic analysis. A coding scheme was derived that covered aspects of interest to the informatics community. The extracted attributes and themes were refined through discussion until a common consensus was achieved.

Results
A summary of the article selection workflow is shown in Figure 1. The integrated database search obtained 57 distinct articles, and we collected another 9 articles from isolated browsing or referral. The 66 articles (57+9) went through first-round screening based on abstract review, where the two annotators agreed to exclude 22 articles as off-topic. Of the 44 articles that got to the second-round screening: 28 had been agreed to include (hence this set was not discussed further), 9 had been disagreed based on abstract, and 7 had been marked as requiring full text review. Of the 16 articles (9+7) discussed among all three annotators, 4 were deemed off-topic and excluded. In the end, 40 articles (44-4) were retained for the synthesis.

Among the final 40 included studies, 10 (25%) dealt with multiple clinical conditions and 6 (15%) did not specify the clinical condition. Breast cancer was the top specific condition (5 studies). All the remaining conditions were covered by only one or two studies, including pressure ulcer, type 2 diabetes, heart failure, hypertension, and soft tissue sarcoma. The frequencies of the involved clinical tasks are summarized in Figure 2a, indicating that treatment (e.g., prescription patterns) was the most studied task with CPV. In Figure 2b we can see that 37 out of the 40 informatics
studies dealt with detection of CPV, which represents the basic task of revealing that variation exists. Characterizing and explaining of CPV follow in counts (27 and 11 studies respectively), where characterizing is identification of associated contexts versus explaining is to establish causal relation with specific variables. Only 5 studies attempted to prevent CPV, and 4 studies tried to generate knowledge by exploiting those detected variations. The derived themes and their sub-themes are summarized in Table 1. The top three by frequency are: Conceptual modeling or methodology design→Algorithm development (6 articles), CDSS implementation and evaluation→Implementation trial (5 articles), and Retrospective auditing of compliance to CPG→machine-assisted chart review (5 articles).

Discussion
Our scoping review found most informatics studies on CPV have focused around treatment variation and simply the detection of CPV. We see a critical missing piece is to capture patient outcomes in the loop and establish causal relations with CPV, which will enable answering the questions of “why” and “how” certain CPV leads to differential quality in care. Accordingly, more research is needed toward the explaining and learning from CPV.

Predicting Hospitalization of COVID-19 Positive Patients Using Machine Learning Methods

Wenyu Song, PhD1,3, Linying Zhang, MS4, Michael Sainlaine, MS1, Mehran Karvar, MD2,3, Min-Jeoung Kang, RN, PhD5, Avery Pullman, BS1, Anthony Massaro, MD1,3, Namrata Patil, MD2,3, Ravi Jasuja, PhD1,3, Patricia C. Dykes, RN, PhD1,3

Introduction
Coronavirus disease-19 (COVID-19) pandemic has had a significant impact on the healthcare system globally(1). With millions of infected people, hospitals are facing big challenges due to the lack of beds and other related clinical resources, such as ventilatory support(2). Among COVID-19 infected patients, there is a disproportionately high mortality burden on older adults. Recent studies demonstrate the elderly are most susceptible to severe respiratory illness with increased mortality(3). In the current study, we applied statistical and machine learning techniques to develop personalized risk models using Electronic Health Record (EHR) data. The outcome of the model is whether elderly COVID-19 test-positive patients are hospitalized during the defined time window close to the COVID-19 test date. The long-term goal of this study is to develop an accurate prediction system to facilitate timely hospital care for COVID-19 patients.

Methods
We identified risk factors for COVID-19 using an iterative combination of literature review, qualitative methods (interviews with clinical experts, physicians, who had experience in treating COVID-19 patients) and EHR data exploration (data clinical review and feature engineering). The inclusion and exclusion criteria were developed based on expert opinion and literature review.

We used clinical databases within the Mass General Brigham (MGB) healthcare system, which is a centralized clinical data warehouse for all types of clinical information from multiple Harvard-affiliated hospitals. Available data items include patient demographics, diagnoses, procedures, medication, laboratories, inpatient and outpatient encounter information, and provider data. Elderly patients (age of 65 and above) with at least one positive COVID-19 test at an affiliated MGB site were included in the study. Patients’ hospitalization records within a four-week time window of test date were extracted as the model predictive outcome. Multiple patients’ features, including demographics (age, gender), lab tests (such as albumin) and chronic diseases (such as respiratory disease and heart failure) were obtained from the EHR database as the predictors. Four statistical and machine learning prediction models were trained with these features, including logistic regression, support vector machine (SVM), random forest, and neural network. The precision, sensitivity, specificity, and area under the receiver operating characteristic curve (AUROC) from the test set were used to evaluate the performance of each model. A five-fold cross-validation was conducted within the training set to select hyperparameters that optimize the model performance. The data pre-processing was conducted using R (version 3.3.3). The algorithm training and evaluation were conducted using Python (version 3.7.3).

Results
Using MGB database, we identified 6,334 COVID-19 test-positive elderly patients. By removing patients with high missing values and low data quality, 1,495 patients remained in the final study cohort. In this cohort, the case group (n=459) has hospitalization record (with hospital stay for more than 24 hours after admission) during a four-week window of the COVID-19 test date and the control group (n=1,036) does not have the hospitalization record. Four predictive models were developed using a subset of 29 potential predictive variables (Table 1), including demographics, disease diagnoses and lab values (Table 2). Random Forest and Support Vector Machine achieved the best predictive performance, with an AUROC=0.84.

Among the statistically significant predictors from the logistic regression model, albumin, a plasma protein which is an important index for nutritional status, was found to have the most impact on the model outcome.

Discussion and Conclusion
The COVID-19 pandemic has caused a huge burden to the healthcare system, leading to maximum hospital utilization in many regions of world. To optimize the usage of the clinical resources, it is important for health care providers to identify those at high risk who need timely in-patient services among COVID-19 positive patients. An EHR based accurate predictive tool can facilitate this decision-making process in large populations. There have been studies to
predict patients at high risk of progression and poor outcomes, especially for ICU admission(4, 5). Our goal is to predict all types of hospitalization, which can be used to identify high risk patients in a more general population. We used a multi-hospital study cohort and iterative feature engineering process for model development. The model was validated by using five-fold cross-validation method. Our study showed a robust predictive performance with both tree-based and support vector machine models. Our results also suggested that albumin could be a strong predictor (protector) of hospitalization risk, which is consistent with a previous study(6). Since all our input variables are routinely available patients' features, we are expecting the algorithm can be easily applied in other health care systems in the current and potential future pandemic.

Abstract
Measurement concepts are essential to observational healthcare research. We developed five methods for making measurement concept sets by a combination of automated, semi-automated and manual approaches. We validated our concept sets by calculating their frequency in the Columbia University Irving Medical Center (CUIMC) database. We matched basic metabolic panel, lumbar puncture panel and coagulation panel concept sets to the most effective concept set generation method. We intend to expand this work into a multisite study.

Introduction
Laboratory measurement data are essential to observational healthcare research. Prior research efforts have focused on a symbolic representation of laboratory measurements into concept-oriented repositories such as the Medical Entities Dictionary (MED) primarily for clinical care purposes. Today, Logical Observation Identifiers Names and Codes (LOINC) or Systematic Nomenclature of Medicine Clinical Terms (SNOMED-CT) terminologies are commonly used to represent measurement concepts within electronic health record systems. Both LOINC and SNOMED have encoded clinical concepts and have categorized them into hierarchies, which can improve research analyses. However, those hierarchies may include a heterogeneous group of concepts that may not be meaningful for clinical use. A lack of measurement concept harmonization is a challenge for using measurement data in large scale observational research. The issues with measurement concept harmonization are more pronounced in research networks that use healthcare data from multiple sites, such as PCORnet, All of Us (AoU) and the National COVID Cohort Collaborative (N3C). We aimed to achieve two goals with measurement concept harmonization. First, we intended to group concepts by a common biological or chemical assay. Second, we intended to validate the groups of lab tests based on their clinical use.

Methods
Data Source
The Columbia University Irving Medical Center (CUIMC) data warehouse contains lab data from the early 1980s to present day. We converted our data to the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) and analyzed them in that format.

Algorithms
We uploaded the LOINC table file, which we acquired from the official LOINC website (https://loinc.org/), into a Pandas dataframe. We used semi-automated, automated and manual algorithms to organize the LOINC terms into concept sets (a.k.a. “value sets”). Our algorithms used a combination of medical knowledge and heuristics. For our semi-automated and automated algorithms we used a combination of the following filters: i) component, which is the biological or chemical entity that is measured (i.e. cholesterol) ii) system, which is the kind of specimen from which the sample is drawn (i.e. serum/plasma, blood, urine, etc.) iii) time aspect, which describes the time interval over which the measurement is run (i.e. point measurement, 1 hour measurement, etc.) iv) status, which differentiates active codes that continue to be used in billing data from passive codes that were used historically v) property, which describes the kind of units reported from the measurement (i.e. mass concentration, substance concentration, etc.) vi) analyte, which is the standardized subpart of component that is independent of suffixes and vii) analyte core, which is a standardized subpart of component that is independent of suffixes or precoordinated ratios.

We made a total of five algorithms that included automated, semi-automated and manual approaches. In our first algorithm, we filtered the data frame by four parameters: component, system, time aspect and active use. In a second algorithm, we additionally restricted by property. In a third algorithm, we substituted analyte for component. In a fourth algorithm, we substituted analyte core for component. In a fifth algorithm, we iteratively created concept sets manually in ATLAS, a web-based research platform created by the Observational Health Data Sciences and Informatics.
To validate our concept sets, we calculated their frequency antecedent to cohorts of interest. For example, we calculated the proportions of heart transplant patients who had basic metabolic panel concepts ordered within 30 days antecedent to the operation.

Results

A representative output for our first algorithm, which filtered on component, system, time aspect and active use, is shown in Table 1. The concept set for sodium includes distinct concepts for measurements drawn from blood and from serum/plasma. Our subjective assessment of which algorithms are most effective for making different kinds of concept sets is summarized in Table 2.

Table 1: Sample concept set for sodium in serum, blood or plasma. A total of 4 parameters were used in this algorithm (Component, Time Aspect, System, Active). LOINC NUM, LOINC number; TIME ASPCT, Time Aspect; Pt, Point measurement; mmol/L, millimoles per liter; umol/L, micromoles per liter; mg/dL, milligrams per deciliter; CS ID, Concept Set Identifier.

Discussion

We created measurement that were improvements over groupings by the LOINC and SNOMED-CT hierarchies in that they were more meaningful for use in observational research. We included similar concepts from different systems, synchronized concepts by time interval of collection and restricted to codes that were used actively. We grouped our concepts into the panels that are ordered by clinicians in order to identify inaccurate concepts since the components of the panel should occur in similar frequencies.

We used a combination of semi-automated, automated and manual methods to create measurement concept sets. Semi-automated algorithms were most effective for making concept sets from heterogeneously named concepts, such as electrolyte concepts (i.e. Bicarbonate in Serum, Plasma or Blood). Automated algorithms were best for making concept sets with homogeneously named concepts, such as lumbar puncture concepts. Our analysis used data from a single medical center. The maintenance of codes over time is an issue that warrants further investigation. We intend to replicate this analysis on a multiple sites of the OHDSI network.

Conclusion

We created measurement concept sets that are meaningful for use in observational healthcare research using a hybrid of semi-automated, automated and manual methods.

Introduction

Poor comprehension of and low compliance with post-emergency departments (ED) care plans increases the risk of unscheduled ED return visits and adverse outcomes. Despite the growth of personal health records (PHR) to support transitions of care, technological innovation focused on the ED discharge process has been limited. There is variable patient engagement with PHRs, including large racial/ethnic disparities. (1) Furthermore, not every patient visiting the ED is part of the associated healthcare system, reducing the incentive for portal use. Recent literature suggests digital communication incorporated into post-ED care can improve patient satisfaction and care quality. We evaluated the feasibility of utilizing MyEDCare, a text message and smartphone-based electronic ED discharge process at two urban EDs piloted in 2019 at NewYork-Presbyterian Hospital Weill Cornell Medical Center and Lower Manhattan Hospital.

Method

MyEDCare sends text messages to adult patients’ smartphones at the time of discharge, containing a hyperlink to a Health Insurance Portability and Accountability Act (HIPAA)-compliant website. Content includes information on therapeutics, new medications, outpatient care scheduling, return precautions, as well as results of laboratory and radiological diagnostic testing performed in the ED. The generic MyEDCare platform display was in English only, but patient-specific discharge instruction content entered by the ED provider and automatically extracted from the EHR was not limited to a single language. Patients discharged from the ED who did not opt-out from MyEDCare were enrolled in the process. The program also excluded patients discharged to locations that would require paper documentation, patients whose employers requested discharge paperwork, patients discharged with a primary psychiatric diagnosis, and patients who were determined by providers to not have sufficient English proficiency. Figure 1 shows the MyEDCare smartphone interface developed by the authors and IT team at the hospital.

Figure 1. MyEDCare smartphone interface

To enroll a patient in MyEDCare, the ED physician confirms eligibility with the patient via verbal consent and verification that he or she is in possession of a functional smartphone with cellular service while in the ED. The physician enters the confirmed phone number into the EHR in a designated section modified specifically for MyEDCare. The physician then places the “ED Discharge Order” in the EHR; this order finalizes MyEDCare enrollment process, triggering the cellular service contracted at our institution to generate the text message. Three text
messages are sent to patients: at time of ED discharge with nurse assistance for initial access of content, as well as 2 and 29 days after ED discharge. The ED nurse guides the patient in their first access of MyEDCare online content on the phone in real-time, confirming content accuracy and patient comprehension, using teach-back method to optimize retention.(2) We collected ED return visit rates, ED staff feedback, and patient satisfaction using ED Consumer Assessment of Healthcare Providers and Systems (ED-CAHPS) patient satisfaction scores.

Results

During the 9-month pilot, 27,713 patients were enrolled in the personal smartphone-based MyEDCare discharge process, accounting for 43% of all treat-and-release patients. A total of 27% of treat-and-release patients further completed MyEDCare ED discharge process, accessing the online content. Scenarios leading to an incomplete MyEDCare discharge process included: lack of smartphone PDF viewing software required to view content, smartphone malfunction or loss of power, data plans prohibiting access to MyEDCare online content, limitations to cellular carrier service, or non-functional hyperlinks. On average, MyEDCare platform was accessed twice per patient. We compared the patient demographics and clinical profile of patients enrolled in MyEDCare; discharged via MyEDCare; did not complete the MyEDCare process; and discharged with standard paper discharge instructions. No clinically meaningful differences in Emergency Severity Index (ESI) levels or diagnosis types were observed between patients who completed MyEDCare ED discharge process compared to those discharged with standard paper discharge instructions. Conversely, we observed significant differences in marital statuses, age, preferred language, insurance status and race. Patients who completed MyEDCare process were more likely to be young, married, commercially insured, and racially White than those who did not. Of the patient who completed MyEDCare discharge process, 9051 (32.7%) patients accessed just once. There are 1009 patients who accessed the online content at least 5 times.

Table 1 compares the ED return visit rate in patients who completed, and did not complete, MyEDCare ED discharge process. Patients discharged via MyEDCare had less frequent unscheduled ED returns at 72 hours and 30 days compared with patients with incomplete MyEDCare enrollment. Patients enrolled in MyEDCare also had less frequent unscheduled ED returns at 72 hours and 30 days compared with patients discharged via standard paper workflows (p-value <0.001). ED providers reported increased efficiency applying the new discharge process, particularly for not having to locate a complete set of discharge papers and then physically deliver the documents to the right nurse caring for the patient at the time of discharge. ED-CAHPS scores for MyEDCare patients demonstrated higher than average scores in the following questions related to nursing care: Nurses explain in way you understand; Nurses listen carefully; Nurses treat you with respect. No other differences in ED-CAHPS questions were determined significant.

Discussion

MyEDCare was not appropriate for chronically ill patients from long-term care facilities without smartphones, and patients from vulnerable sociodemographic groups such as patient who are illiterate, non-English speaking or cannot afford a smartphone or the associated carrier data charges. Additional functions of the MyEDCare platform, such as a chat feature, may further enhance post-ED transitions of care in some patient groups who are excluded from PHR use. Additional barriers were predominantly technological. During this pilot our EDs did not use an EHR with an interfacing patient portal, but text messaging may be an alternative to or complement PHRs. Text messaging enjoys high consumer interface familiarity and continues to be the most widely adopted and least expensive technological function on mobile phones. Our findings suggest that EDs and urgent care facilities may consider developing a HIPAA-compliant, text message and smartphone-based discharge process to improve patient-centered outcomes.

Evaluating Primary Care Provider Work of Managing Asynchronous Messages through Electronic Health Record Access Logs

Bryan D. Steitz, PhD; Adam Wright, PhD
Dept. of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN

Introduction
Electronic health record (EHR)-based asynchronous communications, also known as inbasket messages, are essential to clinical practice. These message communicate numerous aspects of patient care, including visit scheduling, office administration, availability of test results, and general discussion of patient care plans. Despite their utility to managing clinical practice, a high volume of messages and the time necessary to manage one’s inbox has been identified as a major contributor to job dissatisfaction.1 Previous work has identified that primary care providers (PCPs) receive an average of over 400 messages weekly, which is disproportionately high compared to providers in other specialties.2 Message volume, however, presents a simplified view of the wider task of managing these communications. Few studies have quantitatively investigated the articulation work of asynchronous messaging, such as information seeking, to better understand the work of acting on clinical messages. Developing a better understanding of this articulation work supports the opportunity to make EHR improvements both to the information availability and navigation of the messaging workflow. For example, when a provider receives a medication refill request, we could automatically provide the necessary lab values in the message screen and provide a direct link to create an order. In this study, we utilized the breadth of data captured in action-level EHR audit logs to investigate the information seeking work performed by primary care providers to manage asynchronous clinical communications.

Methods
We identified our cohort of PCPs as any physician, nurse practitioner, or physician assistant who independently treated patients in ambulatory general internal medicine or family medicine clinics at Vanderbilt University Medical Center (VUMC) who had scheduled patient appointments during the month of January, 2020. We extracted from VUMC’s Epic EHR all inbasket messages that a PCP either sent or viewed between January 1, 2020 and January 31, 2020. Messaging data contained a unique message identifier, patient identifier about whom the message was sent, the type of message (i.e. patient message, request for chart review, etc.), the respective message action (i.e. send, read), a unique employee identifier, and a timestamp corresponding to each message event. We grouped message types into six functional categories: patient message, staff message, request for action, result notification, workflow notification, and other. We additionally extracted all EHR access events for each PCP in our messaging cohort. The EHR access data contained an action timestamp, a patient identifier, an employee identifier, and the activity that was accessed (i.e. load schedule, view health maintenance activity, view clinical notes, etc.).

We investigated information seeking work in the context of usage sessions. We defined a usage session as a sequence of activity about a single patient or activity with an undefined patient (i.e. viewing clinic schedule) that occurs within five minutes of any other EHR event about the same patient. We measured information seeking respective to the usage session in which a messaging action was performed. We calculated descriptive messaging and session statistics and calculated information seeking statistics respective to message activity and type.

Results
Between January 1, 2020 and January 31, 2020, there were 1215 PCPs who were involved in 531931 total messages. PCPs in our study accessed messaging functionality in 636486 total sessions, an average of 524 (SD=597) sessions per provider. Messaging sessions lasted an average of 4 minutes and 31 seconds and involved an average of 4.2 different EHR actions. Table 1 presents EHR activity statistics by message activity and type. There were an average of 7.8 and 2.7 EHR actions in sessions that involved sending a message and reviewing a message, respectively. The top EHR actions that were accessed before sending a message and after reading a message are presented in Figure 1.

Discussion
Primary care providers have among the highest rates of burnout across clinical specialties, in part due to EHR use.1 This is among the first studies to investigate the wider scope of acting on these messages by evaluating information seeking relative to messaging actions. Our study was supported by the breadth of data contained within action-level EHR access logs, which allowed us to systematically evaluate EHR activity across an entire organization. By better understanding how EHR activity relates to managing clinical messages, we can begin to devise informatics solutions to improve the efficiency of information seeking behavior. We hypothesize that the burden of messaging work is reduced by the ease with which the EHR enables a response. Future work will seek to develop predictive models, based on message content, to improve information availability and reduce the work information seeking.

Introduction
A temporal dimension is essential for the interpretation of clinical narratives. Lack of standardized temporal representation hinders the portability of clinical phenotyping applications using electronic health record (EHR) data. Existing standardized clinical models including HL7 Fast Healthcare Interoperability Resources (FHIR) define data types that can be used to specify the complex timing of events and processes that occur in clinical applications. However, these time models are meant for structured data, and remain untapped with unstructured and semi-structured clinical data. In a previous study, we developed a clinical data normalization pipeline known as NLP2FHIR, which standardizes and integrates unstructured and structured electronic health record (EHR) data using FHIR. The objective of this study is to develop an approach known as FHIRT ime to demonstrate the capability of FHIR for representing temporal patterns identified from clinical narratives. We leveraged the Time Event Ontology (TEO) for standardizing time patterns. Two temporal corpora were used for the preliminary evaluation of the FHIRT ime approach.

Materials and Methods
Materials: TEO is an ontology designed to support semantic representation of, and reasoning about complex temporal relations of clinical events. THYME Corpus is a human-annotated corpus of medical records in which the temporal relations between different events, occurrences, states, dates, and procedures are clearly annotated. Its annotations are organized as Event, TIMEX3 (i.e., phrases that contain time information, having classes of Date, Time, Duration, Quantifier, etc.), TLINK (i.e., relation annotations with subtypes of before, contains, overlap, begins-on, and ends-on), and other types. The 2012 i2b2 Challenge Corpus contains 310 discharge summaries annotated for temporal information (i.e., clinically significant Event, TIMEX3, and TLINK). In simpler terms, TLINK are used to describe a temporal relation from one entity (Event or TIMEX3) to another entity or Document or Section Time. One might view these relations as graph-like with entities serving as vertices and TLINK serving as directed or undirected edges.

Methods: We first analyzed the FHIR built-in time artifacts, and the temporal annotations from two temporal corpora (i2b2 Challenge and THYME) and aligned them with high-level time classes defined in TEO. Second, we developed an approach (called “FHIRT ime”) that handles temporal patterns utilizing FHIR built-in time artifacts and its extension mechanisms. Specifically, the Event annotations can be a clinical event or a non-clinical event. If an Event annotation can be represented as an instance of a FHIR resource such as Condition, Procedure, or Medication Statement, it was treated as a clinical event; otherwise, it was treated as a non-clinical event that was then represented as an instance of the FHIR Observation resource. For the TIMEX3 annotations, if they are associated with an Event, we used the FHIR built-in time artifacts (e.g., fhir:Condition.onset[x]) to represent them. If they have a temporal relationship with an Event, we treated them as a TLINK. For the TLINK annotations, we created a collection of FHIR extensions leveraging TEO time relationships and used them to handle TLINK relations between Events, Times or Event-Time. Third, we evaluated the FHIRT ime approach by converting the temporal annotations from the two temporal corpora into the FHIR-based representation. Specifically, we invoked the NLP2FHIR to identify clinical events with standardized codes (e.g., SNOMED CT or RxNorm). We then mapped the identified clinical events with the Event annotations in the two corpora. We analyzed the coverage of converted temporal patterns in FHIR to demonstrate the robustness of proposed FHIRT ime approach.

Results
Figure 1 shows the alignment results between FHIR, TEO and temporal annotations. Five core FHIR clinical resources Condition, Procedure, MedicationStatement, Observation and FamilyMemberHistory are represented as subclasses of teo:Event. Ten FHIR datatypes are represented as the subclasses of teo:Time, teo:TimeInstance or teo:TimeInterval, and four of them (fhir:date, fhir:time, fhir:Timing, and fhir:Duration) are aligned with TIMEX3
subtypes. We created five FHIR extensions for five TEO time relationships (teo:before, teo:contain, teo:overlap, teo:start, and teo:finish) that aligned with TLINK types.

We were able to convert temporal annotations from two corpora into the FHIR-based representations. For TIMEX3 annotations, we were able to fully represent TIMEX3:DATE from the i2b2 dataset as it represented dates in ISO format, whereas only 4% of THYME TIMEX3:DATE could be represented as fhir:date without any parsing; this improved to 65% when using the temporal NLP Java library SUTime (Stanford University) for parsing. THYME TIMEX3:DATE representations pose a challenge as even annotated TIMEX3:DATE have a loose semantic definition of date including relative dates ("yesterday") as well as phrases that refer to a date ("at that time"). For other TIMEX3 subtypes such as TIME (e.g. "16:43"), DURATION (e.g. "In the interim"), and QUANTIFIER (e.g. "multiple times"), fhir:string was used to represent them due to most annotations of these subtypes consisting of time phrases. For TLINK annotations, the FHIR extensions based on TEO relationships were able to fully represent all TLINK subtypes from the two datasets.

Discussion
In this study, we explored the capability of FHIR to represent temporal patterns identified from clinical narratives and we found that FHIR built-in artifacts can well cover clinical events and TIMEX3 subtypes. For the TLINK annotations, we were able to leverage the FHIR extension mechanism, in which the TEO time relationships were leveraged. THYME captures TIMEX3 from a linguistic approach when describing temporal relations from an NLP grammatical structure perspective, but this poses significant challenges when attempting to resolve these phrases to a standardized date as required by fhir:date. While using NLP to capture temporal relations is a challenging task, temporal relations in unstructured text can capture a clinician’s interpretations of causality that can supplement structured data in EHR systems. Explainable artificial intelligence applications could potentially leverage this to provide more clinician-friendly explanations through causality. There are a number of limitations in this study. First, we focused on common temporal patterns (i.e., Event, TIMEX3 and TLINK). We noticed that THYME corpus also contains some ALINK (aspectual link) annotations which need to be investigated in a future study. Second, we did not address attributes of Event annotations (e.g., polarity, degree, contextual modality) in this study, but we have defined a collection of FHIR extensions in NLP2FHIR to handle many of these NLP-specific data elements. Third, we noticed that many of the TIMEX3 annotations with the type of Date or Time were a time phrase rather than an exact date or time, indicating the complexity of temporal patterns from clinical narratives. For the FHIR representation, we used fhir:string instead of fhir:date or fhir:time to represent such time phrases.

As deep phenotyping is shifting the focus from case ascertainment or cohort identification to precise and comprehensive characterization of a phenotype, we consider the outcome of this FHIRTime work would enable a better characterization of the temporal trajectory of a phenotype in a standardized and reproducible manner. Future work will be focused on integrating the FHIRTime with the NLP2FHIR pipeline to enhance its temporal modeling and temporal reasoning capability.

Introduction

The COVID-19 pandemics has permanently changed the health projections of those who survived and cast shadows over the health of 10 ~ 20% world population, known as past acute sequelae SARS-CoV-2 infection (PASC). A major PASC clinical condition is Sustained COVID-19-related Renal Injury (Sus-CovRI). However, the middle-to-long term health impact of such COVID-induced or exacerbated chronic kidney disease (CKD) is largely unknown. In this work, we use the longitudinal Optum Clinformatics™ claim data and group-based trajectory model (GBTM)5 to explore the middle-term progression patterns of Sus-CovRI.

Methods and Results

Cohort characteristics. As shown in the CONSORT flow diagram (Fig. 1), in this study, we use the Optum Clinformatics™ Data Mart (Jan 1, 2007 to September 30, 2021) of claims data. The study cohort consists of about 19 million patients that have been enrolled between 01/01/2020 and 09/30/2021. Within this cohort, 279,071 (1.47%) patients were diagnosed with COVID-19 (ICD10:U07.1). The demographic and clinical characteristics of the overall study cohort and COVID-19 positive sub-cohort are show in Table 1. For the overall study cohort, the demographic pattern is representative of the U.S. population, with 10.5% as African Americans, 13.8% as Hispanic Americans, and 51.5% as females. For the COVID-19 positive sub-cohort, it recaptures known demographical features as reported by peers, which has significantly increased infection risks for African Americans and Hispanics, with odds ratios of 1.53 (95%CI: 1.51, 1.54; P-value < 2.2e-16) and 1.73 (95%CI: 1.71, 1.75; P-value < 2.2e-16), respectively.

The Sus-CovRI Phenomics. A Sus-CovRI phenomics is defined as a comprehensively and systematically curated collection of phenotypic information for biomedical informatics data analysis of PASC CKD. We extend our previously developed Common CLINic Index for Chronic diseases (CLINIC) CDM to OMOP CDM and comprehensively outline the general health conditions during the development and progression of common chronic diseases. The selection of these clinical indices is a tradeoff of the following considerations: 1) reflect health status and risks of chronic disease with aging; 2) clinically measured and provide strong evidence; 3) available in Optum; 4) relevant to COVID-19 syndromes; and 5) ready to use.

Longitudinal summarization of RWE data. The longitudinal RWE data is grouped into the following two time windows (Fig. 2): 1) the COVID-19/PASC window (red/blue shaded window) is defined as the time range from 14 days before the 1st positive test to the last follow-up; and 2) the Pre-COVID window (green shaded) is defined as
starting from 30 days before the 1st positive test and retrospectively tracked for 2 years. Transient features such as HbA1c levels in the Pre- or COVID-19 period are aggregated or summarized. Sustained conditions such as diabetes and hypertension will be tracked back to all available data. Transient features such as estimated glomerular filtration rate (eGFR) during COVID-19/PASC period are aggregated by day and used as longitudinal data. Baseline is defined as 14 days before the 1st positive test. Patients’ clinical conditions at baseline are composed of the aggregated or summarized transient features in the Pre-COVID window as well as sustained conditions in and before the Pre-COVID period. Such longitudinal data summarization is able to capture the renal injury events associated with the SARS-CoV-2 infection.

Discovered Sus-CovRI trajectory groups. As shown in Tab. 1, the trajectory group learning cohort (n = 99,678, 35.7% COVID-19 patients) is defined as patients who have positive COVID-19 diagnosis and have at least one eGFR values or serum creatinine measurements in the Pre-COVID window. Within this cohort, a COVID Survivor sub-cohort (n = 5,127, 1.84% of COVID-19 patients) is defined as patient with at least one eGFR value after 90 days post the initial COVID-19 diagnosis. Pre-COVID and Post-COVID CKD progression trajectories are identified using the BGTM on the Optum longitudinal eGFR data derived from serum creatinine laboratory results with CKD-EPI 2009 formula. Three Pre-COVID renal trajectories and their corresponding Post-COVID trajectories are discovered: 1) healthy group (blue curve) without existing renal condition. Among them, 2.3% demonstrated long-lasting renal injury after recovering from COVID; 2) mild CKD group (yellow curve), with 16.7% showed PASC CKD symptom; and 3) severe CKD group, with 48.7% patient showed COVID-exacerbated CKD (red curve).

Conclusion

Our work is one of the first large-scale profiling of the disease progression trajectories of the PASC CKD population. We reveal major CKD progression patterns and pave ways to better understanding the complexity of PASC CKD, determining clinical characteristics and risk factors, and providing RWE-based clinical decision support for managing COVID-19 survivors’ kidney health.

Gender Differences in Time to Diagnosis through Fairness and Time Variant Evaluation of EHR Data

Tony Y. Sun, MA¹, Jennifer L. Chen, BA¹, Harry Reyes Nieva, MAS¹, Oliver J. Bear Don’t Walk IV, MA¹, Jaan Altosaar, PhD¹, Noémie Elhadad, PhD¹
¹Columbia University, New York, NY, USA

Introduction

Recent research has identified differences in disease presentation, progression, and treatment responses across a number of health conditions among men and women. Here, we focus on time to diagnosis (TTD), traditionally defined as the interval from first alert symptoms to patient disease diagnosis, and explore potential TTD-related gender disparities. Specifically, across a large number of conditions, we quantify differences in time to diagnosis across women and men in a longitudinal fashion.

Methods

Dataset Using data from Columbia University Irving Medical Center, we selected patients with at least 3 years of continuous observation in 2010-2020. The study was approved by the Columbia IRB. Using 121 established phenotype definitions publicly available from the OHDSI HERA study, we constructed 121 corresponding cohorts, where entry time in the cohort corresponds to time of diagnosis. For each patient in a given cohort, we extracted their gender and all coded condition occurrences observed within 3 years prior to phenotype diagnosis. Along with each coded condition, we kept track of the date of its first occurrence in a patient longitudinal record. The final dataset comprises 533,566 women (mean age, 49.5 years) and 412,498 men (mean age, 49.1 years) with 14,900 unique condition codes.

Time-Variant Model Fairness in Diagnosis Classification For each phenotype, we trained a gender-agnostic binary classifier that diagnoses patients based on their clinical observations (i.e., first-occurrence of condition codes) documented up to 3 years prior to the official disease diagnosis. As such, the trained classifier is “fully knowledgeable” as it contains all observations up to time of diagnosis, particularly the relevant symptoms (e.g., abdominal pain indicating Crohn’s disease). We measured the classifiers’ performance on a cohort of patients with decreasing levels of right censoring (Figure 1(a)) up to 3 years prior to their diagnosis. In essence, this testing procedure aims to mimic a provider diagnosing patients at increasing time steps with knowledge limited to patient history accumulated thus far.

In line with established fairness literature, we measure the equality of opportunity of the positive and negative class (recall and specificity gap, respectively), and the precision and accuracy gap at each test window. For example, recall gap is the recall of diagnosing male patients minus the recall of female patients. In diagnosis, recall gap is important as minimizing false negatives ensures patients with a disease are not left untreated. Our approach to analyzing fairness gap over time is extensible to any definition of fairness relevant to the data domain.

In our analysis, we evaluate bias on the test data in a longitudinal manner, decreasing the amount of right-censoring at each time step and measuring the fairness gap over time. To measure the average fairness gap as information accumulates over time, we leverage mean squared error (MSE) and the overall directionality of bias over each time windows, combining these concepts into mean squared discrimination (MSD).

Results

Out of 121 phenotypes, 65 were excluded from the study because of low prevalence in our patient population. The following results pertain to the remaining 56 phenotypes (Figure 2). We use Crohn’s Disease as an illustrative example.

As the amount of patient history increases, the Crohn’s diagnosis model’s recall for both genders increases, but performance for men is consistently higher than women (Figure 1(b)); we see this in the positive, male-favored MSD recall metric for Crohn’s (0.097), which indicates a consistently male-favored odds of diagnosis.

*We recognize gender is a social construct while sex is a biological variable. We use the terms “gender,” “men,” and “women” based on available labels in our datasets.
†https://data.ohdsi.org/HERACharacterization/
Figure 1: (a) Test sets are generated with varying levels of right censoring, mimicking varying amounts of patient history available to providers (b) Gender-stratified recall at various time-bins for the Crohn’s diagnosis classifier.

Discussion and Conclusion

We propose an approach to evaluate gender differences in TTD in a longitudinal fashion. Using recall MSD as a proxy for diagnosis bias, we observe gender bias in all 56 phenotypes in the study, with 36 skewed towards earlier diagnosis for men (e.g. Crohn’s). Furthermore, women had more documented conditions prior to diagnosis (for instance, in the Crohn’s cohort, on average men had 17 conditions documented prior to diagnosis and women had 19). This might indicate that while women present the right conditions earlier to help detect the presence of a condition, they also present many other conditions that may confuse the classifier (and potentially providers as well), thus rendering a male-biased recall. The marked gender differences we find in recall gaps raise open questions about disparities in healthcare.

Physicians with hybrid skillsets in digital health and informatics facilitate necessary innovation in mental health care delivery: A physician engagement strategy

Tania Tajirian, MD, CCFP, FCFP, DTMPH\textsuperscript{1,2}, Brian Lo, MHI\textsuperscript{1,2}, Gillian Strudwick, RN, PhD, FAMIA\textsuperscript{1,2}, Lydia Sequeira, MHI\textsuperscript{1,2}, Damian Jankowicz, PhD\textsuperscript{1}

\textsuperscript{1}Centre for Addiction and Mental Health, Toronto, Ontario, Canada; \textsuperscript{2}University of Toronto, Toronto, Ontario, Canada

Introduction

Delivering mental health care in innovative ways that do not solely rely on face-to-face care remains an area of priority as the COVID-19 pandemic exacerbates the mental health of Canadians across the country \textsuperscript{1}. However, the effective implementation and adoption of innovative approaches (which may include digital health) into practice continues to remain a challenge \textsuperscript{2}. In many cases, despite best practices from implementation science and change management (e.g., Consolidated Framework for Implementation Research \textsuperscript{3}), many of these innovations fail to become fully embedded into practice at an organization. More problematically, as outlined in the Clinical Adoption Meta-Model\textsuperscript{4}, innovations that are suboptimally implemented may eventually lead to workarounds and unintended consequences.

With this problem in mind, at our large academic and teaching mental health hospital in Toronto, Ontario, we implemented the Physician Engagement Strategy\textsuperscript{5} to address the ongoing burden related to the use of the electronic health record (EHR) system. In this strategy, physicians have the opportunity to engage in driving change through both virtual and in-person modalities. As we implemented this strategy throughout the pandemic, we began to notice how these initiatives have inspired a new generation of “hybrid physicians”\textsuperscript{6} committed to leading changes across the organization in both digital health and practice-related capacity. The impact of these interventions has led to the development of a unique workforce of physicians that strive to reduce silos across Academic Divisions and foster a sense of excitement and collaboration towards innovations in clinical care. In this podium presentation, we share how the Physician Engagement Strategy has led to the transformation of the organizational and informatics workforce at our institution and discuss lessons learned and recommendations for translating this vision into other organizations.

Methods

The Physician Engagement Strategy\textsuperscript{5} is a multi-pronged strategy that includes multiple interventions that aim to engage physicians, inspire change, and measure impact. The development of this initiative has been driven by an academic divisional tour of the ongoing EHR-related challenges and a baseline survey with front-line physicians across the organization \textsuperscript{7}. Based on these findings, several initiatives that focus on inviting clinicians to be agents of change have been developed and implemented. This included:\textsuperscript{5}

- **Physician Think Tanks** – A cross-divisional physician forum that meets every month with stakeholders from IT leadership (Health Records, Clinical Applications), clinical informatics nurses, clinical leadership, and pharmacy and laboratory informaticians. The main objective of this forum is to foster discussion across the members of different departments and divisions in order to support decision-making and strategy development.

- **‘SWAT’ Teams**\textsuperscript{5} – A team comprising of clinician and IT administrators that work with front-line clinicians from each academic division to identify and address issues related to the EHR in an agile manner. Once an issue or challenge has been identified, it is then triaged based on the type of solution needed and the level of changes required (e.g., simple fix vs. new feature).

- **Physician portal and monthly newsletters** - A portal that is a one virtual stop for physicians to find information about a variety of wellness initiatives, personal stories, and educational presentations such as Grand Rounds. Monthly newsletters to communicate IT changes and EHR improvements that are completed through the think tanks and SWAT tours.
Results

Between 2019 and 2021, two rounds of SWAT and over 24 Physician Think Tank meetings were conducted. This work has collectively inspired an evolving workforce dedicated to advocating and driving change in innovative mental health care as part of the organization. These observations are detailed below.

As part of the SWAT team initiative, physicians had a unique opportunity to become closely engaged with IT and informaticians to report any issues that hinder their overall experience with digital tools. While the original intent was a focus on the use of the EHR system, a range of issues have been reported, including speech recognition technology, virtual care, etc. The reporting of these issues has since led to a broader discussion with other clinical departments (e.g., telemedicine) and practice changes. As such, the SWAT initiative has become a unique, low-burden, channel for physicians to advocate for challenges and opportunities to improve the delivery of mental health care.

In addition to the work from the SWAT initiative, the Physician Think Tank has evolved over time to support the development of ‘hybrid physicians’ in various ways. While the initial iteration of the Physician Think Tank comprised of a single physician liaison from each academic division, the membership has since grown to include professional practice stakeholders and physicians with other responsibilities (e.g., research) interested in informatics. Likewise, the topics brought up by the committee members have grown significantly. Recent topics have included virtual care and broader practice workflows that have an intersection with informatics. As such, members of the Think Tank have become advocates for informatics and mental health care on behalf of the user group they represent.

Discussion

In this work, we share our perspectives and experience on how the implementation of our Physician Engagement Strategy has supported the transformation of the organizational and informatics workforce to become advocates for innovative mental health care. As observed in our SWAT initiative, it has allowed for a decentralized approach to participating in the optimization of our EHR system and digital health infrastructure. Alongside the increased membership in the Think Tank, these opportunities have collectively fostered talent and interest amongst physicians in advocating for digital health with IT and other leadership stakeholders.

Conclusion

Fostering a physician workforce dedicated to informatics and the delivery of innovative mental health care has become instrumental in the implementation success of digital health. In this presentation, we share our reflections and experience with how the Physician Think Tanks and SWAT teams have led to a team of ‘hybrid physicians’ at the intersection of medicine and digital health.

Acknowledgements

The authors would like to acknowledge the organization’s physicians and leadership teams for their support in these initiatives.

Urologist Use and Perceptions of the EHR: Perspectives from a Surgical Specialty

Introduction: Electronic health records (EHRs) serve as the backbone of modern care delivery with increasing emphasis given now to improving quality through embedded tools such as clinical decision support. Potential advances, however, may be hampered by persistent usability issues with EHRs, and relatively little attention has been given to surgery and surgical specialties, such as urology. To push forward, we explored the use and perceptions of EHRs among urologists.

Methods: We conducted a national sequential explanatory mixed methods study. Via the 2019 American Urological Association Census, we surveyed practicing urologists on EHR function use and impact on clinical efficiency and patient care. Urologists rated the impact of the EHR on clinical efficiency and patient care using a 5-point Likert scale (1: Strongly Disagree to 5: Strongly Agree). We then calculated the net favorability—the proportion agreeing minus the proportion disagreeing—as a summary measure. We also created a binary measure for agreeing (Strongly Agree and Agree) to identify associated characteristics through bivariable and multivariable analyses. Next, we interviewed 25 respondents on their EHR experiences. Coding-based analysis was applied to identify concepts and themes. These qualitative findings were then integrated with survey findings through a joint display and weaving narrative.

Results: In 2019, 96.4% of practicing urologists used an EHR for a weighted sample of 12,366. Over 90% used the EHR for charting, viewing results, and order entry (Figure). Fewer used the communication functions: 79.6% communicated with providers internally, 64.6% sent/received information externally, and 59.0% exchanged messages with patients. Few utilized information from alerts (43.4%) or reported data to clinical registries (28.4%). In terms of perceptions, less urologists felt the EHR increased clinical efficiency (35.8% agree vs. 47.4% disagree; -11.6%) while more felt it improved patient care (43.1% agree vs. 33.4% disagree: +9.7%). Perceptions differed based on experience, workload, and practice setting (p<0.05), corresponding respectively to themes on prior EHR exposure, administrative burden, and infrastructure/support (Joint Display). Thematically, perceptions of clinical efficiency related to information management (e.g., access vs. excess vs. incoherent/inaccurate data) while the impact on patient care focused on patient safety and the patient-physician relationship (e.g., safeguards vs. extraneous non-clinical tasks).

**Conclusions:** Though EHRs have become widely adopted, the degree of usage varies, and EHRs continue to engender negative feelings, particularly by busy urologists in smaller, less resourced practices. With respect to clinical efficiency, concerns center on information management. While urologists found that the EHR offered greater access to information, they also found that this information can be inaccurate and superfluous, creating administrative inefficiencies that are magnified by a compressed digital work schedule due to surgery and other procedures. From a patient care standpoint, urologists highlighted the potential of the EHR to help them avoid adverse outcomes with relatively little mention of evidence-based medicine or guideline-concordant care. Urologists also highlighted the potential harms of inaccurate information and the impact on physician-patient interaction. EHR-based tools that ameliorate administrative burden and simplify information management may be best positioned for effective use. Moreover, framing the use case of specific functions and tools on how they can improve outcomes and performance and/or how they respect the physician-patient relationship may further promote dissemination and implementation.

ADNet: Identify biomarkers of Alzheimer Disease with MRI and EMR data using Deep Neural Networks

Ziyang Tang, PhD1, Qianqian Song, PhD2, Jing Su, PhD3, Baijian Yang, PhD1
1Department of Computer and Information Technology, Purdue University, West Lafayette, IN, USA; 2Department of Cancer Biology, Wake Forest School of Medicine, Winston Salem, NC, USA; 3Department of Biostatistics, Indiana University School of Medicine, Indianapolis, IN, US

Abstract We develop a data-driven deep learning framework to identify the brain structural differences among the early-stage patients of Alzheimer Disease (AD). Our framework consists of a general approach to extract features from abnormal structures by MRI scans and Electronic Medical Records (EMR), followed by a gradient-based visualization that highlights the positions directly on the original spatial structures. We show that this deep learning framework facilitates the detection of the early preclinical stage of AD that can be used as a reference to assist clinicians.

Introduction Early diagnosis of AD remains a daunting task despite active research in the past two decades. The prevailing diagnostic method mainly relies on the subjects’ behavior and their cognitive development history. Diagnoses can only be made after the subjects demonstrate severe abnormal behaviors, usually after a long period of time. This raises critical concerns/challenges since many patients may have already missed the opportunity for effective early intervention. In this work, we propose a data-driven deep learning framework, named ADNet, to scrutinize and discern abnormal structures from MRI scans of AD patients. After the detection of the structural abnormality and differences, our framework will highlight them over the original images. The overlay process provides guidance and assists clinicians in the early diagnosis of AD. Besides the image data, we also introduce the valuable EMR data as a prior information for more precise diagnosis. We establish a novel approach to build up the graph from the patient information and embed the graph into the framework to predict whether classifying the sample as a potential AD patient.

Methods and Results In the early stage, the abnormal features are not obvious enough to be directly identified by human eyes, while the structural differences are masked behind thousands of voxels of the original images. To unveil the abnormal structural differences, we develop an end-to-end structure called ADNet, to identify the spatial differences between AD and normal control (NC) groups. The framework combines the EMR data and image data for precise predictions. Specifically, based on the patient phenotypes including age, sex, and other cofounders that are highly related with AD, we design a novel graph construction approach to build a patient graph using shared nearest neighbors in canonical correlation vectors that project patient’s information into a correlated low-dimensional space. We then embed the patient information as an input for the prediction. We further investigate the abnormal structure in the MRI data and use the CNN model to learn representative features of brain structure and assign the original images into one of the two groups (AD or NC). A gradient-based visualization method will then highlight the significant features in the original images. To evaluate the selected features, we apply the atlas template AALv3, and compare the features with pre-defined brain areas. Finally, brain areas with highlight features will be compared with previous findings, from which an experienced clinician will check whether the selected areas could be used as biomarkers for AD. To avoid bias, we apply a double-blind test that the clinician is only given the images and patient phenotype without ground truth.

Conclusion We demonstrate ADNet provides an integrated environment for assisting early-stage detection of AD using ADNI dataset. We propose an automotive manner in finding the potential biomarkers that can help the clinicians to diagnose AD in an earlier stage.
Patient Perceptions of Receiving COVID-19 Test Results via an Online Patient Portal

Robert W. Turer, MD MSE,1 Catherine M. DesRoches, DrPH2, Liz Salmi3, Tara Helmer, MPH1, S. Trent Rosenbloom, MD, MPH1

1Vanderbilt University Medical Center, Nashville, TN, USA; 2Beth Israel Deaconess Medical Center, Boston, MA, USA

Introduction

Mounting evidence shows that access to clinical notes empowers patients to better manage their health without burdening clinicians1,2. However, evidence surrounding the immediate release of sensitive test results is controversial3. Vanderbilt University Medical Center (VUMC) has experienced a trend toward increased use of test review features in My Health at Vanderbilt (MHAV), our patient portal4. Historically, VUMC released most results to MHAV within days, only delaying longer for tests with perceived potential for harm if disclosed without the context provided by an interpreting provider. Examples include human immunodeficiency virus (HIV) testing, tumor markers, and genetic testing for Huntington disease.

Patients with COVID-19 have faced stigma in the United States and internationally5, and the disease can cause substantial morbidity and mortality6. As such, we traditionally would have delayed the release of COVID-19 test results to MHAV. However, the overwhelming volume of COVID-19 testing necessitated immediate release of COVID-19 test results to patients after completion7. This online survey-based study evaluated patient perceptions of receiving these results immediately upon completion via MHAV.

Methods

This is a single site online survey-based evaluation of patient perceptions surrounding the release of COVID-19 test results immediately upon completion via MHAV at VUMC - a large, private, nonprofit academic medical center in Nashville, TN. MHAV has more than 730,000 active users representing 62% of clinical encounters since April 1, 2020. This study was deemed exempt by VUMC’s Institutional Review Board. Patients agreeing to direct contact about COVID-19 research opportunities were included in a registry maintained by the Vanderbilt Institute for Clinical and Translational Research (VICTR). From this cohort, we contacted all adult patients with a valid email address who had accessed MHAV since having a resulted COVID-19 test at VUMC.

We partnered with members of the OpenNotes collaborative to design an online survey using REDCap8 to evaluate the following domains: MHAV user role (i.e. patient vs. care partner); ease of use; impact of immediate release; notification of results; impact of viewing results on health management; importance of result sharing; and demographic information.

Results

At VUMC, 25,359 patients who underwent COVID-19 polymerase chain reaction (PCR) testing had logged into MHAV since their first test was ordered. Of this group, 1,390 patients overlapped with the group of patients who had agreed to direct contact about COVID-19 research opportunities and were invited via email to participate. There were 324 (23.3%) responses to the survey. Numbers (percentages) are represented as a fraction of respondents to each question.

MHAV User Role: 310 (96.3%) of respondents were patients themselves, and 290 (90.1%) respondents viewed the results of their COVID-19 test using MHAV.

Ease of use: 262 (95.2%) found the experience “Not very confusing” or “Not confusing at all.” Of the 13 (4.7%) respondents who expressed confusion, 11 reported difficulty interpreting their results and 2 could not find their results.

Impact of Immediate Release: 243 (88.4%) viewed their result before discussing it with a clinician. 99 (40.7%) stated viewing before discussing with a clinician did not change whether they were worried about their health, while 83 (34.2%) felt less worried and 12 (4.9%) felt more worried. 49 (20.2%) were never worried.

Notification of Results: 234 (85.2%) found the default email reminder about their test result “A little useful,” “Somewhat useful” or “Very useful,” while 10 (3.6%) found it “Not at all useful.” 31 (11.3%) respondents reported not seeing an email notification. 119 (43.3%) did not prefer an alternative notification method, while 120 (43.6%) preferred text messages, 58 (21.1%) preferred a phone call from a healthcare professional, and 4 (1.5%) preferred a letter in the mail.

Impact of Viewing Results on Health Management (visual analog scale from 0-100, with 100 being very important):
“...for taking care of your health” - median 86 (IQR 68 – 98).
“...for making next steps for your healthcare” – median 89 (IQR 68 – 99)
“...for helping you feel in control of your care” – median 85 (IQR 67 – 98)

Importance of result sharing: 259 (96.6%) respondents shared their result with someone else - 235 (90.7%) with a family member or relative, 147 (56.8%) with a friend, 80 (30.9%) with a healthcare provider, 24 (9.3%) with a large group of friends (e.g. through social media). Respondents provided additional details mostly related to informing employers or potentially exposed contacts. The importance of COVID-19 result sharing was measured via visual analog scale from 0-100 (100 being very important). The median response was 77 (IQR 50-97). 176 (58.7%) respondents encouraged someone else to get tested because of viewing their result.

Demographics: 284 (95.9%) reported their overall health as good, very good, or excellent. Of 296 respondents, 272 (92.5%) had at least some college education. 16 respondents (5.5%) reported Spanish/Hispanic/Latino ethnicity. 264 (90.7%) respondents identified as white, 14 (4.8%) as black or African American, 1 (0.3%) as American Indian or Pacific Native, 5 (1.7%) as Asian, and 10 (3.4%) as Other. 290 (99.0%) reported speaking English at home. 15 (5.1%) of respondents were unemployed or unable to work. 38 (12.9%) respondents were health care professionals.

Discussion

Our survey indicates that, in our cohort, most patients comfortably viewed and interpreted their COVID-19 results on MHAV prior to any discussion with a clinician without distress, despite concerns about stigmatization or fear of not discussing their result with a clinician. Most were comfortable with email notifications, though some requested text messages or healthcare provider communication. Most respondents reported that viewing their COVID-19 result on MHAV enabled them to take care of their health, make next steps for their healthcare, and feel in control of their care. Sharing of results was important to an overwhelming majority of patients – allowing them to share with a wide range of parties and to encourage someone else to get tested as a result. Other sites may consider providing immediate access to COVID-19 results via online patient portals.

Our limitations are largely demographic in nature: the surveyed cohort was predominantly white, English-speaking, employed, and highly educated. Because we targeted those who had previously responded through electronic means, we may have selected patients with technological literacy compared to the population at large. Further study should evaluate how patient portal-based results sharing impacts patients who are from underrepresented minority groups, who are non-English speaking, or who lack access to technology or higher education.

The added value of natural language processing in automated analysis of patient experiences

Marieke M. van Buchem, MSc1, Olaf M. Neve, MD1, Hileen Boosman, PhD1, Ilse M. J. Kant, PhD1, Erik F. Hensen, MD PhD1

1Leiden University Medical Center, Leiden, the Netherlands

Abstract

Patients’ experiences are important to improve healthcare and are often collected using structured questionnaires. Open-ended questionnaires give patients the opportunity to share their unique perspective. Natural language processing (NLP) can automate the analysis of open-ended questionnaires for an efficient and patient-centered approach to improve healthcare. We created a new, open-ended questionnaire, the AI-PREM, and constructed a NLP tool for automatic analysis. We show that this combination leads to broader insights into the patient’s experience.

Introduction

Value-based Health Care (VBHC) aims to increase patient value by improving outcomes and lowering costs. Patient outcomes are a combination of health outcomes and patient experiences. The latter is often measured using structured questionnaires, called patient-reported experience measures (PREMs). Although structured questionnaires are easy to analyze and can lead to valuable insights, they narrow the scope of patient experiences covered. Many PREMs therefore include open-ended questions, giving patients the opportunity to share their unique perspective in more depth. Previous studies have shown that these open-ended questions can complement the structured PREMs, but manual analysis is time-intensive1. Automated analysis would overcome this problem, however patient experiences often contain multiple sentiments and topics, complicating current analyses1,2. Natural language processing (NLP) could be a good technique to address both the identification of topics and the associated sentiments within patient responses to open-ended questions. We created a new open-ended PREM and built a NLP tool to analyze patients’ responses, aiming for a more efficient way to capture a broad spectrum of patient experiences while creating actionable insights.

Methods

The open-ended PREM, called the AI-PREM, contains five open-ended questions about how the patient experienced certain aspects of care delivery. These questions, based on the Picker principles of person centered care3, cover the following aspects: the received information, the organization of care, the collaboration with other healthcare professionals, and how the patient was approached. The phrasing of each of these questions is the same, asking patients how they experienced the specific aspect of care delivery. The last question asks the patient for any other experiences he or she would like to share.

The AI-PREM was sent to patients who visited the vestibular schwannoma integrated practice unit (IPU) at the Leiden University Medical Center in the past 15 years. These patients also filled out a general, structured PREM for comparison.

We developed the NLP tool with a multidisciplinary team consisting of clinicians and technicians. We used an iterative process with short development cycles that always started with a brainstorm session about ways to improve the applicability of the model and ended with feedback on the new output of the tool. The NLP tool that was created during this process consists of three models: two sentiment analysis models using a pretrained language model (Bidirectional Encoder Representations from Transformers, BERT); and a topic model using Non-Negative Matrix Factorization (NMF). See Figure 1 for an overview. For the sentiment analysis models, we manually labeled 60% of the patients’ responses as negative, neutral, or positive per question. A pretrained, multilingual BERT model was finetuned for two binary classification tasks: first classifying texts as negative or non-negative and then classifying the non-negative texts as positive or neutral. These two models were trained on 80% of the labeled data and validated on 20% of the data.

After the sentiment analysis, the data were preprocessed. Spelling was corrected, words were lemmatized, and stop words and words with less than 3 letters were removed. To make the topics as informative as possible we only kept verbs, adverbs, nouns, and adjectives and split the text into n-grams ranging from one to three words. A separate topic model was created per question and sentiment (negative or positive) to improve the interpretability of the extracted topics. This led to 10 separate categories, for which a separate topic model was created using NMF. The number of topics per category was automatically determined using a coherence metric.
To study whether the extracted topics were relevant, the answers of the AI-PREM were compared to the answers of the structured PREM. Furthermore, we plan to ask end-users to determine whether the extracted topics cover the subjects of a random sample of patient responses.

**Preliminary results**

535 patients filled out the AI-PREM questionnaire. The sentiment models classified the texts as negative or non-negative and neutral or positive with an accuracy of 92%. The number of topics per category ranges between two and six and 96.3% of patient responses can be assigned to a topic. We are currently finalizing the comparison to the structured PREM and the manual analysis of the random samples and intend to present this at AMIA. Our preliminary results show that the majority of subjects addressed by patients is covered by at least one of the topics and that the answers to the structured PREM align with the answers to the AI-PREM. Furthermore, the topics provide several new subjects that are not covered in the structured PREM but negatively or positively affect patients’ experience. We also intend to present the current visualization of the output and the collected feedback from end-users during the conference.

**Figure 1.** Overview of the input, models, and output of the AI-PREM tool.

**Discussion**

In this study, we show that an open-ended PREM specifically designed for NLP analysis is able to capture the most important results from a structured PREM, while also capturing various additional topics that are negatively or positively viewed by patients, in a fraction of the time of a manual analysis. This allows patients to elaborate on experiences they deem important, yielding information additional to structured PREMs and more actionable insights specific for the IPU. Furthermore, the use of an unsupervised approach makes the method easily applicable and potentially generalizable to other settings. Future research and implications of this study will be discussed at AMIA.

Introduction
Ensuring that precision genomic medicine is effective for individuals and for health systems requires clinicians, researchers, and testing laboratories to communicate genomic variation and related information reliably. Although widely-adopted standards for certain classes of variation already exist, many of these formats have been purpose-built for specific applications, including human-readable standards such as the Human Genome Variation Society (HGVS) variant nomenclature, the International System of Human Cytogenomic Nomenclature (ISCN), and the PharmVar Pharmacogenetics nomenclature, as well as genome-oriented flat file formats such as the Variant Call Format (VCF), among others. All current standards have design constraints that preclude a comprehensive coverage of variation types and extensibility to new types, including highly complex forms of variation.

Methods
In response to this need, the Global Alliance for Genomics and Health (GA4GH) Genomic Knowledge Standards (GKS) Work Stream led the development of the Variation Representation Specification (VRS, pronounced “verse”), a community-driven and extensible specification to standardize the exchange of diverse and complex variation data. In the course of development, the standard was applied and tested in real-world data exchange systems hosted by GA4GH Driver Projects, including the Clinical Genome (ClinGen) resource, the Variant Interpretation for Cancer Consortium (VICC), and the BRCA Exchange.

Results
VRS is a computational framework encompassing interdependent components for the precise representation of variation: a formal terminology, an extensible information model, schema, and conventions for normalizing and identifying variation. It is more verbose than other contemporary human-readable variant representations, but better suited to expressing and representing complex variation concepts for computational use. It is also a natural complement of human-readable nomenclatures when used for the exchange of genomic information from databases, clinical reports, or scientific manuscripts. VRS currently covers many classes of variation that are defined in cis on a contiguous molecule such as single nucleotide variants (SNVs), multi-nucleotide variants (MNVs), indels, repeats, and haplotypes.

VRS also provides semantic clarity to more complex forms of variation. For example, due to design constraints in other variant representation systems, resources often represent these variants as a conflation of the similar but distinct concepts of systemic copy variation and tandem repeating elements within a molecule. In addressing this, systemic copy number and repeated sequence expressions were created to precisely express these distinct concepts. This complements existing cross-community concepts in VRS, including variation describing giemsa-stained chromosome banding patterns. Additional progress has been made in the representation of gene fusion and structural variation events, a major objective of the VRS version 1.3 release.

A key design decision of VRS is the representation of Variation as Value Objects: minimal information objects intrinsically defined by their content (e.g. a C>T transition in residue 2 of the sequence CCTAC), rather than records for human presentation from system identifiers (e.g. clinvar:13961). This design choice is fundamental to each component of the specification; objects are immutable and have a specific meaning prescribed by the attributes they contain. Values extraneous to the meaning of a VRS object, such as the name of a location (“chr 7”) or a label for a
well-known variant (“BRAF V600E”) are not captured directly within VRS objects. Combined with a process for normalizing variation objects by implementing the NCBI Variant Overprecision Correction Algorithm (VOCA)(1), this provides a precise, singular representation of a given variation concept. Normalized value object representation also enables the use of the associated GA4GH Computed Identifier Algorithm, a novel mechanism for the federated identification of molecular variation data (Figure 1).

**Figure 1.** VRS provides a mechanism for federated variation identification via the Computed Identifier Algorithm. (A) The Computed Identifier Algorithm is defined in three stages. First, an identifiable VRS object such as an Allele (blue box) is transformed into a well-defined and canonical serialized JSON representation. The serialized Binary Large Object (BLOB) is then digested via the SHA-512 algorithm, truncated to retain only the first 24 bytes, and subsequently encoded using base64url. The resulting digest string (green text) is then appended to the object type identifier; for an Allele object, the identifier prefix is “VA” (blue text). The identifier is then assembled into a compact URI (CURIE) under the ga4gh namespace (orange text). (B) Use of the VRS framework enables de-duplication of identical variation concepts with differing HGVS descriptions. Here, multiple synonymous HGVS descriptions are indicated for a variant on genome builds GRCh37 and GRCh38, the corresponding transcript variant, and predicted protein translation. These four contexts (two genome assemblies, transcript, and protein) resolve to four distinct identifiers, regardless of which synonymous description is used to build the VRS object. Ellipses (“...”) used in objects and strings in this diagram represent content that is omitted for simplicity of presentation. For additional details, see [https://vrs.ga4gh.org/en/stable/impl-guide/computed_identifiers.html](https://vrs.ga4gh.org/en/stable/impl-guide/computed_identifiers.html).

Application of VRS to Driver Project systems revealed novel challenges created by the value object design decision for VRS Variation. Specifically, transmission of human-readable identifiers for genomic variation is a common use case in contemporary molecular variation databases, underlining the need to have complementary formats and nomenclatures for variation description. In addition, we identified that while VRS provides a novel solution to the challenge of federated variation identification, it is beyond the remit of VRS to specify methods or policies for simplifying aggregate variation (e.g. a ClinVar Variation record aggregating multiple genomic, transcript, and protein contexts, such as those illustrated in Figure 1B). To address these concerns we developed VRS Added Types for Interoperable Loquacious Exchange (VRSATILE; [vrsatile.readthedocs.io](http://vrsatile.readthedocs.io)), a set of proposed extensions and a community guide to maximizing the utility of VRS in real-world data exchange.

**Conclusion**

VRS is a framework for the computational representation of molecular variation. The extensibility of this framework enables the representation of disparate and complex classes of variation, including systemic copy number variation, cytogenetic variation, gene product expression, gene fusions, and structural variation. VRS has demonstrated value in production genomic data exchange systems, and is complemented by proposed extensions in VRSATILE.

An Evaluation of Racial Disparity in 30-Day Hospital Readmission Models

H. Echo Wang, MSPH1, Hadi Kharrazi, MD, PhD1
1Johns Hopkins University School of Public Health, Baltimore, MD

Introduction
The potential for predictive algorithms to exacerbate inequity in healthcare has been increasingly recognized.1 Efforts to quantitatively measure bias have also surged in response to the rising concern of algorithmic inequity.2 However, bias measurement methods are rarely reported due to their poor interpretability and mathematical incompatibilities between notions of bias.3 To address the lack of bias measurement, this study aims to explore the potential bias of common 30-day hospital readmission models in generating disparate results for African American vs. White, and for low-income vs. high-income patients.

Methods
Study Population: The retrospective study included 1.5 million adult inpatient discharges 2016-2018 in Maryland. Study Outcome: Unplanned 30-day hospital readmissions were identified using the methodology adopted by CMS.3 The unit of analysis was hospital discharge. If more than one readmission occurred within 30 days, only one readmission was counted. Predictive Models: LACE index,4 HOSPITAL score5, and CMS hospital-wide all-cause readmission measure6 were included in the analysis. The CMS measure was applied “as is” with existing coefficients, or “retrained” using 50% of the sample. Measures: We measured bias between black and white races, and between low-income and high-income subpopulations. Predictive performances of each model were derived for all population and each subpopulation using AUC, Brier statistic, and Hosmer-Lemeshow goodness of fit. Common mathematical bias measures were calculated for each model: statistical parity (equal total positive rates), equal opportunity (equal true positive rates), false positive rate parity (equal false positive rates), and false negative rate parity (equal false negative rates). Generalized entropy index (GEI), which was proposed to measure algorithmic fairness, was also calculated.7 To calculate these measures, standard model thresholds were used: 10 points for LACE, high-risk (5 in the adjusted scoring) for HOSPITAL, and the ideal threshold derived using the receiver operating characteristic (ROC) curve for the CMS measures. Statistical Analysis: Primary analyses were conducted in R. Aggregate condition categories were calculated in SAS. The results were stratified by hospitals serving mostly blacks vs. whites. Sensitivity analysis was performed to explore how different thresholds affect the model accuracy and bias.

Results
Demographics: Among the 829,584 unique patients, blacks and low-income groups were more likely to be on public insurance, have longer length of inpatient stay, more inpatient procedures, higher inpatient charges, higher emergency admissions and more comorbidities. Blacks were more likely to live in urban areas and hospitalized in major teaching or large hospitals (>=200 beds). Low-income groups were more likely to live in rural areas and hospitalized in major teaching or large hospitals. Observed and Estimated Rates: The observed 30-day unplanned readmission rates were 11.4% for all population, 11.2% for white, 13.0% for black, 10.6% for high-income and 12.9% for low-income populations. LACE in general overestimated readmission rates but more so in blacks and low-income groups. The readmission rates estimated by HOSPITAL score are close to observed rates. The CMS as-is model underestimated across subpopulations and the estimated rates were relatively flat, while the retrained CMS model overestimates in all subpopulations to a similar degree. Predictive Performance: For each model, predictive performance measures remained largely consistent across subpopulations. LACE, HOSPITAL and CMS as-is models had moderate predictive performance (AUC 0.62-0.69), but retrained CMS model improved the performance across subpopulations (AUC 0.73-0.74). Bias Measures: Misclassification rates (i.e. FPR parity, and FNR parity) indicated relative between-group bias between models, while the absolute between-group difference (e.g. FPR difference between black and white) may not directly translate to bias as the observed readmission rates vary between groups (Table 1). Retrained CMS model and HOSPITAL score had the lowest racial bias based on FPR parity and FNR parity. The bias between income groups was low across models and lowest in the retrained CMS model. Based on GEI, Retrained CMS model and HOSPITAL score have the lowest GEI indicating the least bias, while CMS as-is model has the highest bias. When stratified by majority black and majority white hospital, the racial bias diminishes in majority black hospitals, in which the observed readmission rates are close between black and white. Sensitivity Analysis: Several trade-offs were observed. The commonly used thresholds of LACE and HOSPITAL maximized accuracy but were not fair between subpopulations. A lower threshold improved fairness but sacrificed accuracy. The thresholds of the two CMS
models were selected based on ROC curve thus minimized overall FNR and FPR; however, a clear threshold to simultaneously improve both bias measures were lacking.

### Discussion

The bias measures related to misclassification were helpful to compare bias between models. Retraining of a model is effective in reducing bias between groups. In addition, as confusion-matrix based metrics are driven by baseline prevalence rates, some proposed bias measures (e.g. equal positive rates) are determined to be inappropriate for the predictive task due to the significant difference in observed readmission rates between groups. For the same reason, the absolute ratio or difference of the misclassification measures should not be simply compared to 1 (or 0) to draw a conclusion regarding bias. When the observed readmission rates were similar between groups, as in the case of majority black hospitals, the magnitude of bias decreased or disappeared, despite that patient-level predicted risk remained the same. Further analysis on misclassified cases showed blacks were sicker than white at the same predicted score; false negative (predicted low risk but readmitted) blacks were sicker when they readmit; and false positive (predicted high risk but not readmitted) blacks were more likely to be hospitalized later (black: 65%, white 59%). It is apparent that blacks need more healthcare intervention across risk levels, including those falsely classified as low risk. Therefore, quantitative bias measures were helpful to compare models under the same condition, but have limited utility in determining the direction, magnitude or implications of bias.

The sensitivity analysis also illustrated the issue of selecting eligibility threshold of predictive models. Regardless of the type of predictive models, it is a common practice to determine an eligibility threshold post-modeling. Classic decision theories do not account for group bias in determining the threshold, but our work demonstrated the danger of creating inequity with slight threshold change. We recognize the selection of the threshold with many competing factors (e.g., accuracy, benefit, harm, bias) is not a straightforward task. However, it is increasing important to recognize and monitor the differential effect between groups, and to seek appropriate adjustments in practice.

Introduction
As of July 2021, there had been over 190 million confirmed cases of the coronavirus disease 2019 (COVID-19) and four million deaths. Emerging prospective and retrospective studies suggest that some patients have persistent symptom, and/or develop delayed or long-term complications after their recovery from acute COVID-19, which may also be referred to as post-acute sequelae of SARS-CoV-2 infection (PASC) syndrome or long COVID.1,2 The onset, scope and duration of these symptoms represent a new phase of the pandemic, with significant implications for health care delivery. With rapid evolution of the scientific literature, characterization of PASC symptoms varied widely by study.1 This heterogeneity of research finding is attributed to multiple factors, including variation in study design, patient populations, “post-acute COVID” timeframe, and sample size.2 Most early studies on PASC symptoms relied on patient survey data, manual chart review, and in person follow-up. These studies were often limited by sample size and reporting biases. Longitudinal electronic health record (EHR) data serve as a rich data source for studying PASC symptoms. However, patient symptoms are predominantly found in unstructured, free text data in clinical notes which require specialized natural language processing (NLP) tools for search and identification.3 NLP to extract long-term symptoms in the post-acute COVID-19 period remains an unmet need. One big challenge is the wide variation in potential PASC symptoms. Therefore, the objective of this study was to develop a comprehensive PASC symptom lexicon by leveraging real-world clinical EHR data, medical ontologies, an NLP tool and manual chart review.

Methods
The study was conducted in the Mass General Brigham (MGB) healthcare system, the largest integrated healthcare delivery system in New England. We used a two-phase approach to develop and evaluate a post-acute COVID-19 symptom lexicon (Figure 1). In the first phase of this study, we focused on lexicon development. First, we identified patients who were ≥18 years of age and had a positive test result for SARS-CoV-2 by polymerase chain reaction (PCR) clinical assay between March 4, 2020 and February 09, 2021. We defined the post-acute COVID-19 period as the days on and after day 51 from first positive PCR test and used all clinical notes from days 51-100 for each patient. Due to the focus on post-acute COVID-19 symptoms, patients who died before day 51 were excluded from the study. We divided the corpus of clinical notes into development (90% of the study cohort) and validation (10% of the study cohort) datasets to meet our study objectives. Second, using the Unified Medical Language System® (UMLS) and SNOMED CT, we compiled an initial symptom lexicon containing selected UMLS concepts and related synonyms. Third, we applied the MTERMS NLP tool4 to extract mentions of the symptoms in the lexicon from the development dataset. Fourth, we refined the lexicon based on an iterative process including: (1) symptom ranking based on prevalence; (2) manual review to identify post-acute COVID-19 symptoms; (3) consolidation of concepts of similar meaning; and (4) evaluation of NLP performance. Once the lexicon reached a satisfactory level of performance during the NLP evaluation in the development dataset, we moved on to the second phase, which evaluated its performance in the NLP system using the validation dataset of a different cohort to gain insights about the lexicon. We measured performance in terms of precision (or positive predictive value) for the 50 most common symptoms and recall (or sensitivity) across all the symptoms. The final symptom lexicon and NLP were used to evaluate NLP performance in the validation dataset. After validation, we applied the lexicon and NLP to the entire clinical note corpus. We calculated the frequency of PASC symptoms within the entire study population during the 2-month follow-up.

Figure 1. Schematic diagram of post-acute COVID-19 symptom development and natural language processing (NLP) system evaluation.
Results

The development dataset contained 299,140 notes from 23,505 patients (14,578 [62.0%] female; mean [SD] age 51.6 [18.2] years). The validation dataset contained 29,739 notes from 2,612 patients (1,599 [61.2%] female; mean [SD] age 51.4 [18.4] years). The initial lexicon included a total of 157,245 unique concepts and 604,056 synonyms. Eleven percent (n=17,701) of the concepts were mentioned in the development dataset. After symptom review and consolidation, the final post-acute COVID-19 symptom lexicon included 355 post-acute COVID-19 symptoms consolidated from a total of 1,520 UMLS concepts. Table 1 shows the most common 50 symptoms in the entire patient cohort and the NLP performance in clinical note symptom extraction for individual symptoms measured in the validation dataset. 46 concepts (92%) had precision measured above 0.90; average precision was 0.94 (range, 0.82 to 1.0). For recall, a total of 1,481 sentences were reviewed from 50 randomly selected notes. Manual review identified 104 symptom terms, among which NLP identified 87 symptoms; therefore, estimated recall was 0.84.

Discussion and Conclusion

This study detailed the development of a comprehensive PASC symptom lexicon from the EHR, and validation of an NLP tool using the lexicon for symptom extraction. Free-text clinical notes represent an underutilized data source in the active field of post-acute COVID-19 research. This work advances the study of PASC symptoms by providing a systematic approach and scalable tool to identify patient PASC symptoms in large datasets. These symptoms can be used to characterize patient populations or organ/system-based domains for targeted preventative or therapeutic interventions, and support future research.

Comparison of Machine Learning Algorithms for Earlier Detection of Cognitive Decline from Clinical Notes in the Electronic Health Records

Li Qin Wang, PhD1,2, John Laurentiev, MS1, Jie Yang, PhD1,2,3, Ying-Chih Lo, MD1,2, Rebecca E. Amariglio, PhD1,2,4, Gad A. Marshall, MD1,2,4, Li Zhou, MD, PhD1,2

Introduction

There are nearly 6 million people diagnosed with Alzheimer’s disease (AD) at the stage of dementia in the US, and the prevalence rises dramatically with age.1 Mild cognitive impairment (MCI) and subjective cognitive decline (SCD) represent precursor stages that can serve as targets for early treatment.2 Early detection of cognitive decline can facilitate participant enrollment in clinical trials and early interventions. However, challenges exist in the early detection of patients with cognitive decline. There are insufficient numbers of specialists with expertise in diagnosing cognitive decline to see all at-risk patients. Instead, primary care physicians and other non-dementia specialists have direct contact with these patients but not necessarily the time or tools needed to diagnose them. Systematically reviewing large electronic health records (EHR) data collected across patients’ full visit history within the healthcare system can facilitate early detection of cognitive decline by tracking back to when patients reported their first signs or symptoms of cognitive decline to any healthcare provider. This in turn may help trigger a more detailed evaluation in primary care settings and beyond, facilitate participant enrollment in clinical trials and early interventions. Given that self-reported concerns about cognitive status do not imply a diagnosis of cognitive decline by a healthcare professional, cognitive symptoms may be merely documented in provider notes. Current approaches to identifying cognitive decline rely on billing codes, which can be insensitive; manually curated keywords, which can be limited and lack accuracy; or manual medical record review, which is costly and non-scalable. Therefore, in this study, we aim to develop and compare machine learning models to detect any evidence of cognitive decline from clinical notes.

Methods

Setting, data sources, and study sample. This study was conducted at Mass General Brigham (MGB, formerly Partners Healthcare), a large, integrated healthcare delivery system in Greater Boston, Massachusetts. We used data from MGB’s enterprise data warehouse (EDW). We first identified patients aged 50 and above with an initial diagnosis of MCI (ICD 10: G31.84) between January 01, 2019 and January 01, 2020. We extracted clinical notes documented four years before the initial MCI diagnosis. Due to the fact that clinical notes can be very long and contain many sections that are not relevant to cognitive assessments (such as the allergy section), we segmented clinical notes into sections. That is, our classification task was to identify whether a note section indicates that a patient has cognitive decline. We used the Medical Text Extraction, Reasoning, and Mapping System (MTERMS) natural language processing (NLP) system to split clinical notes into sections.3

Definition of cognitive decline. This classification task aimed to identify patients at any stage of cognitive decline, ranging from SCD to MCI to dementia. Therefore, cognitive decline can be a cognitive concern, symptoms (e.g., memory loss), diagnoses (e.g., MCI, AD dementia), cognitive assessments (e.g., mini-cog), or cognitive-related therapy or treatments (e.g., cognitive-linguistic therapy). We focused on progressive cognitive decline that is likely to be consistent with or lead to MCI, while we excluded cases (assigned negative labels) that were less likely progressive (e.g., cognitive function has improved), or transient (e.g., temporarily forgetful or occasional memory loss due to medication intake), or cognitive function affected soon after some event (e.g., surgery, injury, stroke), as the cognitive decline might be reversible with a return to normal cognition. We also excluded cases which had broader or uncertain indication of cognitive decline (e.g., altered mental status).

Reference datasets. We manually labeled sections of notes for cognitive decline and created two gold standard datasets. To increase the positive case density of the reference dataset, we applied a list of keywords that were initially identified from cognitive-related topics based on topic modeling and enriched with experts knowledge a priori, to filter for sections that likely contain indications of cognitive decline, including memory delirium dementia psych* neuro* mental Alzheimer confus* mood cognit* forget* agitat* MoCA montreal MMSE remember difficult recall function word evaluat* score drive attention mild impairment speech question disorientation orientation sleep alter

1548
exam decline worse loss. Three annotators (i.e., LW, JL, and YL) achieved a good agreement with a Fleiss’ kappa of 0.83 in labeling sections of clinical notes for cognitive decline. Dataset I contained a random sample of 4,950 note sections filtered by the keywords and was used for model development and testing. Dataset II contained 2,000 randomly selected sections without keyword filtering for assessing whether the model performance was dependent on specific keywords. Any cases for which labeling was uncertain were resolved by the domain experts.

**Model development and validation.** We implemented a hierarchical attention-based deep learning structure and four baseline machine learning algorithms, including logistic regression (LR), random forest (RF), support vector machine (SVM), and XGBoost. The deep learning algorithm was developed in a prior study that incorporates a convolutional neural network (CNN), recurrent neural network (RNN), and attention layers for the purpose of handling word variations, context and interpretation of the prediction respectively. In the deep learning model, each section was regarded as a sequence of tokens, with individual words represented by word embeddings, for which we used a word2vec approach and trained 100-dimensional embeddings on a large corpus of 3,729,838 notes from 10,837 patients with an initial MCI diagnosis between January 2017 and January 2020. In the four machine learning baseline models, each section was represented with term frequency-inverse document frequency vectors based on n-grams (where n=1). The algorithms were trained and tested through 5-fold cross validation using dataset I and further assessed in dataset II. We compared the deep learning model with the four baselines in cognitive decline detection in terms of area under the receiver operating characteristic curve (AUROC) and area under the precision-recall curve (AUPRC).

models. Compared to the four baseline models (i.e., RF, LG, SVM and XGBoost), the deep learning model achieved the best performance, with an AUROC of 0.971 and AUPRC of 0.933 in dataset I, an improvement of 0.018 in AUROC and 0.051 in AUPRC compared to the best baseline model, i.e., XGBoost. The model is generalizable to the dataset regardless of keywords with an AUROC of 0.997 and an AUPRC of 0.929, an increase of 0.009 in AUROC and 0.031 in AUPRC compared to XGBoost. With a 0.5 probability as the cutoff, the deep learning model could achieve a positive predictive rate (PPV) of 0.848 and a sensitivity of 0.925 in dataset I and a PPV of 0.771 and a sensitivity of 0.928 in dataset II.

**Discussion and Conclusion**

Early detection of cognitive decline offers promise to facilitate patient recruitment from EHR for clinical trials or identify those for closer screening in primary care visits. A machine learning approach can be used to automatically identify evidence of cognitive decline from thousands or millions of clinical notes along patients’ longitudinal EHR earlier than it may be detected in structured EHR fields like diagnosis codes, medications, and problem lists. This study demonstrates that a deep learning model that was trained on a small set of labeled sections is effective and reliable in detecting cognitive decline. In the future, we plan to apply the deep learning model to identify patients’ first evidence of cognitive decline in the EHR, to facilitate antecedent risk factor and outcome analyses.

The impact of COVID-19 pandemic on health information sharing and patient-generated health data: findings from the Health Information National Trends Survey 2020

Zidan Wang¹, Jiancheng Ye²*

¹ Department of Statistics, Northwestern University, Evanston, IL, USA; ² Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Introduction
The emerging health technologies and digital services provide effective ways of collecting human behavior information, gathering patient-generated health data (PGHD), and sharing health-related information outside of clinical settings in a systematic way, and thus making interventions timely. PGHD can offer a broader view of the patient experience while generating real-time, continuous streams of health-related data before, during, and after treatment, or as a more general study of disease. Coupled with population health informatics tools, these technologies can track people's digital exhaust, which includes PGHD and social network platform use. The internet and social networking services have become important sources of health-related information on COVID-19 and on critical responses. Virtual health – compounded by the proliferation of sensors, mobile apps, monitors, digital therapeutics, at-home diagnostics, patient surveys, social channels, and other monitoring tools, can be used to make better health care decisions. This study aims to describe and compare characteristics of the population who participated in a national cross-sectional survey before and after the COVID-19 pandemic, including physical health, sleep, and alcohol use. We will also examine the patterns of social networking service use, patient-generated health data on the digital platforms, and health information sharing attitudes and activities.

Methods
Data used in this study were from the fourth round of data collection for HINTS 5 (Cycle 4), which began in February 2020 and concluded in June 2020. Because data collection for Cycle 4 started before COVID-19 became an international pandemic and continued after the pandemic was declared by the World Health Organization, the variable PANDEMIC was created to flag respondents whose survey was received after the COVID-19 pandemic declaration (March 11, 2020). This variable will facilitate the examination of responses before and after the COVID-19 pandemic that became a widespread issue of concern in the United States. The sample was divided into two groups by the dichotomous variable (PANDEMIC). We used participants' self-reported information on age, sex, race, ethnicity, level of education, income, and usual source of care as our sociodemographic variables. We used the survey package in R programming language 5 (R Foundation, Vienna, Austria) to account for the complex sampling design used in HINTS and incorporated the Taylor series (linear approximation) to generate accurate variance estimation. All analyses used weighted data to provide nationally representative estimates. The pairwise deletion was used to deal with missing data to preserve more information. To assess the characteristics of sociodemographic, general health, chronic diseases, social networking use, alcohol consumption, and sleeping variables, we generated weighted 2-way crosstab tables, which were tested with a Pearson Chi-square test of association.

The univariate logistic regression was built to examine the association between each predictor and mental health. Then we used multivariate logistic regression analyses using survey-weighted generalized linear modeling function in R. Odds ratio (OR) and 95% confidence interval (CI) for both models were presented. All reported P-values were two-tailed and the cutoff of P<0.05 was used to determine statistical significance for all analyses.

Results
The final HINTS 5, Cycle 4 (2020) sample consists of 3,865 respondents. Post-pandemic respondents were more likely to be younger (P<0.001), Asian or Black (P=0.001), and Hispanic (P=0.033). They were also less likely to have a usual source of care (P<0.001) or a cancer history (P=0.045). There were no significant differences between the pre-pandemic and post-pandemic groups regarding other sociodemographic and clinical characteristics.

</table>

Table 1 shows the characteristics of health information source, sharing, and social networking service use. Post-pandemic respondents were significantly less likely to use electronics to look for health information (P=0.029). After the pandemic, people were more likely to use a computer, smartphone, or other electronic means to look up medical test results (P=0.018). Surprisingly, post-pandemic respondents were significantly less willing to share health data from wearable devices with their health care providers (P=0.021), while more respondents shared health information with friends. The post-pandemic respondents were more likely to visit social networking sites.

**Discussion**

The context in which patients consume health information has changed dramatically with the diffusion of the Internet, advances in telemedicine, and changes in media health coverage. Digital communication technologies are playing an important role during the COVID-19 pandemic. There is a statistically significant difference in the increased number of sources of PGHD and the use of social networking services after the pandemic. Participants were much more likely to use credible sources and health information sources, especially if they were older, more educated, and had higher literacy levels. The post-pandemic participant group had a much heavier reliance on sources that are often engaging with them in an active information-sharing manner. Leveraging digital platforms and population informatics such as mobile health and social media along with PGHD could offer unique opportunities to develop effective self-monitoring and management strategies for the new normal of the pandemic.

Comparing the Phenomic Profile of All of Us Research Program and National COVID Cohort Collaborative

Kyle P. Webb, M.S. 1, David J. Schlueter, Ph.D. 1, Jacob Keaton Ph.D. 1, Tracey Ferrara, Ph.D. 1, Ariel Williams, Ph.D. 1, Joshua C. Denny, M.D., M.S. 1
1 NHGRI/NIH, Bethesda, MD

Introduction
The National COVID Cohort Collaborative (N3C) and the National Institutes of Health (NIH) All of Us Research Program provide researchers with a wealth of observational data to assist their goals in understanding disease progression and treatment. N3C consists of more than 3.7 million patient electronic health records (EHRs) from over 45 institutions who were tested for COVID-19, exhibited symptoms consistent with COVID-19, or individuals infected with pathogens such as SARS 1, MERS and H1N1. The All of Us Research Program (AoU) is a disease-neutral longitudinal cohort study that seeks to enroll one million participants and spans a variety of data including EHR, biometric, survey, and whole genomes. As of March 10, 2021, AoU contains 315,298 participants, of whom 190,858 have condition occurrence EHR data available in the Research Workbench. AoU collects all available EHRs for individuals, with some providing over 30 years of EHR data.

The goal of this research was to investigate common phenotypic patterns associated with COVID-19 between these data enclaves. Condition occurrence terms were mapped to phecodes1, 2 which aggregate ICD9CM and ICD10CM codes into 1,817 related diagnostic groups and are commonly used in Phenome Wide Association Studies (PheWAS). In addition to directly comparing phecode frequencies from AoU and N3C, we also stratified the data by demographic information and COVID-19 diagnosis (only for those in N3C, since AoU does not provide this data). We provide possible reasons to explain differences in rates of occurrence for phecodes across these substrata.

Methodology
AoU participants were matched by the age distribution for those in N3C and had limited EHR history to four years (since the earliest condition start date in N3C is July 19, 2016). Counts of the unique number of patients were tabulated for each phecode and those with less than 20 were omitted. Log odds ratios were computed where the numerator defined the odds of the phecode’s occurrence in N3C and the denominator defined the odds of the phecode’s occurrence in AoU. With this formulation, a larger value in the log odds ratio compares to a more common frequency of that phecode in N3C than AoU and vice-versa. Chi-square tests for significance were performed and this process was repeated for phecode samples stratified by gender, race, ethnicity, and age groupings.

Results
The number of people in the N3C sample with COVID-19 and without COVID-19 were 367,029 and 1,768,684 and the AoU sample included 76,789 participants. The dashed line in Figure 1 shows the Bonferroni threshold (log Chi-
square statistic of 2.85 for a p-value of 3.201*10^-6) and any phecode with an absolute log odds ratio greater than 1.9 or a log Chi-square statistic greater than 8.5 is labeled in black. Phecodes with a log Chi-square statistic less than zero were omitted. Table 1 provides the counts and percentages for the labeled phecodes in Figure 1 and Table 2 provides phecode counts after filtering on log odds ratios for phecodes and p-values less than the Bonferroni threshold.

Discussion

Overall, the N3C COVID control group and the AoU sample presented more phecodes with a higher rate of occurrence than the N3C COVID positive group. Significant findings from both analyses highlight medical conditions associated with COVID-19 (e.g. phecodes 480.2, 350.6, and 509.2 shown in Table 1). Of note, in this analysis, we found it important to match individuals by length of EHR record, since individuals in AoU tended to have much longer EHR records than in N3C. Comparison studies, such as these, provide insight into the populations and outcomes when using these cohorts for research.

On Constraints and Considerations for Extending Support for Natural Language Processing-Based FHIR Resource Generation

Andrew Wen, MS¹, Luke V. Rasmussen, MS², Daniel Stone, BS¹, Sijia Liu, PhD¹, Prakash Adekkanattu, PhD³, Pascal S. Brandt, MSc⁴, Jennifer A. Pacheco, MS², Yuan Luo, PhD², Fei Wang, PhD³, Jyotishman Pathak, PhD³, Hongfang Liu, PhD¹, Guoqian Jiang, MD, PhD¹

Introduction
With an estimated 80% of clinically relevant information being stored in unstructured form, natural language processing (NLP) has been of significant interest in the digital healthcare community, particularly with respect to development of digitized clinical decision support and learning health systems. Concurrently to these efforts, interest in deploying these same systems outside of academic environments and into clinical settings has highlighted issues relating to algorithm portability and data interoperability, leading to a push to adopt standards for health information exchange. Most notably, the HL7 Fast Healthcare Interoperability Resources (FHIR) standard has seen significant adoption amongst the healthcare community, with many of the dominant EHR solutions, including Epic and Cerner, offering FHIR-compliant representations of their data. Despite this, these solutions largely focus on presenting FHIR-based representations of information already encoded in structured format and do little to present FHIR-based views of unstructured information, such as that which can be obtained through NLP. This hinders portability, deployment, and adoption of any applications that rely on NLP as an information extraction component, and efforts to circumvent this issue are problematic as the composition of what information is contained within structured vs. unstructured data varies between institutions.

It is therefore highly desirable to also standardize NLP artifacts to the FHIR standard. To that end, in a prior study, we introduced the NLP2FHIR pipeline¹, which aimed to address this deficiency by offering generalized clinical NLP information extraction capability with FHIR-resource output. Despite this effort being successful, there are several considerations to be made with respect to FHIR resources generated from NLP output that may cause the generated output to have semantically relevant differences as compared to if that same output were to be generated from structured data. To that end, we have proposed several FHIR-compliant NLP-specific extensions for inclusion with any NLP-produced FHIR resource¹. Here, we discuss our experience implementing mappings for NLP-specific FHIR resource extensions, and present lessons learned from our experience.

Methods

```

*Figure 1.* (Truncated) Example of a populated extension definition for an NLP-derived FHIR resource derived from clinical text. Here, we see specifically the conditional, negated, and certainty modifiers, as well as a is-document-date modifier.
NLP2FHIR version 1.0.0 (https://github.com/BD2KOnFHIR/NLP2FHIR) was used as a baseline for modification, while the NLP extensions proposed in Hong et al. were used as a base guideline for implementation. FHIR output produced by the NLP2FHIR pipeline was then incorporated into a variety of downstream pipelines including obesity/comorbidity detection and colorectal cancer modeling. Data representation and modeling issues encountered during implementation and further usage in downstream applications were documented and are now reported here for informative purposes. Figure 1 shows an extension field of an NLP-derived FHIR resource with the NLP-specific extensions populated.

Results and Discussion
We encountered some issues during implementation and downstream consumption of NLP-based FHIR artifacts. Firstly, an important note with NLP-extracted clinical output is the issue of temporal information: while the date a clinical document was created can serve as a general temporal indicator for extracted NLP artifacts, this is not always accurate. For instance, documents may refer to a “past history of” a condition with an unspecified date, and it would therefore not be accurate to present the condition resource’s date as the document date. On the other hand, documents may refer to conditions with a phrase similar to “patient presented on May 1st 1999 with condition x”, in which an explicit date is made known, or present a relative date (e.g. “two weeks ago”) to the document, from which an explicit date can be derived. Such information would be appropriate for inclusion in the resource, but it is not feasible to completely resolve this issue and harmonize NLP-based output with that of structured data, as the requisite information is simply not present. Rather, it is important to make note of exactly what kind of date (document date vs. an explicit date) is used in conjunction with the resource, and downstream consuming applications should be aware of this distinction if applicable to their use case. In addition to the “term_temporal” modifier proposed in Hong’s original work, we therefore also propose a “is_document_date” true/false extension flag that denotes this difference.

Another issue encountered when implementing NLP extensions was value set consistency, which is closely tied to the main reason why one would go through standardization in the first place. The certainty modifier extension and other contextual modifiers are prime examples of this issue: unlike the semantic equivalent in the cTAKES NLP system, which offers only Boolean output for the assertion modifier, the ConText algorithm in use by NLP2FHIR for these components offers more nuanced options, with not only the standard “certain” and “possible”, but also “hypothetical”, which is not semantically equivalent to “possible” but nevertheless does contain some clinical meaning. On the other hand, the OHDSI CDM standard defines uncertainty as both “true/false” or “high/moderate/low”. As we are discussing these NLP extensions in the context of standards, it is important that these definitions and the way they are standardized into FHIR resources be consistent even across differing NLP systems, such that consuming applications can expect that the way the information is presented does not change. For that reason, while we have adopted a boolean flag for such cases to normalize to for our particular use cases, further discussion amongst the community is necessary.

Finally, it should be noted that much like structured data FHIR representations, NLP-derived FHIR output can suffer from non-normative differences in levels of granularity. NLP2FHIR is by default greedy-matching in behavior, meaning that it will take the maximum length match for normalization. A “ST-Elevated Myocardial Infarction” will therefore be codified using the SNOMED CT code specific to that condition, rather than just “Myocardial Infarction” in text. Depending on the structured data source, this behavior may be inconsistent and/or the supplementary information may be presented in a different manner when compared to structured data. Consuming applications should be aware of this distinction, and handle appropriately if necessary.

Predicting COVID-19 Regional Case Loads with Synthetic Data

Adam Wilcox PhD, Noa Zamstein PhD, Randi Foraker PhD MA, Jason A. Thomas BS, Kenneth J. Wilkins PhD, Jon D. Morrow MD MA MBA

aUniversity of Washington School of Medicine, Seattle, WA; bMDClone Ltd., Be’er Sheva, Israel; cWashington University in St. Louis, School of Medicine, St. Louis, MO; dNational Institutes of Health, Bethesda, MD; eNew York University School of Medicine, New York, NY

Introduction

One of the major challenges for researchers, public health officials and policy makers during the COVID-19 pandemic in the United States (US) has been predicting future disease trajectories in the population based on current infections, hospitalizations and deaths. Public health officials, policy makers and health care leaders have many different options to address infection rates in the population with varying impact on the disease and economies, ranging from mask mandates, restricting elective procedures in hospitals, to lockdowns. Using publicly-available data on infections, hospitalizations and deaths, many researchers have attempted to predict regional and local disease trajectories with limited success. One reason regional prediction has been difficult is that varying levels of community testing and hospital resources can lead to differences in detection, creating regional inconsistencies in public infection data (1). Data from emergency departments (EDs) on the number of positive cases may be a more accurate indicator of current community disease activity, which may be better for predicting future case levels; however, ED case levels are not shared in public data sets and are generally only available at the institutions providing care. The National COVID Cohort Collaborative (N3C) brings together patient-level data across multiple institutions in different geographic regions in a centralized repository; these data include positive test results and site of care information for patients in participating institutions. As such, N3C data create an opportunity to measure community trends in infections at different points in healthcare, such as ED visits. In this study, we use data from N3C to predict infection rates and disease trajectories regionally using overall community infection rates and ED visit rates. Because application of prediction using healthcare data at different institutions requires sharing of data, we performed this study using synthetic N3C data, which can allow broader sharing of data outside institutions while protecting patient privacy (4).

Methods

We predicted daily infection rates using prior infection data for multiple regions during regional disease “waves” of the COVID pandemic in the US. Our cohort included all patients in the N3C enclave who were lab-confirmed COVID-positive during 2020 (n=299,755). We extracted diagnosis date, associated encounter type (inpatient admission, ED visit, other outpatient visit, or unknown), state of residence, and length of stay. We used a Delayed Elasticiy Method (DEM) modeling approach (5) to forecast deaths at the state level, using cumulative cases at an earlier time (7 to 9 days, using the first 90 days for training the model). We report our results by state, highlighting Massachusetts (MA) and North Carolina (NC) as important examples. Synthetic derivative data sets were computed from the limited data sets using the MDClone ADAMS Synthetic Data Platform [MDClone Ltd., Be’er Sheva, Israel].

Results

Data from MA and NC showed distinct waves during autumn of 2020 and early in 2021, within which we were able to perform the prediction. Figure 1 shows the actual daily incidence rates from the data set that were used -- we used the first 90 days for training the model (light blue dots) and the following 90 days for prediction (dark blue dots). The 90 day period was selected from an established trough through a rising period in the epidemic curve; it was not selected to match the peak of the curve, as predicting the change in slope and the peak was a primary goal of the model. While the MA curve shows a clear inflection point and a peak in case load, the NC curve does not; the second wave in NC had not yet ended by the time these data were collected and only subsided in March 2021. Figure 2 shows the predicted cumulative cases for both states along with the actual cases, and Figure 3 shows the epidemic curves calculated as the change in the cumulative cases. Our model correctly predicted the change in slope of the epidemic curves for both states.
We demonstrated successful prediction of regional disease progression based on positive cases from electronic health record data in a national registry. We specifically used ED incidence rates in the prediction models, which improved the ability of the model to predict changes in the slope of the epidemic curves. Where there was a peak in the curve (MA), our model correctly predicted the peak period, even if the cumulative number of cases were different. Where there was only a flattening of the curve (NC), the model correctly predicted this change in slope and did not predict a peak where it did not exist.

This analysis was done using synthetic data, which is significant for how it could be used generally. The COVID-19 disease progression moved regionally in waves, either according to how the disease initially spread or due to state-specific mitigation policies. Training models based on other states’ data in earlier waves is necessary to create a prediction model that can be used for another state. Since this approach requires collaborative data sharing, synthetic data allow easier sharing of data while preserving privacy. Of note, this analysis could not have been done with de-identified “safe-harbor” data, because precise dates of service, which must be removed under the safe-harbor rules, are critical for determining epidemic curves.

The ability to predict disease progression in a community is critical for decision-making in a pandemic. Different states or regions reached different levels of prevalence at different times, which led to different mitigation measures being applied. For example, during the Autumn 2020 wave, some states had infection levels high enough that hospitals became overwhelmed, and temporary field hospital structures were created. At the same time, other states had less-severe outbreaks. However, states with less-severe levels did not know whether they needed to plan for creating field hospitals, and preventative measures were often used in anticipation of higher disease levels that did not occur. Many less-extreme decisions also were taken throughout, often based on incomplete information. Using more-accurate predictive models could have dramatically improved public and institutional response to the pandemic.

Enabling Digital Compassion in a Technology-Enabled Healthcare Environment: a Modified eDelphi Study to Establish Professional Competencies and Health Information Technology Standards

David Wiljer, PhD1,2,3, Gillian Strudwick, RN, PhD2,3, Rebecca Charow, MSc1,2, Nelson Shen, MHA, PhD3, Allison Crawford, MD, PhD, FRCPC2,3, Sanjeev Sockalingam, MD, MHPE, FRCPC1,2,3, and Peter Rossos, MD, MBA, FRCPC, FACP1,2
1University Health Network, Toronto, Ontario, Canada; 2University of Toronto, Toronto, Ontario, Canada; 3Centre for Addiction and Mental Health, Toronto, Ontario, Canada

Introduction

Healthcare is becoming increasingly digital, introducing innovative technology-enabled ways to deliver and expand access to care. In this evolving landscape, healthcare professionals, learners and organizations may not be prepared or equipped with the knowledge, skills, and behaviors required to use these digital tools in the delivery of compassionate care; moreover, the tools themselves, may not be designed and implemented in a manner to facilitate digital compassion. The notion of digital compassion is still in its infancy; however, it will be central to healthcare in the coming decades. The objective of this study is to identify: 1) essential digital compassion competencies for health professionals; and 2) digital compassion health information technology attributes.

Methods

This study is currently in progress and uses a modified eDelphi method for consensus-building through structured group communication amongst a panel of experts to address the study objectives1,2,3. The first round consisted of multiple online sessions/focus groups instead of a questionnaire. Subsequent rounds will follow a more traditional approach where web-based surveys will be emailed to panelists1. The number of rounds will continue until consensus is met. The rounds are as follows:

I. Round 1 Ideation: brainstorm domains of digital compassion
   o List professional competencies & technical attributes developed through small group activities & large group discussions

II. Round 2 Conceptual Clarity: define and rate each domain, assess conceptual clarity, generate competencies & attributes statements
   o Revise statements rated with a median score <5 for conceptual clarity based on feedback provided

III. Round 3 Refinement: assess competency and attribute statements; refine statements
    o Include statements with an “automatic consensus” if they have a median score >4

IV. Rounds 4 & 5 Consensus: come to consensus on inclusion & exclusion of competency & attribution statements (round 5 only if necessary)
   o Include remaining statements with a median score >3 and an “acceptable consensus”

The expert panel consists of 55 individuals (patients/patient advocates and professionals) who possess deep experiential knowledge, with over 5 years of experience in health informatics or digital health, health professional education, inter-professional practice, and/or compassion research. Majority work in a large urban setting (≥1 million people; 69%), and live in Ontario (60%), followed by British Columbia (13%), then Nova Scotia (9%), and the remaining in other provinces (Alberta, Saskatchewan, Manitoba, Quebec and New Brunswick). The expert panelists work in a variety of settings including academic health sciences centers, community-based health organizations (family medicine and long-term care), post-secondary institutions, non-profit organizations, healthcare IT or informatics consulting companies, mental health and substance abuse facilities, and government/provincial health authorities. To achieve this diversity, purposive and snowball sampling strategies were used. The expert panelists were recruited using an email recruitment letter sent directly to individuals using publicly available emails addresses and through the Associated Medical Services (AMS) and their organizational partners, such as Canada Health Infoway, Digital Health Canada, and advocacy groups. In Round 1, expert panelists were asked to ‘ideate’ the concept of digital compassion as it relates to a conceptual framework, healthcare delivery, professionalism, organizational culture and technological attributes. Due to COVID-19 recommendations, the format consisted of a modified world café methodology4,5, where a progressive discussion and brainstorming was facilitated through nine online Round 1 group sessions held from Sept-Nov 2020 using Microsoft Teams. Expert panelists participated in a
single Round 1 session with a group size ranging from 4-10 panelists, having multiple options to choose from. For each session, expert panelists were provided definitions and participated in a free-writing narrative activity to level-set knowledge and structure the brainstorming discussion. The free-writing narrative activity consisted of the expert panelists taking 5 minutes to think and write about a specific time where they did or did not experience compassion in a digital environment. Expert panelists had to write in the first person, starting with “I was,” and could approach this prompt from any vantage point they wished, (e.g., as a care provider, a patient, an administrator, or researcher). Afterwards, panelists shared what they wrote, if they felt comfortable, and for those listening, they wrote keywords of their observations, thoughts or feelings in the chat. As the panelists shared, these keywords were collected and rapidly thematically sorted by members of the study team on a Miro Board®. Once all the panelists had shared their stories, the Miro Board® was screen-shared for member checking (i.e., panelists can comment and provide feedback on the emerging themes and how their keywords were sorted). These themes were then used to discuss and identify professional competencies and technology standards or attributes that would address those emerging themes. Themes from the previous Round 1 sessions were also discussed – noting any overlaps or significant differences. Each session was audio recorded, anonymized, and transcribed for thematic analysis. An inductive, constant comparative approach is currently ongoing. In place of a large group discussion at the end, a draft list of guiding principles developed from the analysis as well as digital compassion professional competencies and technological requirements will be included in Round 2 for comments and assessment in the subsequent rounds.

Results

Key findings of Round 1 discussions are currently under review using thematic analysis. Emergent themes thus far have been organized within the following domains: Digital Environment, Processes, Professional Competencies and Technology Attributes. Within the Digital Environment domain, clinical interaction, connection, enabling compassionate care, time, and a sense of trust in the system emerged as the main themes. Organizational processes, policies/procedures that would allow healthcare providers (HCP) to deliver compassionate care included: choosing the appropriate modality for communication with patients, embedding digital tool use into existing workflows, providing support and being mindful of whether compassion was considered when selecting digital tools or systems. The professional competencies domain comprised of attitudes, knowledge and skills HCP should demonstrate/have when providing digitally compassionate care. Standards for the design of technology should encompass accessibility, ease of use, layout and seamless interaction, interoperability, security, understandability and user-centered co-design.

Discussion

Evidence-informed domains from Round 1 will be used to initiate discussion for subsequent eDelphi rounds (through online surveys), which will test and refine these domains, competency statements, and technology attributes. Data analysis will be conducted after each eDelphi round, and results from engagement activities will be analyzed and discussed with expert panel members. Mean scores for each domain, attribute and competency statement will be generated from the surveys. Following our work with Round 1, we hope to integrate technology attributes identified to guide the development of evaluation criteria for health information technology, and recommendations for education/training to support the incorporation of digital compassion knowledge, skills, attitude and behaviors by trainees and health professionals (Phase 2). Phase 3 will involve development of interventions utilizing the criteria and recommendations from Phase 2, and pilot testing these interventions for feasibility.

Lesbian, Gay, and Bisexual Patient Perceptions of Collaborative Communication: Implications for Access to Health Information

Alicia K Williamson, BA,1 Lindsay K Brown, MHI,1 Tiffany C Veinot, PhD,1,2 Denise L Anthony, PhD1,2,3

1University of Michigan, School of Information, Ann Arbor, MI; 2University of Michigan, School of Public Health, Ann Arbor, MI; 3University of Michigan, Department of Sociology, Ann Arbor, MI

Introduction
Patient-centered care is a crucial element of high-quality health care. Patient-centered care uses active collaboration and shared decision-making (SDM) between patients and providers to tailor care to patients’ health information needs. Collaborative communication (CC) is one key component of patient-centered care; it includes building rapport between patients and providers, exchanging health information, meeting patients’ emotional needs, involving patients in SDM, and enabling patient self-management. Patient-centered approaches to communication can establish strong interpersonal relationships and facilitate information exchange. Barriers to patient-centered approaches may impede health information exchange within clinical encounters, which could impact electronic communications through technologies such as patient portals. CC during the use of electronic health records within clinical encounters can increase patients’ engagement in their own care. Other informatics considerations such as using non-judgmental language in patient portals and collecting data on things like pronouns in an affirming manner are crucial. Such patient-centered communication (PCC) approaches can positively impact patient-provider relationships, adherence to medical advice, and diagnostic accuracy.

Despite the observed benefits, PCC with lesbian, gay and bisexual (LGB) populations may be lacking. Medical training regarding patient-centered care and communication for LGB patients is often insufficient; this may leave physicians feeling unprepared to address LGB patient needs. This lack of training, combined with general cultural biases against LGB people, may lead to negative experiences, such as providers making heteronormative assumptions. LGB patients are often aware of providers’ limited competence for dealing with LGB health issues, and are less likely to seek information from a doctor as their primary source of health information. Negative relationships with providers may also influence how LGB patients disclose information to healthcare providers.

Insufficient or biased communication with providers, as well as limitations in LGB patients’ likelihood to access health information through their healthcare providers, may exacerbate existing health disparities experienced by LGB people. For instance, LGB people have higher rates of mental health concerns, STIs, and obesity when compared to heterosexual populations. Additionally, bisexual people have high rates of negative health outcomes like anxiety, depression, suicidality as well as disparities in relation to the use of healthcare. This study seeks to determine if lesbian or gay (LG) or bisexual (B) patients differ from heterosexual patients in their perceptions of provider PCC. Few nationally representative surveys have studied differences in PCC for these groups outside of the context of cancer care, and fewer have examined bisexual patients separately from LG patients.

Methods
We used data from the Health Information National Trends Survey (HINTS) 5, Cycle 4 conducted from February 24 – June 15, 2020. HINTS includes six questions about PCC, asked of respondents who had a non-emergency health care visit in the previous 12 months: managing uncertainty, responding to emotions, making decisions, fostering healing relationships, enabling self-management, and exchanging information. HINTS also provides a PCC scale measure computed as a mean of the six measures converted to a 100 point scale. Bivariable and multivariable linear regression was used to assess whether LG or bisexual patients differed from heterosexual patients, adjusting for patient binary birth sex, age, race/ethnicity, education level, self-reported health status, health insurance status, having a regular provider, and whether the survey was completed after the start of the COVID-19 pandemic. We also conducted bivariable and multivariable logistic regressions of each of the six PCC questions, with responses of always coded as 1, and responses of usually, sometimes, and never coded as zero, indicating optimal PCC.

Results
In unweighted analyses, of 2,671 respondents, 95.2% identified as heterosexual, 2.4% identified as lesbian or gay (LG), and 2.4% identified as bisexual. The average unadjusted PCC rating was 80.8, and was 81.0 for heterosexual, 81.9 for LG and 72.0 for bisexual patients. In both bivariable and fully adjusted linear regression, the PCC rating for bisexual patients was significantly lower than for heterosexual patients (Beta=-7.0 [SE 2.6] for multivariable model), but there was no significant statistical difference between heterosexual and LG patients (Beta=1.7[SE 2.6]). In multivariable logistic regressions, bisexual patients were significantly less likely than heterosexual patients to report optimal levels of PCC for responding to emotions (OR=0.58[CI 0.34-0.98]), making decisions (OR=0.60[CI 0.36-1.0]), and enabling self-management (OR=0.53[CI 0.32-0.88]).

**Discussion**

As indicated by the results, bisexual patients reported significantly lower levels of PCC compared to heterosexual patients. However, there were no significant differences between LG and heterosexual patients. These findings for bisexual patients supports literature identifying negative attitudes towards bisexual people, further demonstrating the need for special attention paid to bisexual patients and their PCC needs. Poorer PCC may result in bisexual patients accessing health information from sources other than their provider, such as the internet.

Despite increased provider training on cultural competence for LGB groups, these findings indicate that more work is needed to improve patient-provider communication, particularly for bisexual patients. Improving clinical communication between LGB patients and providers may improve care and reduce health disparities. LGB people are more likely to search for health information online, and less likely to seek information from a provider, so improving clinical relationships/interactions between LGB groups and providers may improve health information access for LGB patients. Changing perceptions of communication may also impact the likelihood of using mHealth technologies, such as patient portals, to communicate with providers. As new technologies are used increasingly in healthcare, such as patient portals and telehealth, ensuring high quality PCC becomes paramount to facilitating quality care and securing equitable treatment of bisexual patients, other sexual minorities, and indeed all patients.

Improving Clinical Decision Support by Empowering Users: The Clickbusters Program

Adam Wright PhD, Elise Russo MPH, Arianna E. Nimocks, Jon G. Jackson PharmD, Jonathan P. Wanderer MD MPhil, Neal Patel MD MPH, Kevin B. Johnson MD MS, Allison B. McCoy PhD

Vanderbilt University Medical Center, Nashville, TN

Introduction:
Clinical decision support (CDS) systems have been shown to improve quality and safety of care (1, 2); however, poorly designed CDS can frustrate users and lead to alert fatigue. Development of CDS typically involves knowledge engineers, analysts, subject matter experts (3). User feedback is also valuable for evaluating and improving CDS (4); however, users are rarely empowered to take ownership of CDS.

Recently, many organizations, including our own, have begun investing in “Physician Builder” programs, where interested clinicians can get training on electronic health record (EHR) customization and build content in their area of expertise (5). Despite the name, physician programs are often open to other healthcare professionals, such as nurses, pharmacists, advanced practice providers and informaticians.

Vanderbilt University Medical Center (VUMC) has a large and effective physician builder program with 69 participants. These builders were trained and certified to build and maintain clinical content and functions in our Epic EHR. While they had developed documentation tools, order sets, reports and CDS alerts, they did not focus on optimizing existing alerts. At the start of our project, VUMC had 419 clinical decision support alerts, many of which had not been reviewed since the EHR went live.

Methods:
To improve decision support at Vanderbilt, the Vanderbilt Clinical Informatics Center (VCLIC) developed a new program to review, refine and validate CDS alerts, called Clickbusters. Clickbusters started with Vanderbilt’s existing physician builder program; Clickbusters built on this foundation with the following components:

1. Empowering our physician builders to “adopt” one or more CDS alerts in their area of expertise, evaluate the alerts and directly make improvements, with reduced bureaucracy.
2. Creating an inventory of our CDS alerts, and prioritizing them for review based on firing rate, acceptance rate and complexity.
3. A ten step Clickbusting process, shown in the figure.
4. A series of videos and knowledge base articles which taught participants how to analyze and improve a CDS alert.
5. A management process and database to support tracking of participant progress.
6. Centralized support for participants who needed assistance.
7. Gamification, including a point system, leader board, certificates, trophies and prizes.

Results:
Prior to beginning the Clickbusters initiative, VUMC had 305,841 alert firings (11,164 of which were interruptive) each week. The alerts were placed into 141 logical groups (for example, alerts related to suicide screening were grouped together). We conducted two rounds of the Clickbusters program: one in Mar-May 2020, and the other in June-Sep 2020. In the first round, eight participants selected 18 alert groups (29 total alerts) for Clickbusting. 13 alerts were modified and 4 alerts turned off, leading to a reduction of 49,026 clicks per week (a 16% reduction). In the second round, twenty participants selected 24 alert groups (55 total alerts) for Clickbusting, resulting in 29 alerts modified, 6 alerts turned off, and 22,201 weekly clicks busted (a combined 23% reduction):

We gave each winner a Golden Computer Mouse Trophy, as well as an Amazon gift card ($250, $150 and $100). All received a framed certificate, and the option of having VCLIC leadership send a letter of commendation to their department chair.

Key accomplishments included elimination of a frequently-firing alert related to enrollment in a congestive heart failure readmission risk reduction program that no longer existed, targeted improvements to several medication safety-related alerts, and refinement of alerts related to bronchiolitis and to administration of live-attenuated vaccines to immunocompromised patients. The Clickbuster participants were poised to make these improvements given their personal experience with the alerts, their clinical expertise and their review of relevant data.

In addition to the direct improvements in CDS, the initiative also increased user engagement and involvement in CDS. After Clickbusters, our CDS team benefited from a new corps of users with increased interest, engagement and knowledge of CDS, who could also serve as liaisons to clinical departments as diverse as pediatrics, general medicine, oncology, cardiology, surgery, nursing and pharmacy. This program helped build a culture of continuous evaluation and improvement of clinical content in the EHR.

Conclusion:
At VUMC, the Clickbusters program was useful for improving the quality of CDS alerts and involving more users in the process of evaluating and improving CDS. The process could be readily replicated at other clinical sites, and applied to other functions of the EHR, such as order sets, clinical documentation tools and information displays.

Multi-horizon prediction for extracorporeal support in COVID-19 patients

Introduction
The SARS-CoV-2 (COVID-19) pandemic has put unforeseen strains on the global healthcare system. These challenges are particularly pronounced when deploying high-risk, resource intensive therapies, such as extracorporeal membrane oxygenation (ECMO). ECMO is a life sustaining therapy, typically initiated only after standard therapies have been exhausted, but the required expertise and resources to provide ECMO only exist in advanced centers. Guidelines continue to discourage commissioning new ECMO centers during pandemics and encourage early recognition of patients needing ECMO to allow resource allocation within ECMO capable centers or early transfer to improve patient outcomes(1). However, there remains a lack of the ability to predict which patients will require ECMO and when, causing unexpected constraints even at high resource institutions. In response to this challenge, we evaluated a time-aware prediction approach(2), developing a machine learning based multi-horizon prediction tool, “ForecastECMO”. Our prediction model focuses on identifying patients who are likely to require ECMO at various prediction horizons, providing clinicians with a needed decision support tool.

Methods
Clinical deterioration is often preceded by a period (up to hours) of changes in vital signs or laboratory results that could be unrecognized. As patients deteriorate, there is a paralleled increment in lab frequency and interventions. To account for the variability in volume of input variables at different timepoints and to identify patients during windows of increasing instability to facilitate early interventions, we developed multi-horizon predictive models called ForecastECMO, comprised of a set of machine learning models trained to predict ECMO at different time horizons. The tool was developed by constructing the optimal machine learning model at each time horizon X (hours) to predict ECMO at X hours prior to ECMO initiation. At each clinical decision point, the set of predictive models corresponding to different prediction horizons (X values) are invoked, using clinical data available till that decision point to generate a set of predictions for the need for ECMO in the next X hours. The association of the alert with the time horizon for the prediction allows clinicians to plan ECMO intervention.

This study was approved by our institutional review board with waiver of consent. Data were extracted from a registry of all patients tested for COVID-19 at our institution since January 1, 2020. The database utilizes EHR-derived data spanning 15 hospitals part of the Barnes-Jewish Healthcare system. We included all patients with a positive COVID-19 test associated with a hospital admission for ≥ 24 hours. We excluded non-ICU admissions and those meeting institutional ECMO contraindications (age >70 years and BMI > 45 kg/m²). Patients less than 3 years old were also excluded given the difference in their normal range of vital signs compared to adults and further, because there are no reported cases of patients less than 3 years receiving ECMO support for COVID-19(3, 4). Patients who received ECMO underwent detailed chart review to confirm that ECMO was directly related to COVID-19. Variables included in the ensuing database included demographics, comorbidities, laboratory values, medications, and flowsheet variables (including vital signs and respiratory support data). Clinical interpretation was incorporated into laboratory variables; creating test indicators (0: within normal range, 1: above normal range, or -1: below normal range). For patients transferred between hospitals within our system prior to ECMO, variables from the pre-transfer encounters were concatenated into the input data. Categorical variables were converted to numeric discrete values by factorization. Continuous variables were first processed by 5-percentile outlier removal, and then normalized to range [0,1] by min-max scaling. Missingness of measurements was taken into model structure.

A set of Gradient Boosting Tree (GBT) predictive models were trained for time horizons ranging 0 - 100 hours prior to ECMO initiation (51 steps of 2 hours). To train the predictive model at a time X, the input data for ECMO positive patients included measurements collected between admission and X hours before ECMO initiation, and the input data for ECMO negative cases included the worst measurements collected during hospitalization. Models were trained and evaluated with 5 random shuffles of 5-fold stratified cross validation.

Results
The registry contained 33,017 COVID-19 positive patients from March 13, 2020 to January 7, 2021. After filtering by inclusion and exclusion criteria, we identified 67 ECMO positive and 2,251 ECMO negative COVID-19 positive...
patients, admitted to ICU, with hospital stays ≥24 hours (Age: 52.88±15.41 years, BMI: 29.08±7.21 kg/m², 56.13% males, LoS: 337.65±421.39 hours). We identified a total of 348 variables of potential interest (26 demographics and comorbidities, 124 flowsheets, 52 medications, 73 laboratory variables and 73 laboratory indicators).

The model’s performance of was compared against to an a GBT model of 30 a priori identified most clinically relevant variables (Clinical GBT) and a linear model of PaO2/FiO2 (PF ratio), the only available recommendation for ECMO decision making(5). In addition to a LR regression model of all variables and a LR model of Sequential Organ Failure Assessment (SOFA) score(6, 7). Figure 1 illustrates how the model outperformed the risk scores on both the Area Under (AU) Receiver Operating Characteristic (ROC) Curve and the AU Precision Recall Curve (PRC)(8, 9) evaluation metrics.

**Discussion**

We describe a multi-horizon machine learning model capable of predicting the need for ECMO support several hours prior to initiation. Current guidelines emphasize the value of worsening respiratory failure immediately before ECMO initiation in decision making, yet fall short in providing clinicians with early warning tools for triaging resource allocation or early patient transfer to ECMO capable centers(10). Our proposed ForecastECMO model outperformed the PRESET/SOFA-based ECMO prediction in both the AU ROC and AU PR Curves across all time ranges. The model performance in this time frame, in the absence of input variables from the expected escalation in support and monitoring in the hours preceding ECMO, emphasizes the potential clinical utility of the ForecastECMO tool in identifying patients at risk of needing ECMO support in a relevant time-frame, for clinicians to reallocate resources or transfer patients to centers with more ECMO expertise.

**Conclusion**

We have developed and validated a machine learning based multi-horizon prediction tool (ForecastECMO), which has clinical utility as an ECMO decision support tool that could be used to improve patient outcomes and relieve unexpected resource burden on healthcare systems during a pandemic or equivalent public health emergencies.

Synthetic Data to Support Engineering and Demonstrations in the All of Us Research Program

²Vanderbilt University Medical Center, Nashville, TN

Introduction

One of the greatest barriers to the advancement of biomedical research is a lack of data with sufficient diversity from patients and research participants. The All of Us Research Program¹, launched in 2018 with a goal of enrolling more than 1 million American volunteers, aims to change this situation by collecting and provisioning access to a wide range of personal data derived from, but not limited to, electronic health records (EHRs), biospecimens, questionnaires, behavior and physiological data. The general belief is that making such data available on a broad scale will facilitate hypothesis generation and, given sufficiently large quantities of data, hypothesis testing regarding a number of diseases and their treatments. While making data accessible is a core goal of the program, there is also a belief that maintaining the privacy of the participants is critical to ensuring trust and sustaining a long-lasting and healthy relationship. As such, it is the priority of the program to uphold privacy principles throughout the life cycle of the All of Us program.

At the core, All of Us is a software suite, built on top of a cloud-based platform, which provides for analytic tools that access the participant-level data. To develop and develop such a suite over time, it is necessary to provide systems developers with access to such data, so that system prototypes can be engineered and the functionality and workflows associated with such systems can be sufficiently stress-tested. Moreover, it is critical to develop multiple representative case studies, based on participant-level data, for the purpose of system demonstration to the public (as well as approved prospective researchers). To mitigate privacy risks, the program developed synthetic data to support these use cases.

Generative adversarial networks (GANs) are a recently developed technique that have shown a remarkable ability to simulate structured EHR data, through a deep neural network, with a realistic feel, while simultaneously protecting privacy². GANs are composed of a generator which is forced to produce increasingly realistic instances, such that an evolving discriminator, cannot distinguish them from real data. In this abstract, we report on how we developed and applied a GAN-based framework to support the engineering and demonstration use cases of All of Us.

Methods

We focused on a dataset of approximately 235,000 participants and their associated demographics, physical measurements, and survey responses. These data are stored across multiple database tables based on the observational medical outcome partnership (OMOP) schema³. These tables were processed by a generative adversarial network (GAN) and synthesized via an iterative and incremental process. The All of Us outreach program has a study that focuses on the analysis of participant provided information (PPI) in the form of gender, race, ethnicity and various attributes in the participants’ EHR, such as height and weight. We realized the dataset by applying filters, joins and projections across the OMOP tables. The projections capture attributes of interest and filter out unnecessary records.

The GAN training process is iterative with a goal of determining an adequate representative sample size and number of epochs that can enable the neural network to converge. Once adequate sample size is determined and epochs, we perform this task in parallel in order to have multiple candidate models. Each model is used to generate data, and the models that will be retained are the ones with the least rows copied. The GAN uses a statistical method during training and will discard outliers that can be critical to a study for instance participants with diagnosis codes for rare conditions like Wolfram syndrome. Outliers are reinserted at random according to the rate at which they are observed in the original data.

Results

The synthetic data generated using the GAN-based framework were leveraged to support gold standard software development and release management processes. Synthetic data not only enable the Researcher Workbench (RW) software engineers to develop and test new features, but also to complete critical quality control and assurance tasks.

In addition to supporting software development, synthetic data are relied upon to support All of Us RW outreach and training. Since the RW launched in May of 2020 for beta testing, the synthetic data described here have been used in...
more than 30 researcher outreach and training events with over 1,800 users. The primary audience for these outreach demonstrations are prospective researchers who may be interested in registering to become All of Us Researchers. During these demonstrations, members of the RW team walk through example analyses using synthetic data within a software environment that mirrors the production RW. A primary goal of the demonstrations is to train researchers to use the tools available within the RW and educate prospective researchers key characteristics of the All of Us dataset.

Within the production All of Us RW, we provide tutorials on real data to train registered, approved All of Us researchers how to do basic analyses on All of Us data. These include tutorials that describe how to, such as querying the database and characterizing the number of participants that have contributed multiple data types in All of Us (Figure 1A). Using synthetic data in the mirror RW environment, we run the same tutorial analysis, demonstrating similar key features within the data (Figure 1B), without requiring all attendees of the demonstration to have prior approval to access participant-level data. Similarly, we regularly conduct demonstrations that show an example end-to-end analysis examining standing height data derived from two different program sources. As one might expect, in the real data (Figure 1C) we observe that the distribution of height derived from EHRs closely resembles that derived from the program baseline assessment. While the distribution of heights using the synthetic data (Figure 1D) does not precisely mirror that of the real data, the general shape and agreement of the distribution of height data has similar features to that of the real data. In practice, audience members attending these demonstrations find the synthetic data plausible enough that the demonstrations are successful in meeting their stated goals.

Discussion and Conclusions

GAN-based data synthesis framework and the yielded synthetic data have been used in large scale to support the two important use cases in the All of Us program—system engineering and demonstration. Due to the sufficiently high quality of the generated data, software development and testing, and case study demonstrations have been efficiently expanded. The great performance of synthetic data drives us to move beyond these two use cases with a goal to develop publicly accessible synthetic datasets, which can be used for research purposes. However, there exist several challenges we would highlight as opportunities for future investigation. First, due to an extremely large feature space, the current implementation of data synthesis does not represent the relationships between features and tables. New synthesis frameworks that account for consistency in the feature space need to be developed. Second, though GANs have the potential to preserve privacy, it is unclear whether a synthetic copy of the All of Us data with a very large feature set will sufficiently maintain privacy. Further investigation is needed to evaluate residual privacy risks that may be incurred in synthetic data, such as membership attacks (e.g., recognition of records in the underlying dataset upon which the synthetic data generator is based).

Introduction
The novel Coronavirus SARS-CoV-2 has caused a global pandemic. As the case counts rise and more people are hospitalized, patient-level health data becomes a viable and crucial resource for researchers to understand disease patterns and design evidence-based interventions against the disease.[1] Due to the private and sensitive nature of patient data, restrictions have been put in place for the sharing of this data. To overcome this problem, we implemented a model-to-data continuous benchmarking challenge - the COVID-19 EHR DREAM Challenge - to enable the data science community to validate clinically relevant prediction models on a private EHR dataset without ever accessing the data.[2,3] This challenge used COVID-19 patient data from University of Washington to enable citizen science and predictive model benchmarking.

Methods
We ran the COVID-19 EHR DREAM challenge as a continuous benchmarking exercise where the datasets were updated every 2-4 weeks to incorporate new patients and update existing patients’ clinical trajectory. In our COVID-19 Challenge, we asked participants to address two clinically pressing questions: Question 1 (Q1) Of patients who receive a test for COVID-19, who will test positive and Question 2 (Q2) Of patients who tested positive for COVID-19 in an outpatient setting, who is at risk for hospitalization within 21 days. We curated two sub-datasets (diagnostic Challenge Dataset and prognostic Challenge Dataset) separately for the two challenge questions for the purpose of model training and evaluation. We also had a cumulative dataset for model analysis. Between February 2020 and January 2021, the UW COVID-19 patient dataset accumulated 108,000 patients who had been tested for COVID-19. Among all patients who received a COVID-19 test, 4,980 tested positive, 3,100 tested positive during an outpatient visit and 170 were hospitalized within 21 days after testing positive during an outpatient visit.

We implemented a model-to-data approach for the COVID-19 challenge to facilitate the delivery of participant models to the challenge datasets in order to train and evaluate their predictive models. COVID-19 patient datasets were hosted in a UW on-premises server behind a UW Medicine IT provisioned firewall. Challenge participants never had direct access to the patient data; instead, they were required to build and submit Dockerized (containerized) models. A synthetic dataset was provided to the participants to help them become familiar with the format of the data and to aid in technical debugging. A submitted model underwent validation procedure on an Amazon Web Service (AWS) cloud environment and once validated, was then pulled in a UW secure environment where it was trained and then applied to patient data (the holdout set from the full patient dataset) to generate

![Figure 1. Model performance AUROC and AUPRC (box plots) and challenge participation (grey bars) for Question 1(a,b) and Question 2(c,d) weekly. Different colors are used to represent different dataset versions.](image-url)
predictions. The performance of the models were evaluated by computing the Area Under the Receiver Operating Characteristic Curve (AUROC) and Area Under the Precision Recall Curve (AUPRC). These two performance scores were returned to participants.

**Results**

By January 2021, this challenge engaged 482 participants from over 90 teams, with 26 having submitted valid models to challenge questions. Datasets for Q1 had 30 weeks with 7 versions and for Q2 had 18 weeks with 4 versions. The best scores achieved during the challenge were AUROC 0.827 and AUPRC 0.303 for COVID-19 diagnosis prediction, and AUROC 0.982 and AUPRC 0.897 for 21-day COVID-19 associated hospitalization prediction. (Challenge participation see Figure 1). In the analysis using cumulative data from different versions of the challenge dataset, the best performance for COVID-19 diagnosis prediction was AUROC 0.776 (95%CI 0.775, 0.777) and AUPRC 0.297, and for hospitalization prediction, AUROC 0.796 (95%CI 0.794, 0.798) and AUPRC 0.1875. Analysis on top 10 models submitting to Question 1 showed consistently better model performance on the female group than male group. The best performance was obtained for the 25-49 age group and the worst performance was obtained for 0-17 age group among all age groups. (Figure 2)

**Discussion**

We succeeded in implementing a model-to-data approach to operate a continuous benchmarking challenge and enable model training and evaluation on up-to-date COVID-19 patient EHR data with a worldwide data science community. The benchmarking challenge provided an unbiased evaluation of models submitted by participants. Across submitted models, we observed discrepancies of performance in this temporally evolving dataset and between demographic sub-populations (gender and age), indicating the existence of potential bias in machine learning approaches, which warranted attention prior to implementation of such models in clinical practice.

Introduction

PubMed (https://pubmed.gov) is a search engine providing access to a collection of more than 30 million biomedical abstracts. About 5 million of these articles have full text versions available in PubMed Central (PMC; https://www.ncbi.nlm.nih.gov/pmc), however, it is not currently possible for a user to simultaneously query the contents of both databases with a single integrated search.

With the growing availability of full-text articles, integrating abstracts and full texts of documents into a unified representation becomes essential for performing comprehensive biomedical literature search. An obvious benefit is improving the handling of queries that produce no retrieval in PubMed, for which incorporating full text information can yield useful retrieval results. For example, the query cd40 fmf retrieves no articles in PubMed, but finds dozens of articles in PMC, which discuss protein cd40 and a computational technique of flow microfluorometry (FMF).

Here we examine how to combine abstracts with available article full texts to improve the overall retrieval performance. We first create the PubMed Click evaluation dataset, which incorporates PubMed queries, retrieved documents and user clicks. Using the PubMed Click dataset, we establish the connection between the BM25 score (currently powering PubMed search engine (1)) of a query term appearing in a section of a full text document and the probability of that document being clicked or identified as relevant. Probability is computed using Pool Adjacent Violators (PAV) (2), an isotonic regression algorithm, providing a maximum likelihood estimate based on the observed data. Using this probabilistic transformation of BM25 scores we show an improved performance on the PubMed Click dataset, and the TREC Genomics collection (3). By using these datasets, we examine how to combine information coming from various parts of a full text document for improved retrieval. We find evidence that different sections of a full text document are of different value in deciding relevance and propose a novel method to convert the information to log odds scores which can be treated uniformly.

Methods

PubMed Click Evaluation Dataset. To address the problem, we create a new evaluation dataset based on indirect human judgements. The dataset is constructed based on retrospective analysis of PubMed queries under the assumption that a clicked document is relevant to a user issuing a query. For each query, clicked documents are collected and labeled positive. Clicks on the top rank are ignored as a precaution, as these might simply represent a user’s urge to click on something indiscriminately. Documents displayed above the clicked document are assumed to have been seen by the user and rejected and are labeled negative. Documents displayed below the lowest clicked document on the document summary page are ignored as the user may not have considered them. In addition, we only consider documents for which none of the query tokens appear in the title, to remove the click bias associated with the presence of query terms in the title. We also dropped articles where the token did not appear in the full text. As the same query string may be searched multiple times within a year, we merge the data from each query and remove from the negative set documents that also appear as positives. For the evaluation dataset, we randomly sampled 2 million unique queries from the PubMed 2017 query log.

Log_Odds BM25 Term Scoring. Here we examine how to optimally use BM25 scores coming from the abstracts and full text sections to improve retrieval performance. Following (4), we consider thirteen full text section types: Abstract, Abbreviation, Caption, Discussion, Case Study, Keyword, Conclusion, Result, Methods, Introduction, Supplement, Appendix, and Generic Section Title. This means that for a given token, for any document we have potentially thirteen different BM25 scores for that token, one from each section type.

We first define the score of a token within a section of a full-text document. For each token, we compute a BM25 score representing the relevance of the token to a paragraph of text. Since there are generally multiple paragraphs within each section of a paper, we keep the largest BM25 score for a paragraph to represent the section score for that token.
Because of the structure of full text documents, the appearance of a token in different sections makes different contributions to the relevance of the document. The same BM25 score may have a different significance depending on the section: a high score in the Results section would likely be more indicative of importance than a similar score from the Methods section of a paper. We propose converting these BM25 section scores into probabilities of a document being identified as relevant, using the PAV Algorithm (2, 5). The PAV-based probabilistic transformation allows one to directly compare the value of section scores to each other. We will refer to the PAV-based transformed scores as Log_Odds BM25.

Here we compare the raw BM25 score with Log_Odds of BM25 to learn the benefits of the proposed probabilistic transformation. Following earlier studies, we consider two flavors for Log_Odds BM25 score: one based on taking maximum score over all sections (6) and the sum over section scores (7). BM25 Abstract score is also computed as it is related to the current PubMed search system.

Results

Preliminary experiments are performed on PubMed Click Dataset and TREC Genomics collection. Two retrieval ranking approaches are compared: using the raw BM25 scores and PAV-transformed Log_Odds BM25 scores. For each approach sum of scores and max score are considered for combining section scores.

Figure 1 demonstrates our findings computed on the complete set of single tokens that appeared in the queries of PubMed Click dataset and TREC genomics datasets. In both datasets, Log_Odds BM25 Sum and Log_Odds BM25 Max demonstrate an improved performance compared to Sum and Max on raw BM25 scores. Based on these results we believe that log odds scoring is a useful approach for measuring the value of the body text.

Discussion

We studied how to integrate full text and abstract information for scoring a query token. Our experimental results demonstrate that PAV based log odds scoring is a useful way to compare the contribution of occurrences of a token in different sections of a document for predicting relevance. Raw BM25 scores are not comparable with each other for making those predictions. The same BM25 score is of different value depending on the section type in which it is found.

1Weill Cornell Medicine, New York NY

Introduction
The pressing public health threat of COVID-19 fundamentally altered the landscape of clinical research, opening an urgent need for data for clinical, research, and operational applications - a need to which many institutions responded accordingly. Our institution created a COVID Institutional Data Repository (IDR), comprised of data retrieved through manual abstraction and automated extraction from EHR systems, including medications, comorbidities, labs, symptoms, and more. This resource afforded the opportunity to explore the comparison between manually and automatically derived data, further elucidating their relative strengths and weaknesses. Manual chart abstraction is often considered the gold standard for retrospective observational research, and many variables require manual adjudication from clinically trained personnel (1). However, human reviewers are not infallible and are still less accurate in certain cases while suffering the key shortcoming of linear scaling as cohort size increases (2).

In part to address these shortcomings, studies have demonstrated that automated data extraction can perform on par with manual abstraction for certain variables (3,4). Automated extraction from the EHR can have data quality issues, due to high complexity or fragmentation of data (5). Both automated and manual techniques ultimately depend on the EHR, which is not an objective, canonical source of truth but rather an artifact with its own bias, inaccuracies, and subjectivity (6,7). We sought to compare data collected through manual chart review to the data populated via automated extraction to determine their level of concordance regarding exposure to home and inpatient medications, to assess the relative performance of the two abstraction techniques by re-reviewing discrepancies to determine which was correct, and to generate a taxonomy of discordance by classifying instances of discrepancy.

Methods
To compare data collected between methods, a query was developed in SQL to identify, for each patient, whether the automated extraction agreed with manual abstraction for administration of inpatient and home medications (queries can be found at https://github.com/wcmc-research-informatics/covid_comparison). The query was designed to align with the manual abstraction instructions (e.g. searching for medication names as opposed to RxNorm codes or sometimes having requirements for duration). For each medication, we calculated Cohen’s kappa and 95% CI to quantify agreement between data abstracted manually and automatically. Based on the query output, 10% or 20 identified discrepancies for each medication, whichever was greater, were randomly selected to be audited and reviewed by two team members (AY and WG). After initial review of a subsample of discrepancies, results were classified into categories and harmonized through discussion, which was repeated until thematic saturation. Descriptive statistics were calculated once all discrepancies (n=680) were reviewed.

Results
All 25 medications and drug classes (16 inpatient and 9 home) included in the manual abstraction were included. For inpatient medications, kappa values ranged from 0.96 to 0.0. For home medications, kappa values ranged from 0.77 to 0.18. Discrepancies were divided into three principal categories: human error, ETL/mapping error, or abstraction-query mismatch. For inpatient medications, 310 discrepancies were audited: 119 were due to human error, 46 to ETL/mapping, and 145 to abstraction-query mismatch. For home medications, 370 discrepancies were audited: 77 were due to human error, 199 to ETL/mapping, and 94 to abstraction-query mismatch.

| Table 1. Rater agreement data and all calculated statistics for inpatient and home medications |
Conclusion
This study demonstrates the viability of automated collection of inpatient medication data from the medical record, with home medications showing weaker results. Institutions with large databases should be able to employ similar methods. Although the findings and implications are broadly applicable, the query was tailored to this specific IDR; replicating this analysis will require site-specific adaptation depending on EHR data transformation and database structure. Second, although the audit process was extensive, it focused on discrepancies rather than a random audit of all results, thus possibly overlooking errors among agreeing results. Third, there may be underlying bias within the data collection methods that impacted data quality for certain populations. Fourth, this study does not attempt to evaluate the severity of errors, and some errors may be considered more critical than others. Lastly, the current work focuses on the important but specific domain of medications, which we hope to expand upon in the future.

The study results call into question the consideration of one data collection method as a “gold standard” for observational retrospective research. It is important to be rigorous and transparent about data sources and methods used, accepting that errors will occur. In certain circumstances, available resources will vary, requiring alternative methods with which to acquire and analyze data. Targeting manual and automated abstraction efforts at data domains where performance is demonstrably superior can lessen the time and effort needed and enhance data quality overall.

PAGER-CoV-Run: An online interactive analytical platform for COVID-19 functional genomic downstream analysis

Zongliang Yue⁴, Nishant Batra¹, Hui-Chen Hsu², John Mountz², and Jake Chen*¹
¹Informatics Institute, School of Medicine, the University of Alabama at Birmingham, Birmingham, AL 435233, USA
²Division of Clinical Immunology and Rheumatology, Department of Medicine, the University of Alabama at Birmingham, Birmingham, AL 435233, USA

Background: COVID-19 has become a global public health threat for over a year. Recently, the emergence of the SARS-CoV-2 coronavirus Delta variant has brought additional concerns due to its unusually high transmissibility and potential vaccine break-through. To interpret genomic and functional genomic effects of SARS-CoV-2 on human tissues and perform comparative analysis among various SARS-CoV-2 infected samples, we developed an online tool called “PAGER-CoV-Run”. PAGER-CoV-Run takes pathways, gene sets, and gene signature information from the PAGER-CoV database and performs advanced functional genomics data analysis online for users without the need for any coding. PAGER-CoV-Run also implements advanced visualization and network analysis features, potentially serving as a model for future functional genomics tools for target identification.

Result: As of the current implementation, PAGER-CoV-Run enables the pre-configured analysis of 629 samples covering six cell types, i.e., primary human lung epithelium (NHBE), lung alveolar (A549 cell line), the transformed lung-derived Calu-3 cells (Calu3), peripheral blood mononuclear cells, leukocytes, Human induced pluripotent stem cell-derived cardiomyocytes, and four tissues, i.e., lung, liver organoid, pancreatic organoid, and nasopharyngeal. By comparing the pathways enriched in A549 cell line, we found that pathways that are associated with the interferon-alpha/beta response, the peginterferon alpha-2a/peginterferon alpha-2b response, the OAS antiviral response, and the human immune response to tuberculosis are commonly enriched shared among RSV, HPIV3, and SARS-CoV-2 infection. Our results suggest that interferon-alpha/beta treatment in RSV and HPIV3 may have similar effects for SARS-CoV-2. By comparing the pathways enriched in SARS-CoV-2 infected NHBE and SARS-CoV-1 NHBE, we found that SARS-CoV-2 specifically alters NF-kappa B signaling pathway, suppresses HMGB1 mediated inflammation by Thrombomodulin (THBD), triggers genes involved in RUNX2-mediated cell migration, and affects lipoxin and 15-eicosatetraenoic acid biosynthesis. This case study suggests that potential drugs in targeting the pathways above may further suppress SARS-CoV-2–mediated lung damage and inflammation.

Conclusion: PAGER-CoV-Run is a powerful public tool to perform functional genomic analysis across cell types and tissues. Additional data configured into the PAGER-CoV-Run should improve end-user exploration of major pathogenic mechanisms in COVID-19 patients with the potential to identify pathways that promote long-haul sides effects in various tissues. PAGER-CoV-Run is publicly accessible from http://discovery.informatics.uab.edu/pager-cov-run.
Clinical Term Embeddings from SNOMED CT

Fuad A. Zahra and Rohit J. Kate
Department of Computer Science
University of Wisconsin-Milwaukee, Milwaukee, WI, 53211

Introduction: Word embeddings represent semantic properties of words in the form of fixed-length vectors and are critical for applying deep learning based methods for natural language processing tasks, including in the biomedical domain [1]. Word embeddings are commonly obtained from large text corpora based on the assumption that words with similar meanings will appear in similar contexts. However, semantic properties of words or terms are often directly encoded in their ontologies in the form of relations between them. Examples of such ontologies include WordNet [2] in the general domain and SNOMED CT [3] in the clinical domain. For example, one can infer from SNOMED CT relations that “asthma” and “pneumonia” are similar terms because both are disorders related to lungs. Given that clinical concepts are defined in SNOMED CT in terms of their relations with other concepts (this is unlike the relations in UMLS [4]), it makes it an invaluable resource for obtaining clinical term embeddings. But SNOMED CT has remained mostly underutilized as a resource for obtaining clinical term embeddings. In this work, we used only SNOMED CT relations to obtain embeddings for clinical terms and evaluated them using four benchmark datasets of clinical term similarity. Our results show that our SNOMED CT-based embeddings performed competitively against four other embeddings that were obtained using corpus-based methods. To the best of our knowledge, there is only one previous work that had reported embeddings obtained from SNOMED CT [5], but the authors had used a different method and had evaluated it only for concept similarity and not for clinical term similarity.

Methods: We adapted the method that had been previously used to obtain word embeddings from WordNet in the general domain and was shown to perform well [6]. The method is based on the intuition that two concepts are semantically closer if in their ontological graph there are larger number of paths between them as well as if these paths are shorter. Computationally, the method proceeds as follows. We first obtain an n x n adjacency matrix M from the SNOMED CT ontological graph G where n is the total number of concepts in SNOMED CT. An entry $M_{ij}$ in this matrix is 1 if there is a relation between the concept represented by the i’th row with the concept represented by the j’th column, otherwise the entry is 0. An entry in the k’th power of matrix $M^k$ then represents the number of paths of length k between the two concepts corresponding to the matrix entry. Thus, the matrix sum $M_0 = I + \alpha M + \alpha^2 M^2 + \alpha^3 M^3 + \ldots$ where I is the identity matrix and $\alpha$ (< 1) is a decay factor, depicts the total number of paths of all lengths between any two concepts where longer paths are progressively counted with less weights. This sum can be analytically obtained using the inverse matrix operation: $M_0 = (I - \alpha M)^{-1}$.

The matrix $M_0$ thus obtained represents each concept with a vector that has as many dimensions as the number of concepts in SNOMED CT, which is more than 400,000. However, in order to be practical, an embedding needs to be of much lower dimensions. Hence, we next apply Principal Component Analysis (PCA), a well-known method for dimension reduction. Because the matrix is too large, we used Incremental PCA (IPCA) method [7] instead. We chose 850 as the dimensions for the embeddings and $\alpha = 0.75$ based on pilot studies. It should be noted that this method generates embeddings for SNOMED CT concepts (i.e. an embedding for each SNOMED CT concept ID) and not for clinical terms or words. However, for natural language processing applications as well as for our evaluation of clinical term similarity in this work, we need embeddings for clinical terms instead. Although clinical concepts in SNOMED CT are paired with their associated clinical terms, getting embeddings for clinical terms from embeddings of clinical concepts is not trivial because there could be multiple concepts or no concept in SNOMED CT corresponding to a clinical term. Hence, we use the following method to derive embeddings of clinical terms from the embeddings of clinical concepts. If a clinical term is not ambiguous, i.e. if there is a unique concept corresponding to it in SNOMED CT, then the clinical term’s embedding is considered same as the concept’s embedding. If multiple concepts correspond to a clinical term in SNOMED CT, then its embedding is obtained by vector summing all those concept embeddings to represent an aggregated meaning. In case a clinical term does not correspond to any concept in SNOMED CT, then its embedding is obtained by vector summing the embeddings of all the concepts whose clinical
terms include that term as a sub-term. This happens for less than 5% of the clinical terms in our data. In the above procedure, we first expand the synonym sets of clinical terms in SNOMED CT using more synonyms from UMLS.

Results and Discussion: We evaluated our clinical term embeddings obtained from SNOMED CT on four benchmark datasets of clinical term similarity that have been widely used previously [8]. Each of these datasets contains a list of clinical term pairs along with expert-judged scores of similarity between them. Using embeddings, the similarity between a pair of clinical terms is determined as the cosine similarity between the embeddings of the clinical terms.

In the results shown in Table 1, we report the Pearson correlation coefficient scores between the expert-judged similarity scores and the similarity scores obtained using the embeddings. We compare our results with the results obtained using four embeddings obtained using corpus-based methods as reported in [8]. The embeddings GloVe and Google News were obtained from general domain text corpora, the embedding EHR was obtained from a corpus of clinical notes, and the embedding MedLit was obtained from a corpus of biomedical articles.

It can be observed from Table 1 that our SNOMED CT embeddings obtained the best score on the first dataset and was competitive on the rest of the datasets. It was consistently much better than GloVe and Google News embeddings showing that our method gleaned far superior knowledge from SNOMED CT to encode in the embeddings than the knowledge about clinical terms the corpus-based methods could glean from general domain text. Compared to EHR, our embeddings did worse on three datasets and better on one dataset. Our embeddings did better than MedLit embeddings on three datasets and was slightly behind on one dataset. These results show that embeddings obtained from SNOMED CT without using any text corpora are comparable to embeddings obtained using state-of-the-art corpus-based methods from biomedical text corpora.

Table 1. Performance comparison of our SNOMED CT-based embeddings and four corpus-based embeddings as reported in [8] on the four clinical term similarity benchmark datasets. The numbers are Pearson correlation coefficients between the expert-judged similarity scores and the similarity scores obtained using the embeddings.

Conclusions: We presented a method to obtain embeddings for clinical terms directly from SNOMED CT ontology without using any text corpora. The embeddings we obtained performed well on four benchmark datasets compared to embeddings obtained using corpus-based methods. Developing a method that combines the two types of embeddings thus combining their strengths will be an avenue for future research.

Introduction

The COVID-19 pandemic is a rapidly evolving public health and economic crisis, with over 34 million people infected in the United States and 194 million globally. The virus's high transmissibility, lack of native immunity, high mutability, and the dearth of effective treatments make managing COVID-19 uniquely challenging. The public health authorities first had to identify and draw attention to signs and symptoms of specific to COVID-19, which can enable rapid symptom screening, diagnostic testing, and contact tracing. Previously, the primary efforts to track COVID-19 symptoms relied on scanning scientific publications or Twitter1, deploying questionnaires2, or releasing apps to self-report symptoms, but results from publications and questionnaires are often delayed; data from scientific publications or Twitter are often delayed; data from publications and questionnaires are often delayed; data from social media or self-reported apps do not always include proper controls and lack physiological assessments to determine COVID-19 status. To timely recognize the emerging symptoms and clinical characteristics of COVID-19, we utilized natural language processing (NLP) to analyze clinical notes from Electronic Health Records (EHR) of people tested for COVID-19. We developed a method called the concept-wide association study (ConceptWAS)3 to identify clinical concepts associated with COVID-19 and performed a temporal analysis. By analyzing clinical notes of 19,692 adult patients who received COVID-19 testing at Vanderbilt University Medical Center (VUMC) between March 8 and May 27, 2020, we were able to detect loss of smell and loss of taste three weeks prior to their inclusion as symptoms of the disease by the Centers for Disease Control and Prevention (CDC).

Materials and Methods

Study setting. The study was performed at VUMC, one of the largest primary care and referral health systems serving over one million patients annually from middle Tennessee and the Southeast United States. We used data from patients represented in the VUMC EHR aged ≥18 years. The study was approved by the VUMC Institutional Review Board (IRB #200512).

Cohort definition. We identified patients who received at least one SARS-CoV-2 polymerase chain reaction (PCR) test between March 8 (when the first COVID-19 case emerged at VUMC) and May 27, 2020 (Figure A.1). The COVID-19 status was determined using the PCR test result. The case group (COVID-19-positive) was defined as patients who had ≥1 PCR positive result, and the control group (COVID-19-negative) consisted of patients with only negative PCR tests. We excluded patients who had no clinical notes on the day when the PCR test was ordered.

Data collection. We extracted clinical notes from 24 hours prior to PCR testing date (day0) for the cohort. If a patient first tested negative and then subsequently tested positive or if a patient tested positive more than once, we used the date of the first positive PCR test as day0. We also segmented the study period into a 2-week interval window and performed a temporal analysis using every 2-week cumulative data. The primary types of clinical notes that we extracted included progress notes, problem lists, Emergency Department (ED) provider notes, ED triage notes, imaging reports, social histories, etc.

NLP processing. We utilized an NLP pipeline to preprocess, analyze, extract, and identify the clinical concepts from the clinical notes. The NLP pipeline employs knowledge map concept indexer and several rule-based parsers to map from text mentions to Concept Unique Identifiers in the Unified Medical Language System (UMLS) and SNOMED Clinical Terms. We also employed additional UMLS semantic types to accommodate relevant items such as symptoms, mental or behavior dysfunction, or social behaviors. We enabled the negation detection and developed multiple rules to enhance such detection and filter out unrelated concepts, e.g., excluded any concepts that arose from family history sections, removed any sentences with future tense or subjunctive mood (e.g., "should", "could", or "if") that describe uncertainty.

Statistical analysis. We applied Firth's logistic regression to examine the association for each concept, adjusted by age, gender, and race. We chose Firth's logistic regression because it has become a standard approach for analyzing binary outcomes with small sample. We used a Bonferroni correction for the significance level. For each concept, we report the odds ratio (OR), p-values, and the prevalence in case and control groups.

Two medical students performed a manual chart review to evaluate the clinical plausibility of identified signals. For concepts p-value met Bonferroni-corrected significance, we randomly selected 10-20 notes for each concept to review whether the notes mentioned the symptoms in the expected attribute (e.g., affirmative or negated).

Results
We identified 19,692 patients with COVID-19 PCR test results during the study period. A total of 1,483 (7.5%) patients tested positive for COVID-19. Patients' mean age was 45 (44.6 ± 16.9) years. The COVID-19-positive group was younger (41.5 ± 16.2 vs. 44.9 ± 16.9), more often male (48.0% vs. 41.7%), less often white (49.6% vs. 66.7%), and newer to VUMC (EHR length 7.3 years ± 8.1 vs. 9.2 ± 8.5) compared to COVID-19-negative patients. We processed 87,753 notes from 19,692 patients. After using the NLP pipeline to process the notes, we recognized 19,595 unique concepts (including negated status). Within that corpus, we identified concepts positively associated with COVID-19 including "anosmia" (loss of smell, odds ratio [OR] = 4.97, 95% confidence interval [CI] = 3.21–7.50), "fever" (OR = 1.43, 95% CI = 1.28–1.59), "cough with fever" (OR = 2.29, 95% CI = 1.75–2.96), "ageusia" (loss of taste, OR = 5.18, 95% CI = 3.02–8.58), as well as those concepts that were negatively correlated with COVID-19 such as "depression and anxiety" and "smoking" (Fig. 1). Earlier epidemiological studies found that fewer smokers are among COVID-19 patients or hospitalized COVID-19 patients, which are consistent with our findings of the negative correlation between smoking and COVID-19.

Notably, by performing temporal analysis on every two-week cumulative data, this study detected the signal of loss of smell and taste as early as April 5, 2020 (Fig. 2), nearly three weeks earlier than the date that they were listed as COVID-19 symptoms by CDC. The chart review finally reviewed 260 notes for the significant concepts, and 83.46% were true signals, which means mentioning the concepts in excepted attributes.

Discussion
Our work describes a high-throughput and reproducible approach (ConceptWAS) to use EHR notes to early identify pandemic disease symptoms and investigate clinical manifestations for further hypothesis-driven study. We examined clinical concepts distinguishing COVID-19-positive patients from negative controls and ran the analysis through cumulative time windows. Our results showed that ConceptWAS detected the loss of smell and taste three weeks before CDC added smell and taste disorders to its list of COVID-19 symptoms, demonstrating the power of the EHR to enable early disease detection, and its potential for improving our clinical and public health response to the pandemic.

Code availability. Up-to-date developments of ConceptWAS are available in GitHub (https://github.com/zhaojuanwendy/ConceptWAS).

Modeling Variant Annotation (VA) Therapeutic Association Statements using a SEPIO-Based Workflow

Yiqing Zhao, Ph.D.¹, Matthew Brush, Ph.D.², Hongfang Liu, Ph.D.¹, Robert Freimuth, Ph.D.¹*

¹Department of Artificial Intelligence and Informatics, Mayo Clinic, Rochester, MN.
²Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR.

Background

The Global Alliance for Genomics and Health (GA4GH) is a standards development organization that aims to enable sharing of genomic data and knowledge. The GA4GH Variant Annotation (VA) Project seeks to develop a common data model to represent annotations made about genomic variants, and the evidence and provenance that underlie those annotations. The model will support a wide variety of variant annotations, including causal association to disease/phenotype and interpretations of clinical relevance and actionability, and it will support existing clinical lab standards such as the ACMG/AMP variant interpretation guidelines. As a step toward a generalized VA model, we developed and implemented a detailed process to model one specialized type of VA statement: the Therapeutic Association Statement.

Methods

The modeling procedure adopted the Scientific Evidence and Provenance Information Ontology (SEPIO) workflow(1). The first two steps of SEPIO workflow were: 1. Conduct domain analysis through a comprehensive survey of relevant knowledgebases and clinical databases, collecting use cases in the domain; and 2. Identify data elements from the domain that are required for modeling use case. We examined database structures of existing knowledgebases including PharmGKB, ClinVar, CIViC, OncoKB, MyCancerGenome, PharmVar, and CPIC guidelines. Unstructured statements/assertions curated by those knowledgebases were extracted using natural language processing, which was used to analyze the phrases and data elements in those statements. That analysis identified several statement subtypes, which were modeled in detail.

Results

In our study, we identified five statement subtypes, shown in Table 1.

<table>
<thead>
<tr>
<th>Statement Subtype</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Therapeutic Response (TR) Association</td>
<td>An association between a genetic variation and the response of a patient or other biological system to a therapeutic intervention - specifically, the extent to which an intended benefit is achieved, or an unintended consequence is manifest</td>
</tr>
<tr>
<td>Treatment Course (TC) Association</td>
<td>An association between a genetic variation and the manner in which a treatment is most effectively applied (e.g. the timing, duration and dose of treatment)</td>
</tr>
<tr>
<td>Pharmacokinetic (PK) Association</td>
<td>An association between a genetic variation and how a drug is processed by body (including its uptake, distribution, metabolism, elimination, as well as its concentration in the body)</td>
</tr>
<tr>
<td>Molecular Response (MR) Association</td>
<td>An association between a genetic variation and the expression, activity, or functions of a specific gene product following a treatment</td>
</tr>
<tr>
<td>Clinical Outcome (CO) Association</td>
<td>An association between a genetic variation and a defined clinical outcome that follows a treatment</td>
</tr>
</tbody>
</table>
Based on the five statement types identified, a common data model was developed. The core data model includes four mandatory attributes: Subject (the Variation that the Statement is about), Predicate (the relationship asserted to hold between the Subject and the Object), Object (the Therapeutic Intervention for which the Variation is asserted to have an association, often in the context of a disease), and variantOrigin Qualifier (e.g., germline vs. somatic). Several optional attributes were identified (Table 2) that may link to ontologies, other VA models or shared vocabularies by all VA models.

<table>
<thead>
<tr>
<th>Qualifier</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>treatedCondition</td>
<td>A qualifier that refines the scope of the core statement to apply in the context of a particular genetic condition that is being treated by the intervention.</td>
</tr>
<tr>
<td>population</td>
<td>A qualifier that refines the scope of the core statement to apply in the context of a particular population of individuals.</td>
</tr>
<tr>
<td>comparator</td>
<td>A qualifier that extends the core statement to report a variation or genetic state relative to which the association asserted for the subject Variation holds as true.</td>
</tr>
<tr>
<td>specificSideEffect</td>
<td>A qualifier that extends the core statement to capture a specific unintended consequence associated with the presence of the subject variant, following the indicated treatment.</td>
</tr>
<tr>
<td>clinicalAspect</td>
<td>qualifies a side effect by describing a specific aspect of the side effect that is associated with the subject variation (e.g. its severity, onset, rate of progression, etc.)</td>
</tr>
<tr>
<td>affectedGene</td>
<td>For the MolecularFunction Response Statement type - a qualifier that extends the core statement to capture the specific gene/product being described</td>
</tr>
<tr>
<td>clinicalOutcome</td>
<td>For the Clinical Outcome Association Statement type - a qualifier that extends the core statement to capture a specific clinical outcome associated with the variant (typically an unintended side effect).</td>
</tr>
<tr>
<td>responseMeasure</td>
<td>A qualifier that captures the specific trait/phenotype/characteristic measured to assess response to treatment. This may be a measure to determine if the treatment is having its intended effect (typically a direct symptom or marker related to the condition the drug is given to treat). Or a measure to determine the presence/extent of an unintended side effect.</td>
</tr>
</tbody>
</table>

**Conclusion**
We analyzed curated statements from several community knowledgebases and proposed a VA Therapeutic Association Statement model. The core model follows subject, predicate, and object structure and eight qualifiers were identified in addition to the core model. We are currently expanding the validation of this model using content from clinical genetic reports. The impact of our work is two-fold: 1. the validated model could potentially facilitate integration of genomic medicine information and knowledge into clinical systems with a high-level of consistency, scalability, and computability, and 2. this model will inform the development of a generalized VA model that extends beyond the scope of Therapeutic Association.

Introduction

“Hackathons” are focused events used to develop or improve software. Recently, this concept has been applied to healthcare data science1 in the form of datathons or data challenges. Baylor College of Medicine (BCM) held a datathon in 2020 to showcase our ability to perform quality improvement and population health studies and launch new research initiatives. Our goals were to (1) inform potential users of available data, (2) leverage local data to address clinical questions, (3) test local data and identify limitations of data use, and (4) facilitate cross-institutional collaborations among faculty, postdoctoral trainees, and students.

Methods

BCM is a leader in medical education, supporting the training of over 3,000 medical and graduate learners annually. Its faculty support numerous healthcare organizations. These include Baylor St. Luke’s Medical Center (BSLMC, a teaching hospital) and a large Faculty Group Practice (FGP) for outpatient visits. These organizations use separate electronic health records and have variable degrees of data governance and data access. The BCM data warehouse, an integrated data repository, is hosted as an Epic Caboodle database. It houses clinical data on 4.3 million unique individuals, 151 million encounters, and 122 million lab tests from February 2009 to the present.

Datathon planning began in Fall 2019. The event was championed by BCM leadership and the leaders of the FGP and BSLMC. It was endorsed and supported by the Chief Information Officer and other informatics leaders. We established a datathon planning committee to determine event policies, facilitate collaborations, and identify potential projects. The planning committee reviewed preliminary data from the BCM data warehouse, and four test case projects were conducted to ensure data delivery processes and usability. Between April and July 2020, we developed approaches for submitting and reviewing proposed projects. We solicited applications to participate in August 2020, with a particular focus on reaching trainees (students, residents, fellows), and a panel of senior faculty from across the College reviewed the applications. Because we conducted the datathon as healthcare operations and identifiable data if needed, only participants within BCM were eligible. They must file a protocol with the institutional review board to continue analyses or present any generalizable knowledge discovered. The committee selected proposals based on feasibility and relevance to quality improvement of population health. Although the COVID-19 pandemic affected the initial plans for an in-person event, we transitioned to a virtual format, and no delays in planning or hosting the datathon occurred.

Datathon projects were vetted for feasibility and impact and selected in September. Data extraction began immediately. Project teams submitted data requests to BCM Information Technology (IT) and received a schedule for data availability. Teams had iterative consultations with IT to refine parameters for data extraction. Microsoft Teams was used for real-time collaboration. Project teams began analysis when data were available. Consequently, some groups had more time for analysis than others. Our datathon was innovative because it involved sustained effort rather than a few days of intense work. Most analysis took place in October, with a preliminary presentation of lessons learned on October 8. IT provided a final dataset to teams for analysis; final presentations were on October 27. A six-person judging committee, including faculty of the affiliated hospitals, gave four awards (most clinically innovative, most innovative use of data, excellence in collaboration, greatest potential for impact on patient care). The judging committee and coauthors determined opportunities and challenges by reviewing participants’ work and comments during the datathon. A survey of datathon participants is also underway to identify areas of success and opportunities for improvement.

Results
Altogether, we received 33 proposals and selected 13 (3 outpatient, 8 inpatient, 2 combined inpatient/outpatient). The following topic areas were covered: early warning for acute kidney injury (AKI) after surgery, seasonality of AKI and respiratory viruses, designing surgical instruments using radiographs, characteristics of COVID patients with complications, referrals and quality in chronic kidney disease using geoanalytics, blood pressure variability and intracerebral hemorrhage outcomes, predictors of COVID outcomes, fluid balance effect on outcomes in patients with subarachnoid hemorrhage, complications of cancer treatment, smoking and cancer screening, inappropriate recording of antimicrobial allergies, and disparities in fragility fracture care between two hospitals.

Discussion

This datathon met our goals by familiarizing investigators with available data and its limitations, familiarizing IT with investigators’ requests, and identifying challenges in the secondary use of clinical data. This will allow BCM to address relevant and timely research questions in the future by utilizing locally integrated data sources.

We uncovered several opportunities through this experience. The greatest opportunities pertained to collaboration. Staff with diverse expertise across the organization engaged in many projects, leading to timely and innovative project ideas. A common platform for collaboration would continue to support interactions between IT and clinicians/researchers. Second, the questions posed by teams were highly dependent on data availability, thus presenting an opportunity for self-service tools like Epic SlicerDicer and i2b2 (only recently broadly deployed at BCM) to provide insight into data availability. Lastly, an executive champion was critical. We hope that this report of a datathon’s benefits will help others decide to use this strategy.

In addition to opportunities, we identified several challenges: many relating to communication within the team itself or the data request and extraction. First, the perception of a data request differs between IT and clinicians. What a provider sees on a daily basis is not reflected in the architecture of the data warehouse. Therefore, outreach and promotion could help manage these expectations. Second, clinicians and IT project members interact and communicate well, but each has expertise that creates barriers to efficient dialogue. This is manifest at times in documentation for some data domains. For example, laboratory studies exist in a database table called “procedures,” a label clinicians would not typically apply. Taking the names of tables and fields at face value runs the risk of overlooking important data or including irrelevant data. This discrepancy in technical language consequently made data request/acquisition and analysis more time-intensive in our projects. Interactive tools or staff with cross-training in clinical and IT domains could improve efficiency. While these challenges were greater with less experienced users, team members with expertise in clinical and IT fields could steer projects efficiently. Third, we found that project tools were a challenge. Tools such as i2b2 and Epic SlicerDicer can retrieve and analyze data, but not all teams were familiar with them. Agreeing upon a common set of tools at the beginning of a project coupled with targeted instruction can improve understanding and support efficient transitions between project tasks. Fourth, most projects required extensive data cleaning, a common phenomenon when using clinical data for secondary analyses. Increased integration of data sources could reduce time and effort spent on data cleaning, but projects still need to budget time for cleaning. Integration or patient linkage across data sources should also be automated as much as possible. Fifth, large, high-resolution datasets (e.g., critical care vital signs) were challenging to curate; however, these granular data were valuable when analyzed appropriately. Also, the demands of image retrieval and analysis suggest a need for a dedicated platform for imaging analysis and facile data transfer in the future.

We have illustrated a new use of a datathon: to “kick-off” a new data warehouse and familiarize users with it. We will continue to learn from challenges and leverage opportunities to help BCM and others use their valuable clinical data.

The Role of eHealth Developers and Medical Professionals in Reducing Ageism and Geriatric Digital Exclusion

Dani Zoorob MD MHA MBA MHI, Yasmin Hasbini MD, Victoria Wangia-Anderson PhD MS, Brian Miller MD, Debi Brobst MBA

Introduction
Even though the field of telemedicine and e-health is expanding, the rate of uptake of telemedicine among the elderly does not match the expansion rate, leading to disparities and inequity in care availability between populations. This phenomenon contributes to the digital inverse care law, whereby those who need the services the most (in this case, the elderly with the service in question being digital medicine) are in fact excluded from receiving it, and thus result in worse outcomes.1 This results in digital exclusion and ultimately ageism.

Ageism is expressed in two ways: the lack of accommodations specific to the elderly during the development of telemedicine platforms, and in providers presuming lack of interest or ability to use digital technology by the elderly.2,3 When experienced, perceived ageism leads to lower uptake of digital medicine by the older population.4,5 This leads to digital disparity and exclusion, which is now being characterized as a social determinant of health due to it being a social and economic factor impacting health outcomes.1 Thus, the objective of this study was to identify the motivators, concerns, and issues contributing to the uptake (or lack of) of e-Health platforms among the elderly in order to propose clear and quantifiable measures that developers and providers can consider to decrease access inequity.

Methods
This was a cross-sectional study whereby an anonymous survey was administered to patients at a Urogynecology and Menopause Center. A total of 205 completed the survey (225 total surveys, 93% response rate). The survey was divided into sections: motivators of use of e-health platforms, concerns and issues experienced when using them, enhancements desired in the platform, and women’s health specific questions for insight into care planning.

Results
The average age of the participants was 68.9 (SD 4.9). The surveyed population was mostly Caucasian (83.9%), with 11% Hispanics/Latinas and 3% African Americans, while up to 80% had a college degree. Privacy, cost, and technical issues were evaluated (Fig 1. a) with the majority being concerned about running into technical issues (50%) and privacy (45%). The most encountered technical issue was that the system requested much information upon startup (36%), followed by being unable to print/save/send documents from EHR (35%) (Fig 1. b). Of those above the age of 75 years, 25% experienced difficulty from physical limitations such as arthritis and finger mobility, and 20% complained of eye strain/joint. Experiencing anxiety when using portals was reported in up to 36% of the participants (Fig 1. c). The telehealth portals feature changes requested included the ability to freely change the size of the icons and text (47%), a simpler design (46%), and more drop-down lists to choose from (40%) (Fig 2. a).

Up to 40% of those surveyed reported that portals make their medical visits less stressful, and 24% specifically correlated that to logistics. Regarding condition-specific telehealth visits (Fig 2. b), 74% were comfortable with medication checks via telehealth, 66% were interested in post-operative visits being online (excluding those requiring a pelvic exam), and 52% verbalized preference for preoperative counseling via telehealth. When questioned about the potential motivators for using technology-enabled care, 73% of the participants reported that they would consider portal use if specifically encouraged by their providers (Figure 2. c)

Discussion
As the population ages, the proportion using the portals will be increasing significantly within the next two decades. Ensuring uninterrupted healthcare access to these patients is necessary - although this is gradually being addressed since the pandemic started. The study suggests that the health informatics field has not yet reached adequate accessibility maturity, specifically from an ageism standpoint. Although platforms are becoming more user-friendly, their tailoring of age-focused accessibility options has been limited. Our study suggests that when designing for such a population, it is essential to incorporate a flexible and modifiable platform that can be changed to the patient’s desires or at least adapt to the age group. Although only the older segment of our population complained of physical or medical limitations impacting their use of portals, more complained of anxiety when using technology, indicating that more time and effort should be spent educating and assisting patients in understanding how to use the platforms and addressing concerns.
Additionally, the promotion of portal use may be hindered by the ageism inherent in the behavior of providers and medical staff. An important outcome of our study is the indisputable role providers - and healthcare systems as a whole - could play in increasing uptake of e-Health among the geriatric population. This is through direct promotion by providers, active patient education, and on-site enrollment. Additionally, there is a clear consensus on the importance of addressing privacy concerns when developing the educational material. Since our study was administered to urogynecology patients, it is essential to note the versatility of e-Health applicability, as indicated by our results of a generally positive attitude. This can be expanded to other medical and surgical specialties.

**Conclusion**

Tackling ageism in health informatics is necessary. Accessibility and adaptability in portals and platforms must include age-related needs. Policymakers and healthcare leaders should develop a more standardized method of educating and enrolling their geriatric population in e-health services, as well as investing in developing more flexible interfaces that can be modified to the patient’s desire.

Network Analyses on Hyperlinked Online Resources for COVID-19 Vaccine

Meredith Abrams, MS, MPH; Dongwen Wang, PhD
Biomedical Informatics, Arizona State University, Phoenix, AZ

Introduction
Since the outbreak of the COVID-19 pandemic, the related online information resources have been exploding and constantly changing. Timely collection and analysis of these resources is critical for effective dissemination of the latest clinical evidence. Here we report a pilot study to develop a process to analyze the hyperlinked online resource networks for COVID-19 vaccine and to assess the change of the networks over time. This work is part of a methodology development to integrate information “freshness” into network analysis for timely dissemination of clinical evidence.

Methods
We developed a webcrawler to automatically collect the hyperlinked online resources based on a list of 252 keywords related to various topics of COVID-19. On Feb. 15, 2021, we started the first webcrawling from the COVID-19 resource pages of the CDC and WHO websites (the top authorities of related information), recursively searched the hyperlinked resources to a depth level of 4, and constructed networks at the resource and the hosting site levels. To narrow down the resources to focus on COVID-19 vaccine, we processed the network data, only kept resources matching with keywords related to COVID-19 vaccine, and constructed a subnetwork. We then visualized the networks and assessed their metrics using the Gephi tool. We examined the top resources, the associated keywords, and the hosting sites for both the overall network and the subnet. We repeated this process on Mar. 4, 2021, and assessed the changes of the networks over time.

Results

<table>
<thead>
<tr>
<th>Overall Network of COVID-19</th>
<th>Subnetwork of COVID-19 Vaccine</th>
</tr>
</thead>
<tbody>
<tr>
<td>unique resources</td>
<td>hosting sites</td>
</tr>
<tr>
<td>Feb 2021</td>
<td>158,778</td>
</tr>
<tr>
<td>Mar 2021</td>
<td>610,990</td>
</tr>
</tbody>
</table>

For the COVID-19 overall network, we found the top keyword hits across February and March included CDC, COVID-19, vaccine, R0, and treatment. The top individual resources based on PageRank were sponsored by government, such as the homepage of USA.gov, the homepage of HHS.gov, and the CDC’s YouTube channel. The top hosting sites included government agencies, such as CDC, and social media platforms, such as Facebook, Twitter, and Instagram. The COVID-19 vaccine subnetworks are visualized in Figure 1.

With regard to the change of the overall network, we recorded significant increase of both the unique resources (284%) and hosting sites (215%) between February and March. Only 33% (51,785 out of 158,778) of the unique resources and 40% (2,518 out of 6,374) of the hosting sites identified in February remained in the network in March. Meanwhile, 92% (559,205 out of 610,990) of the unique resources and 87% (17,562 out of 20,080) of the hosting sites in March were newly identified. For the COVID-19 vaccine subnetwork, 72% (809 out of 1,126) of the unique resources and all (100%) the hosting sites identified in February remained in the subnetwork, and 40% (547 out of 1,356) of the unique resources and 20% (21 out of 104) of the hosting sites in March were newly identified.

Discussion and Conclusion
We successfully explored a process to construct an overall network of hyperlinked online resources for a specific domain (COVID-19) and a subnetwork for a specific topic (COVID-19 vaccine). We identified the most popular resources and hosting sites, and categorized the resources based on specific keywords. We observed a radical change of the overall network for COVID-19 over a period of three weeks, but a more stable subnetwork for COVID-19 vaccine. To account for the dynamics of the networks over time, we are now developing measures on information “freshness” and incorporating them into online resource network analysis for timely dissemination of the latest clinical evidence.
Exploring the impact of perceived usability and cognitive workload on objective performance using supervised machine learning classifiers

Karthik Adapa, MBBS, MPH\textsuperscript{1}, Shiva Das, PhD\textsuperscript{1}, Prithima Mosaly, PhD\textsuperscript{2}, Fei Yu, PhD\textsuperscript{2}, Carlton Moore, MD\textsuperscript{1}, Lukasz Mazur, PhD\textsuperscript{1,2}

\textsuperscript{1}School of Medicine, \textsuperscript{2}School of Information and Library Science, UNC-Chapel Hill, North Carolina, USA

Introduction

In health informatics, suboptimal usability of electronic health records (EHRs) and cognitive workload (CWL) of healthcare professionals (HCPs) are known to independently impact performance (e.g., increased likelihood of medical errors)\textsuperscript{(1)}. However, limited studies have examined the combined effect of perceived usability and CWL on the objective performance of HCPs\textsuperscript{(2)}. In radiation oncology, most medical centers typically develop and implement Quality Assurance (QA) checklists to reduce errors but often do not evaluate the impact of usability and workload on HCP’s performance\textsuperscript{(3)}. Therefore, we explore the combined impact of perceived usability and CWL of a quality assurance (QA) checklist on dosimetrists’ performance during the radiation therapy planning process for cancer patients.

Methods

Dosimetrists performed QA tasks on 73 different types of radiation therapy plans with varying degrees of difficulty (low (35), medium (35), and high (6) based on subjective rating by physicists). The perceived usability of the QA checklist was assessed using the System Usability Scale (SUS) and Post-study System Usability Questionnaire (PSSUQ). The perceived CWL was assessed using National Aeronautical Space Agency Task Load Index (NASA-TLX) and Workload Profile (WP). Performance was measured objectively as the time taken to complete QA tasks (with two classes: low-22 and high-51 based on the average time taken to complete the checklist). To correct the class imbalance, we used the synthetic minority oversampling technique and randomly sampled the minority to achieve the same size of majority class (low-51 and high-51). The usability (SUS & PSSUQ) and workload (NASA-TLX & WP) measures were treated as independent variables and employed individually and in combination to create models aimed at predicting the two classes of objective performance. Five different supervised machine learning algorithms that work best for binary classifications were adopted to predict performance a) Naive Bayes(nb) b) k-Nearest Neighbors(knn) (k=5) c) Logistic Regression (lr) d) Support Vector Machine (svm) e) Random Forest (rf). We used 10-fold stratified cross-validation (CV) strategy and kept the same training and test sets across the classification techniques and the different combinations of independent features to ensure a fair comparison of the different trained models using the same data of training and test sets.

Results

Most of the combined variable models (highlighted in blue; see Table 1) achieved higher average accuracy than the single variable models. Except for knn, among single variable models, SUS or WP were worse in predicting objective performance across the other four classifiers. However, the addition of NASA-TLX and PSSUQ respectively significantly enhanced the prediction of objective performance.

Conclusion

Preliminary findings from this on-going study suggest that centers implementing QA checklists may employ usability and CWL jointly to predict performance. Future research will build on these findings by expanding the sample size, utilizing multiple validation strategies, testing for statistical significance, among others.

Introduction

Physiological signals represent a major source of information in intensive care units (ICUs). Previous studies have addressed data quality issues for vital signs routinely entered in EHRs by healthcare practitioners. However, those studies have not assessed data quality for large-scale capture of higher frequency physiologic signals that is now possible within ICU settings. In this study, we explore the data quality issues, specifically completeness, accuracy and timeliness, of higher frequency (minute-by-minute) time-series vital signs data captured in ICU settings.

Methods

We used Medical Information Mart for Intensive Care (MIMIC-III) database¹. We measured the completeness, accuracy, and timeliness of four time-series (minute-by-minute) vital signs data streams: heart rate (HR), respiratory rate (RR), blood oxygen saturation (SpO2), and arterial blood pressure (ABP), in MIMIC-III. Completeness of time series vital signs data was measured: (1) by the presence of a non-NULL record for a given physiologic variable (HR, RR, SpO2, ABP) corresponding to an ICU stay for a patient, and (2) by the proportion of non-missing data for each physiologic variable in a given ICU stay for a patient. If an entire record corresponding to a physiologic variable was non-existent or NULL, then the corresponding physiologic variable for that ICU stay for the patient was flagged as incomplete. Accuracy of the vital signs was measured by a series of rules examining the physiological limits of the vital signs. Timeliness of the vital signs was assessed as the overlap of the minute-by-minute records with the ICU stay.

Results

Of the 22,247 time series vital sign records in the MIMIC-III Waveform Database Matched Subset¹, 21,326 records were: (a) mappable to and representative of distinct ICU stays; and, (b) associated with patients aged 16 or older. The 21,326 vital signs records corresponded to 16,009 distinct ICU stays and 9,410 unique patients. We applied certain filtering steps associated with timeliness, completeness, and accuracy of vital signs with a minimum duration of one minute being collected during the ICU stays. When these filtering steps were applied, the minimum one-minute HR, RR, and SpO2 records were found for most patients (>98%), but only 7,496 (49.6%) of patient-ICU stays had ABP records available. We observed a ~28% drop in the number of HR, RR, and SpO2 records per ICU stay after applying the timeliness constraint (i.e., having at least one minute overlap with the vital sign’s associated ICU stay). This percentage for ABP time series records was ~13%. We finally explored the proportion of ICU stays (0 to 1) against the percentage of ICU length of stays (0% to 100%) that were covered by acceptable vital signs data (i.e., complete, accurate, and timely) in the study population (Figure 1). The proportion of patient-ICU stays that had 100% of their length covered by an acceptable vital sign data were 9.2% for HR, 8.8% for RR, 7.9% for SpO2, and 3.9% for ABP (represented by the lowest point of each vital sign line in Figure 1).

Detecting Major Depressive Disorder from Clinical Notes using Neural Language Models with Distant Supervision

Bhavani Singh Agnikula Kshatriya, MS1, Nicolas A Nunez, MD3, Manuel Gardea-Resendez, MD3, Euijung Ryu, PhD2, Brandon J Coombes, PhD2, Sunyang Fu, MPH1, Mark A Frye, MD3, Joanna M Biernacka, PhD2, Yanshan Wang, PhD1,4
1Department of Artificial Intelligence & Informatics, Mayo Clinic, Rochester, MN; 2Department of Quantitative Health Sciences, Mayo Clinic, Rochester, MN; 3Department of Psychiatry & Psychology, Mayo Clinic, Rochester, MN; 4Department of Health Information Management, University of Pittsburgh, Pittsburgh, PA

Introduction: Major depressive disorder (MDD) is a prevalent psychiatric disorder and is associated with significant healthcare burden worldwide1. Although structured Electronic Health Records (EHRs), such as ICD-9 or ICD-10 codes, have been used to represent MDD phenotypes2, lots of MDD phenotypic information is documented in free-text EHRs, such as clinical notes. Using natural language processing (NLP) techniques to detect MDD phenotypes from clinical notes are vital to phenotype patients with MDD. In the literature, only a few studies utilized clinical notes for phenotyping MDD, and, to the best of our knowledge, no studies deployed deep learning based neural language models for detecting MDD from clinical notes. In this study, we applied the state-of-the-art neural language models, namely BERT and Bio-Clinical BERT within a distant supervision framework to identify MDD using clinical notes and compared with conventional machine learning models.

Method: In this study, we used the Mayo Clinic Biobank cohort to build a corpus of clinical note documents. We first used MDD-related ICD codes to identify cases and controls from the biobank cohort. We randomly selected 500 cases and 500 controls, and retrieved clinical notes from the Mayo Clinic Data Warehouse. This resulted in 168,139 clinical note documents. The goal is sentence-level identification of MDD instances, i.e., Positive (e.g., “Patient has history of dysthymia”), Possible (e.g., “Patient is a depression suspect”), Negative (e.g., “There is no evidence of depression”), or unknown MDD instances, for each sentence in each clinical note document. We randomly selected 500 documents as a gold standard testing dataset and asked two psychiatrists to manually annotate MDD at the sentence level. For the remaining 167,639 clinical note documents, we developed a rule-based NLP algorithm to generate weak labels. This weakly labeled data was used as training data to train neural language models and machine learning models. Since the dataset was highly imbalanced with 98% unknown and 2% (i.e., 53,569) MDD related instances out of total 3,081,359 sentences, we performed under-sampling to balance the data and created a final training dataset of 107,138 sentences. We have used pretrained BERT base model and Bio-Clinical BERT with an additional dropout along with a classifier layer with output dimension of four. Cross entropy loss function was used with the Adam optimizer. For the conventional machine learning models, we tested Random Forest (with n=100 estimators), K-NN (with K=7), SVM (with linear kernel) classifiers with word embeddings as the input features. We used Precision, Recall and F1 score metrics to evaluate the models.

Results: Bio-Clinical BERT has achieved the best performance for all defined MDD classes with F1 scores of 0.99 for unknown, 0.95 for positive MDD, 0.87 for possible MDD, and 0.91 for negated MDD. BERT is inferior to Bio-Clinical BERT but still performed better than machine learning models.

Conclusion: The results indicate that Bio-clinical BERT with domain specific clinical contextual representations performs better for clinical NLP tasks. Since the models were evaluated on manually annotated gold standard, it shows that the distant supervision is an effective technique to be combined with neural language models for detecting MDD from clinical notes which consequently can reduce a lot of efforts and time for manual annotation.

Building a Self-Service Analytics Ecosystem for Program Data Sharing and Dashboards (NIH ‘All of Us’ Precision Medicine Initiative)

Authors: Toufeeq Ahmed PhD¹, Robert Abram BS¹, Bhinnata Piya MPH¹, Keri Wolfe MS¹, Dylan Klomparens MS², and Paul Harris PhD¹.  
1 Vanderbilt University Medical Center, Nashville, TN  
2 National Institutes of Health, Rockville, MD

Summary: The All of Us Research Program (AoURP) has embarked on a historic mission to build a comprehensive dataset that includes health information shared by a diverse cohort of at least one million participants across the United States. In addition to making data available for approved researchers to advance precision medicine, the AoURP will also make research results accessible to participants. With the growing need to understand program operations and related monitor key performance indicators (KPIs) for strategic decision-making, the Vanderbilt University Medical Center (VUMC) Data and Research Center (DRC) has worked with the NIH and other AOURP program partners to create a self service analytic dashboard ecosystem and business intelligence platform for review of program operations data using Tableau server on the frontend and with Apache NiFi and PostgreSQL in the backend. This scalable, access and privacy enabled design is created to facilitate our platform as a “Bring Your Own Data (BYOD)” model, enabling our technology partners to bring in operational data using open source ETL tool Apache NiFi into dedicated PostgreSQL (open-source) datamarts to ingest, transform, and create custom analytics dashboards using Tableau server.

The DRC Analytics Ecosystem includes dashboards to display program analytics support program awareness and decision making, operational analytics to support business operations, and partner operations dashboards which are created by AoU consortium partners to support their business operation. Tableau Server and Google BigQuery were selected for their best-in-class offering for BI/data visualization and cloud-based data storage, respectively.

This poster presentation will illustrate 1) a model that research institutions can adopt to build a robust and collaborative analytics ecosystem, 2) the strengths of free, open-source systems such as Apache NiFi and PostgreSQL, and 3) the challenges associated with implementing an analytics platform in a FISMA-moderate cloud infrastructure.

Conclusion: Open source tools, such as Apache NiFi and PostgreSQL, can play a key role in enabling research institutions of all sizes to adopt a data sharing model that is scalable, robust, and collaborative.
Machine Learning for Predicting Hospital Acquired Pressure Injuries in ICU Patients: From Explainable AI to Ensemble Super Learners

Jenny Alderden¹ Ph.D. APRN; Andy Wilson¹² Ph.D. MSTAT; Sergey Krikov¹ MS; Ryan Butcher¹ MBA; Jonathan Dimas¹ Ph.D. RN; Tracey Yap³ Ph.D. RN FGSA FAAN
University of Utah¹ Salt Lake City UT; Parexel² Durham NC; Duke University³ Durham, NC

Background: Hospital-acquired pressure injuries (HAPrIs) occur on the skin caused by pressure in 6-10% of ICU patients, and annual costs for treatment exceed $65 billion annually. Preventing HAPrI requires accurate risk assessment to enable nurses to allocate preventive resources. Currently available tools such as the Braden Scale tend to classify nearly all ICU patients as ‘high risk’ and therefore have limited clinical utility in the ICU. Advances in machine learning (ML) present an opportunity to modernize and improve HAPrI risk assessment using Electronic Health Record (EHR) data. Yet, it is not possible to know a priori which ML algorithm will perform best. Because there is no single best-practice technique, we used a super learner approach to stack multiple ML models into a composite model with enhanced predictive accuracy. Explainable AI was also leveraged to understand how specific features in the model influenced the predicted outcome.

Methods: For 5,101 University of Utah surgical and cardiovascular ICUs patients, including 399 (7.8%) with HAPrI, we applied machine learning best practices, including addressing informative missingness in data, class imbalance, and leveraging multiple models with ensemble (super learner) models. Inclusion criteria were age ≥18 and admission date between 2014-2018. All analyses were performed in open source software (R v 4.0.3 via H2o v 3.32.0.1 packages). The code will be made available via a dedicated open science framework (OSF) page for reproducibility and transparency.

Results: Ensemble (super learner) models outperformed all individual models (AUC 0.862 for the best base learner [xgb] vs. 0.878 for ensemble) on a 20% held-out test set. All models modestly improved after minority oversampling. Partial dependence plots produced for each variable indicate differences in individual models’ use of predictor variables (Fig 1).

Conclusions: Ensemble ML methods such as super learners are a useful tool for predicting HAPrIs, particularly when compared to current tools, which tend to identify all patients as ‘high risk.’ The next steps include external validation and subsequent implementation with associated clinical decision support.
Colonizing Microbiome as a Determinant of COVID-19 Outcome: A Pilot Study

Alexander V. Alekseyenko, PhD, FAMIA, Bashir Hamidi, MPH, Stephane Meystre, MD, PhD, FACMI, FIAHSI, FAMIA
Medical University of South Carolina, Charleston, SC, USA

COVID-19 is characterized by immune modulation following exposure to the SARS-CoV-2 virus. This condition in the worst cases results in polymicrobial infectious complications involving bacteria and possibly fungi. Surprisingly, not all patients follow the same course, and many have little symptoms and/or no complications. We hypothesize that the colonizing microbiome is linked to the clinical status of the COVID-19 patients and may provide early leads for stratification of cases into risk categories. The rationale for this hypothesis comes from the following facts: (i) colonizing opportunistic pathogens may turn infectious following immunosuppression; (ii) diversity of the colonizing microbiome has been shown to correlate with disease severity in many conditions; (iii) microbiome diversity can be viewed as a robust proxy of the host immunological state, with loss of diversity indicating a severe infectious state and proneness to medical complications. The conceptual model for the premise of this study is shown in Figure 1.

At MUSC Program for Human Microbiome Research (PHMR), we are in a strong position to evaluate our hypothesis. First, we have established IRB- and IBC-approved protocols for access to surplus COVID-19 testing materials using the Living uBiome Bank (1). Currently, we have biobanked 1,160 positive and negative specimens from these materials and we anticipate prospective access to over 400 additional specimens per day. Second, we have demonstrated that useful microbiome information is available in similar surplus specimens. We have previously obtained preliminary data on the composition of bacteria co-colonizing with methicillin resistant Staphylococcus aureus and vancomycin resistant Enterococci. These data have been obtained from surplus infection surveillance swabs, similar to those used for COVID-19 testing. Finally, our current MUSC IRB grants us access to medical records to allow for precise interpretation the microbiome compositions, which is a major plus compared to many existing microbiome research studies, where availability of such detailed clinical information is often a major limitation. Access to detailed clinical information is further enhanced by the recently developed COVID-19 clinical data mart under the direction of the Translational Biomedical Informatics Center (TBIC).

Beyond immediate clinical significance of our project, organization of the relevant clinical data using the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) standard will allow for future linkage into national and international research efforts. This project will generate new data on composition of commensal microbiota and how it relates to susceptibility to SARS-CoV-2 infection and complications in COVID-19 disease course; little to nothing is currently known about this. Integration of the EHR clinical data with high-throughput molecular data (like the microbiome) is an urgently needed and actively developing area of quantitative methodological research. Use of the OMOP CDM with clinical data as well as microbiome molecular data is innovative and would contribute to preliminary data on a novel application of the G-CDM extension for genomic information.

Evaluating the Utility of a Prototype Clinical Decision Support Tool for Chronic Pain Treatment Choices in Primary Care

Katie S. Allen, BS1,2, Elizabeth C. Danielson, PhD3, Sarah M. Downs, MPH1, Olena Mazurenko, MD, PhD1, Julie Diiulio, MS4, Burke W. Mamlín, MD1,5, Christopher A. Harle, PhD6

1Fairbanks School of Public Health, Indiana University, Indianapolis, IN; 2Regenstrief Institute, Inc., Indianapolis, IN; 3Northwestern University, Evanston, IL; 4Applied Decision Science, LLC, Cincinnati, OH; 5Indiana University School of Medicine, Indianapolis, IN; 6University of Florida, Gainesville, FL

Introduction

Patients suffering from chronic conditions often require clinicians to complete complex tasks related to identifying and choosing the most promising treatments1,2. To address the management of chronic pain, we designed a prototype decision support tool called the Chronic Pain Treatment Tracker (Tx Tracker)3. The Tx Tracker is intended to be a point-of-care tool that summarizes an individual patient’s treatment history and new treatment options based on history, trends in health outcomes, and treatment-related risks. The objectives of this study were to (1) evaluate the perceived utility of Tx Tracker for meeting clinicians’ needs; (2) evaluate the perceived utility of Tx Tracker for identifying pain treatment options; and (3) identify clinician preferences for layout and visual design of the Tx Tracker.

Methods

We conducted a qualitative system design and evaluation study with twelve primary care physicians from two health systems in the state of Indiana between February and May 2019. The twelve interviews consisted of background questions, prototype exploration, a use case scenario, and evaluation questions. Two researchers (ED, SD) jointly reviewed their interview notes and created a single, detailed composite note for each section of the user testing interview for each participant. The same two researchers then created a codebook, and then qualitatively coded the text of each note using the codebook. After coding, two researchers (CH, KA) used a process of upward abstraction, to identify emergent themes within and across the coded data that related to each research objective.

Key Findings

The primary theme was clinicians’ preference to use the Tx Tracker for the right patient at the right time point of time in workflow. Clinicians expressed a preference for access to comprehensive patient history at the point of care. Currently, much of this needed history information is found in clinical notes, which limits searchability and is often spread across time, discipline, and locations. While many clinicians indicated the Tx Tracker could help overcome these limitations, some expressed skepticism about having enough time to utilize Tx Tracker. In terms of interface design and layout, one theme was the value of presenting contextual information that links past treatments to other relevant clinical information, such as diagnoses, goals, and patient preferences. Similarly, our analysis indicated the potential value of visually co-locating information on historical treatments with treatment options and supporting interactivity allowing users to. Finally, clinicians expressed a general preference for visual cues, such as color and prominent screen placement of needed information.

Conclusion

The widespread use of EHRs and proliferation of electronic patient information necessitates research on how to best communicate with users at the point of care, especially for patients with complex chronic conditions. Decision support tools, such as the Tx Tracker, may reduce cognitive burden and increase use of lower risk and more effective treatment options. In this study, we found support for tools like the Tx Tracker to meet clinicians’ information needs, aid identification of treatment options, and improve patient-centered care.

Extracting Social Variables from Clinical Documentation to Better Facilitate Response to Patient Need

Katie S. Allen, BS\textsuperscript{1,2}; Dan Hood, MPH\textsuperscript{1}; Jonathan Cummins, BS\textsuperscript{1}; Suranga Kasthuriratne\textsuperscript{1,3}, PhD; Peter J. Embi, MD, MS\textsuperscript{1,3}; Joshua R. Vest, PhD, MPH\textsuperscript{1,2}

\textsuperscript{1}Regenstrief Institute, Inc., Indianapolis, IN; \textsuperscript{2}Richard M. Fairbanks School of Public Health, Indianapolis, IN; \textsuperscript{3}Indiana University School of Medicine, Indianapolis, IN

Introduction

The Covid-19 pandemic has underscored the differential impact of social needs on the health outcomes, specifically across racial groups.(1) Much of the analysis examining these disparities utilize race as the variable of interest, however, race as a social construct, does not embody the underlying root causes of many health disparities, including the social disparities created by systematic racism(1). To facilitate closing the gaps on health disparities, we need to consider the underlying social needs driving them. The goal of this project is to develop methodologies for identifying and extracting social needs from clinical documentation.

Methods

Data and Tools. This study leverages the clinical repository of notes from the Indiana Network for Patient Care, which includes approximately 80 hospitals within the State. To develop the algorithms, the team utilized a systematic, iterative process with keyword identification and state machine development. A training set was identified by selecting twelve months of clinical notes from one health system and a testing set was created utilizing six months of clinical notes from a second health system. To create the natural language processing state machines necessary to identify the presence of a social need, the team leveraged Regenstrief Institute’s nDepth\textsuperscript{™} platform.

Keyword Identification. Utilizing one month of the notes, nDepth\textsuperscript{™} produced a list of continuous sequence words (n-grams) for review. This list was filtered utilizing Term Frequency-Inverse Document Frequency measurements, to identify and remove words not contributing value. Each set of n-grams was reviewed to determine whether it connects the topics of interest. Additional keywords were gathered from validated and literature.

State Machine Development. nDepth\textsuperscript{™} indexes and searches the collection of clinical notes based upon the dictionary created by the selected keywords. State machines were created for each of the social needs and were deployed on the training set. An initial manual review of 200 randomly selected notes was completed. Performance was measured by examining positive and negative predictive value (PPV, NPV). Adjustments were considered and, with the state machine dictionaries then updated, another round of reviews completed. The final iteration was against the test set of notes. For each of the top ten note types, a random sample of 50% of machine positives and an equal number of machine negatives were manually reviewed (KA, DH).

Results

For housing instability, the final dictionary contains 54 keywords and includes rules for negation of certain keywords as well as rules for dictionary terms within a certain word count of other keywords (e.g., sleep within 5 words of car). Two iterations were needed to arrive at the final state machine (See Table 1.) For financial insecurity, the final dictionary contains 51 keywords and includes a grammatical rule denoting when a patient is able “to afford” vs. unable “to afford.” Two iterations against the training set were undertaken (See Table 1.)

Table 1. PPV and NPV results for each state machine iteration

Conclusion

This project demonstrates the feasibility of utilizing natural language processing to identify and extract social needs from clinical text. This is a critical first step in advancing efforts to address the underlying social needs of patients and to address the health disparities created by systematic racism within our existing healthcare practices and tools.

Policy Alienation as a Source of HITECH Act-Related Burnout
Joseline Amado,1 Yousef Latif,2 Mustafa I. Hussain, PhD3
School of Public Health, University of California Irvine (UCI); 2School of Business, UCI; 3DMICE, OHSU, Portland

Introduction
Burnout has been recognized as a crisis in US medicine associated with the introduction of electronic health records (EHRs), mandated by the HITECH Act. The EHR has been recognized as a tool which facilitates the limitation of physician autonomy,[1] and in this work we offer policy alienation,[2] previously used in the Netherlands to understand the effects of neoliberal policy reforms on public professionals, as a framework for guiding research on recent US healthcare reform. Here we report early results from a review.

Background
Burnout tends to emerge when one sees a large number of patients while working under political regimens that associated each client or patient with a number of repetitive tasks.[2] Burnout can lead to an increase in resignations and sick leave in addition to creating communication barriers to effective care.[2] See Figure 1 for an overview.

Figure 1. Conceptual overview of policy alienation.[2]

Methods
A structured keyboard search was conducted on several electronic databases, including Cochrane, CINAHL, PubMed Central, and PubMed. Studies on physician burnout in hospitals from 2015–2019, the period following the HITECH incentive sunset, were considered. We identified 37 studies for inclusion in this iteration of the review.

Preliminary Results
The disconnect in policy awareness among physicians stems from their psychological disengagement from the health policy program. There is widespread resentment about the present structure of the EHR and use of CDS that pressures physicians to meet new policies and accreditation guidelines. The pressure to perform the tasks of documentation and care limits physicians’ creative range and discretion with patients, resulting in burnout which may contribute to systemic dysfunction.

Conclusion
EHRs are promising for enhancing care coordination, error reduction, and care quality enhancement. However, these tools in the context of a litigious and metric-driven policy environment has led to consequences such as increased clinical burden, policy alienation, and physician burnout, in the Netherlands and in the United States. Perhaps it is time for technologically-facilitated innovation in the social mechanisms of healthcare governance.

Understanding the use of pharmacological knowledge bases in clinical care

Shilo Anders, PhD¹, Laurie L. Novak, PhD, MHSA¹, Nawshin Kutub, PhD², Carrie Reale, MSN, RN-BC¹, Daniel France, PhD, MPH¹, Christopher L. Simpson, MA¹, Courtney Van Houten, MA², Karlis Draulis², Rubina Rizvi, MD, PhD², Tiffani J. Bright PhD², Gretchen P. Jackson, MD, PhD², Anita M. Preininger, PhD²

¹Vanderbilt University Medical Center, Nashville, TN USA; ²IBM Watson Health, Cambridge, MA, USA

Background: Pharmacological knowledge bases (PKB) provide current medication-related information that clinical staff use on a regular basis. They cover a wide variety of drug interactions¹ and are often used to answer pharmaceutical or pharmacological questions including adverse drug reactions, intravenous (IV) compatibility, and other drug-related topics.² Little research has been done on such tools and factors that contribute to clinical use.

Objective: The objectives of this study were to identify medication-related information needs of pharmacological knowledge base users and to examine roles and modes of access of the users, to inform system improvements and feature design. We first conducted a survey of informational needs and usefulness in users’ everyday clinical work. We then interviewed users from the survey to identify specific informational needs sought by users, to gain in-depth insights about how medication-related knowledge bases help them in their day-to-day work.

Methods: Clinical staff that used a pharmacological knowledge base were asked to participate in an electronic survey about information needs and use cases. Subsequently, selected survey respondents were interviewed about their system use, including a walkthrough of their typical practices. Across user types, practice areas, and years of experience, we compared the types and frequencies of information sought, modes of use, and overall experience.

Results: 155 medical personnel completed surveys including nurses (31%), residents (24.5%), fellows (19.4%), pharmacists (8.4%), nurse practitioners (7.1%), attending physicians (4.5%) and others (5.2%). In surveys, users cited accessibility as the most important feature driving use, followed by reliability and general ease of use. We found statistically significant differences (Pearson Chi-square: 20.777, P = 0.008) across user roles and frequency of use of Micromedex; nurses and pharmacists used Micromedex daily or several times per week; nurse practitioners and residents, several times per month; and fellows, less than once per month. There were no significant differences in ratings of Micromedex by role, years in role, or practice area. Figure 1 shows the results what tasks each role used Micromedex for from both the surveys and interviews (N=13). Most interviewees use Micromedex on a larger form factor and resort to smaller tablets and smartphones when moving around, such as during rounds.

Conclusion: Pharmacological knowledge bases are commonly used tools to help hospital staff in medication management. Nurses and pharmacists are the most frequent users of such resources; physicians and nurse practitioners use them much less frequently. Areas of IV compatibility and drug/dosing information are the most common information types sought using a pharmacological knowledgebase to ensure and maintain patient safety. Information needs associated with various user roles and contexts of use can be used to inform future developments and product design that best aligns with user needs and workflow processes.

COVID-19 Trial eSource Data Capture Efficiencies using OneSource

Adam Asare, PhD1,2, Alejandra Jauregui1, Andrew Robinson1, Mitra Rocca, PhD3, Cal Collins4, Heidi Collins, MS1, Laura Esserman, MD, MBA1 and Kathleen Liu, MD1

1University of California, San Francisco, CA, 2Quantum Leap Healthcare Collaborative, San Francisco, CA, 3U.S. Food & Drug Administration, Silver Spring, MD, 4OpenClinica, Waltham, MA

Introduction:
Standardized and efficient approaches to data capture are critical elements in clinical drug development. However, the abstraction of electronic health record data and entry into case report forms represents a major barrier for timely data capture, particularly where toxicities and safety must be monitored in near real time. This is especially relevant during a public health crisis such as COVID-19, where there is an urgent need to efficiently enroll a diverse population of subjects for rapid identification of safe and effective treatments. We leveraged the OneSource platform in the I-SPY COVID platform trial, in which integrations with local Electronic Health Record systems (EHRs) support automated capture of structured source data across multiple clinical centers.

Methods:
The OpenClinica (Waltham, MA) Electronic Data Capture (EDC) system was configured to support randomized subjects for 4 concurrent investigational agents and a control arm (remdesivir). A daily data entry electronic case report form (eCRF) of critical clinical data elements was defined that included the World Health Organization (WHO) Clinical Progression Scale and key Acute Respiratory Distress Syndrome (ARDS) clinical questions. A SMART on FHIR App was developed to launch within the EPIC Electronic Health Record (EHR) with support for source data capture of laboratory, concomitant medications, and demographic data using FHIR APIs. The solution allows research coordinators and investigators a one-click launch of the participant’s record in the EDC directly from the patient chart in the EHR, with single sign on and linkage between the records, eliminating need to separately log in to research applications. From the interface they can populate eCRFs with structured EHR data via FHIR by pushing a button, and allows review and/or manually enter data into eCRFs for which structured EHR data is not available.

Results:
The trial launched 30 July 2020, and as of 27 July 2021, 1,461 subjects had enrolled, with 742 randomized subjects receiving investigational agents. There were a further 719 subjects followed in the observational or RWD cohort. One of the I-SPY COVID sites with the highest I-SPY COVID accrual rates showed a 22% data entry error rate for D Dimer 3 and 4.5% error rate for lymphocyte count due to incorrect reference range entry for a subset of participants. This site is accelerating OneSource production implementation for August 2021. At UCSF, manual laboratory daily data entry for 5 subjects on average took 60 minutes, post OneSource implementation showed the same laboratory result data entered within 5 minutes through the EHR integration.

Table 1: Manual data entry errors for laboratory results for one of the I-SPY COVID sites over an 8-month period prior to OneSource implementation. OneSource capture prevents such errors. Figure 1: Efficiencies in laboratory result data capture by manual entry into the trial EDC vs OneSource EHR integration for 5 participants

Discussion:
Conducting clinical trials during a pandemic with limited research support staff requires streamlined approaches to data capture to rapidly assess drug efficacy and toxicities. This automated and EHR-integrated approach removes potential barriers and encourages adoption of the trial at hospitals with limited research infrastructure or where clinical research is not routinely performed.
Impact of Coronavirus-2019 on Pediatric and Adult Heart Transplantation Waitlist Activity and Mortality in the United States: A Descriptive Approach

Awais Ashfaq MD1, Geoffrey M. Gray PhD2, Jennifer Carapelluci3, Ernest K. Amankwah PhD4, Luis M. Ahumada PhD2, Mohamed Rehman MD2,5, Michael Puchalski MD6, Andrew Smith MD7, James A. Quintessenza MD1, Alfred Asante-Korang MD3

1Cardiovascular Surgery, Heart Institute, Johns Hopkins All Children’s Hospital, St. Petersburg, FL; 2Center for Pediatric Data Science and Analytic Methodology, Johns Hopkins All Children’s Hospital, St. Petersburg, FL; 3Heart Transplantation, Cardiomyopathy and Heart Failure, Heart Institute, Johns Hopkins All Children’s Hospital, St. Petersburg, FL; 4Epidemiology and Biostatistics, Johns Hopkins All Children’s Hospital, St. Petersburg, FL; 5Department of Anesthesia and Pain Medicine, Johns Hopkins All Children’s Hospital, St. Petersburg, FL; 6Division of Cardiology, Heart Institute, Johns Hopkins All Children’s Hospital, St. Petersburg, FL; 7Division of Cardiac Critical Care, Heart Institute, Johns Hopkins All Children’s Hospital, St. Petersburg, FL.

Abstract
This work provides a descriptive approach to characterizing the effects of the COVID-19 pandemic on the heart transplant community, with attention given to pediatric transplants. Transplants are found to increase in the adult community, while remaining consistent in the pediatric community. Mortality remains similar in pediatrics, while decreasing in adults.

Introduction
Transplant centers saw a substantial reduction in deceased donor solid organ transplantation since the beginning of the coronavirus 2019 (COVID-19) pandemic in the United States.1 There is limited data on the impact of COVID-19 on pediatric heart transplant volume and variation in transplant practices. We hypothesized that pediatric heart transplant activity decreased during COVID-19 with associated increased waitlist mortality.

Methods
The United Network for Organ Sharing (UNOS) database was used to identify patients at the time of listing for heart transplant from 2017–2020.2 Patients were categorized as pediatric (<18 years) or adult (>18 years) and as pre-COVID (2017-2019) or post-COVID (2020). Regional and statewide data were taken from United States Census Bureau. CovidActNow project was used to obtain COVID-19 mortality rates.

Results
The average number of pediatric transplants (n=39 per month) did not change significantly during 2020 (data not shown). However, there was a decline in the first quarter of 2020 followed by an increase. Absolute pediatric waitlist mortality decreased from 5.31 to 4.73. In adults, there was an increase in the number of transplants from 242 to 266. Adult waitlist mortality had a larger decrease from 18.44 to 15.70, with an increase in female mortality of 7%. Regional and demographics differences in mortality were observed and will be discussed further.

Conclusion
Pediatric heart transplant volume declined in early 2020 followed by a later increase, while adult transplant volume increased all year round. Although, overall pediatric waitlist mortality decreased, female waitlist mortality increased for both adults and pediatrics. Regional differences in waitlist mortality were observed for both pediatrics and adults. Future studies are needed to understand this initial correlation and to determine the impact of COVID-19 on heart transplant recipients.

Ensuring Covid patient end-of-life goals documented in an eMolst are honored through a novel and scalable health information exchange

Jonathan Austrian MD 1,2, Alex Low1, Victoria Javier RN1, Christine Wilkins PhD, LCSW2
1Department of Medicine, NYU Langone Health, New York, New York
2Medical Center Information Technology, NYU Langone Health, New York, New York

Introduction
Clinicians used Medical Orders for Life Sustaining Therapy (MOLST) as a means of for documenting healthcare preferences for individuals with serious illness and advanced frailty. The eMOLST is a digital version that is created and incorporated into the New York State eMolst registry. Health care systems in New York City worked to rapidly incorporate eMOLST to support advance care planning during the Covid crisis. Despite its importance, significant barriers to incorporating the eMOLST into patient care workflows have limited its potential. In order to determine if patients had eMOLSTs generated outside the health system, the clinician had to proactively search a separate eMOLST registry based on patient demographics. The objective of our work was to enhance the visibility of eMOLST status from within the electronic health record (EHR) regardless of where the eMolst was generated and streamline the review of those eMOLSTs.

Methods
In response the Covid-19 pandemic, our health system partnered with the state eMOLST registry, the health information exchange (HIE) (Healthix), and our EHR vendor (Epic Systems). We leveraged the HIE’s existing patient matching service. To ensure the availability of eMOLST status in real time, the HIE updated its clinical event notifications service to include the eMOLST number, if it exists, for all new or existing patients at our institution. Finally, we devised a new workflow within the EHR to promote awareness of a patient’s eMOLST status and ensure the content was readily available to clinicians. (Fig 1).

Fig. 1 Emolst Clinical Workflow

Conclusions
We successfully implemented this technical workflow on May 4, 2021. As a result of this partnership, our academic health system identified an additional 1,557 patients with eMOLSTs generated by other institutions, representing 11.5% more patients with eMOLSTs than previously known.

The Covid pandemic highlighted the importance of assessing goals of care and ensuring patients’ preferences were available at the point of care. Governmental registries can help overcome patient data siloes by centralizing the storage of this important information. We describe a clinical and technical workflow that enables care team members to visualize a patient’s eMOLST status directly in their clinical workflow using common vendors and processes that are readily scalable to other institutions.
A Machine Learning Approach to Identify EHR-based Cohorts of Pain Sensitivity for Genetic Analysis

Amelia J Averitt, MPH MA PhD1, Nilanjana Banerjee, PhD1, Michael N. Cantor, MD MA1
1Regeneron Genetics Center, Clinical Informatics, Tarrytown, NY, USA

INTRODUCTION. Among the many barriers to effective pain management is the variability in how patients respond to noxious stimuli, or response heterogeneity. The extent of these inter-individual differences is known as pain sensitivity. Patients that demonstrate an increased response to stimuli have high pain sensitivity (HPS); and patients that demonstrate a decreased response to stimuli have low pain sensitivity (LPS). Such classifications of the observable characteristics of pain sensitivity are phenotypes. Research demonstrates that an individual’s phenotype for pain sensitivity is attributable to a complex interaction of environmental factors and genetic variants. As such, genetic analyses that identify causal variants are a crucial tool for our understanding of pain sensitivity.

METHODS. This research presents a new machine learning approach to identify cohorts of high and low pain sensitivity from the electronic health record (EHR) to support a genetic analysis of causal variants. Our approach leverages each patients’ unique pain score responses within a single clinical encounter. For each patient, a density distribution is created from their pain score responses. We hypothesize that this distribution characterizes a patients’ pain sensitivity. A K-means algorithm is applied to partition the densities into clusters. Cluster centroids are defined by the mean, normalized density of cluster members. During the learning procedure, patients are re-assigned to nearest clusters, with this distance quantified with the Kullback-Leibler (KL) Divergence. Because the KL divergence is not symmetric, our clustering algorithm uses a distance \(D_{KL}(P,Q) = 0.5KL(P||Q) + 0.5KL(Q||P)\). We applied our model to real-world clinical data from the Geisinger Health System (GHS) EHR, subset to patients with whole exome sequencing (N=145k). To resist confounding by indication, we selected patients that underwent a total hip arthroplasty (N=1,904) or a total knee arthroplasty (N=3,696) with at least 1 pain score (NEMSIS) after the surgery end-time but within the same surgical encounter. We learned three clusters and kept those with the highest (HPS) and lowest median density (LPS). Cluster densities were evaluated by the Silhouette coefficient and a simulation and permutation t-test to determine significance of differences in densities skewness. To better understand the discriminative features between the clusters, we fit an L2 regularized logistic regression using age, gender, race, ethnicity, and the 500 most common diagnosis codes. To examine the genetic underpinnings of pain sensitivity between the HPS and LPS cohorts, we performed a genome-wide association study (GWAS).

RESULTS. The LPS cluster included 3,460 (64.6%) patients, the HPS cluster included 780 (14.6%) patients (Figure 1). The Silhouette coefficient of the clusters is 0.336. The simulation permutation t-test demonstrates at skew of -0.375 in the HPS cluster and 0.670 in the LPS cluster (p<0.0001). The regression indicates HPS patients have increased odds for painful conditions, mental health disorders, and exposure to tobacco. There were no genome-wide significant hits (Table 1). However, the variants with the most significant associations implicate genes involved with pain sensitivity in neurons (FCGR2), abdominal pain (FARS2), spinal nerve ligation-induced neuropathic pain (MNX1), and chronic pain after surgery (SOX4).

DISCUSSION. The results indicate that our machine learning approach is able to identify clinically meaningful cohorts of pain sensitivity from the EHR. The GWAS suggests that cohorts likely also represent different genetic architectures. Such insights into the molecular basis of pain may facilitate the identification of new potential targets for drug discovery. However, this method is not compared with a gold standard, as there is neither a preferred methodology for this task nor an objective measure. Greater evaluations are planned for future work.

A Monte Carlo Estimation of the Narrow-Sense Heritability of COVID-19 Infection and Severity from AncestryDNA Survey Data

Amelia J. Averitt, MPH MA PhD1, Deepika Sharma, MHI1, Michael N. Cantor, MD MA1
1Regeneron Genetics Center, Clinical Informatics, Tarrytown, NY, USA

INTRODUCTION. Respiratory infectious diseases, like COVID-19, demonstrate a host genetic component that contributes to inter-individual differences.1 This contribution of the host’s genetics, in tandem with environmental factors, determines disease susceptibility and infection. Narrow-sense heritability ($h^2$) summarizes the average proportion of total phenotypic variance that is due to additive genetic factors, rather than the environment. Knowledge of the $h^2$ of COVID-19 may be helpful to guide public health intervention.

METHODS. This research presents a Monte Carlo (MC) estimation of the $h^2$ of COVID-19 infection and severity from AncestryDNA survey data. This data is from a private collaboration with AncestryDNA and Regeneron Pharmaceuticals and was collected online from volunteer respondents. The survey was given to AncestryDNA customers (N=210k) and aimed to assess each respondent’s COVID-19 infection status, exposure, risk factors, and symptoms. An MC method was applied to this data to stochastically estimate the parent’s phenotypic variance using parameters that are grounded in real-world epidemiologic data (Algorithm 1). Stochastic parameters include the rates of two-parent households ($\eta$); household co-infection ($\rho$)$^2$; and hospitalization among COVID-19 infected individuals ($\phi$)$^2$. $h^2$ was then estimated from the slope of a linear regression that models the simulated, mid-phenotypic value of the parents by the phenotypic value of the respondent (the proband). This research presents an application of the proposed methods to (i) simulated data, and (ii) the AncestryDNA survey data to estimate $h^2$ of COVID-19 infection ($h^2_{\text{inf}}$) and severity ($h^2_{\text{sev}}$).

Simulation. Proband and parent phenotypes were simulated such that the ‘true’ $h^2$ was hard-coded into the data. If 1 or 2 parents were infected, the data was then masked to only indicate if 1 or more was affected, which aligns with the uncertainty in the AncestryDNA data. The MC algorithm was applied to this masked, simulated data and an $h^2$ estimate was made. This experimental setup was repeated using varying ‘true’ $h^2$ values of 0.1, 0.3 and 0.5.

Application to AncestryDNA data. In the event that a survey respondent noted that “Parent(s)” were infected or hospitalized (a proxy for severity), this data was fed into the MC simulation to stochastically model the parent phenotype -- if 1 or 2 parents were infected ($p^1$) and hospitalized ($p^h$). Models for both phenotypes of interest, were adjusted for the age, gender, and ever-smoking status of the proband. Given the high variability in reported household co-infection, $\rho$, the MC simulation was repeated using three reported statistics to inform this parameter.$^3$\-5

RESULTS. When applied to simulated data, in which ground-truth $h^2$ is known, the method is able to recover $h^2$ with high accuracy (Table 1). The application to AncestryDNA survey data indicates that $h^2$ of COVID-19 infection susceptibility and ranges from 0.155 to 0.183 and severity ranges from 0.070 to 0.075 (Figure 1). These results suggest a moderate genetic contribution to COVID-19 infection susceptibility and a low genetic contribution for COVID-19 severity.

CONCLUSIONS. This research provides evidence that variability in COVID-19 infection is, in part, explained by inherited genetic factors. However, this approach does not account for recessive effects or gene-gene interaction and is reliant upon the estimated parameters. These results are limited by the heterogeneity of AncestryDNA. Further experimentation is necessary to understand the limitations and validity of this method.

---

Dashboard for Machine Learning Models in Health Care
Wejdan H. Bagais, BS, Janusz Wojtusiak, PhD
Department of Health Administration and Policy, George Mason University, Fairfax, VA

Introduction
Presentation of machine learning (ML) models and their results plays an important role in analysts’ and clinicians’ understanding of predictions and consequently trust in the models. Visualization methods are among the best ways to explain the model performance as noted by Tonekaboni et al. who emphasize that carefully designed visualizations increase the clinicians’ understanding. While a considerable amount of literature has been published on explaining the performance of ML models, most studies focus on one measure or a specific ML method. This work summarizes the most important factors for evaluating any classification supervised ML model in one place using a dashboard.

Methods
Figure 1 shows a high-level design of the dashboard that is split into three main sections: statistical measures, features importance, and sensitivity analysis.

Statistical measures: This section visualizes model training and testing performance: AUC, accuracy, recall, precision, and f-score using a heatmap followed by the ROC curve with the best threshold. Then the confusion matrix is shown using stacked mosaic plots suggested by Raymaekers et al. paper to show the proportion of observations in each class by the squares’ size to indicate if the data are skewed. Finally, distribution of predicted values is displayed to show the model’s confidence levels.

Feature importance: This section visualizes the correlation, feature importance based on LASSO, random forest (embedded methods), and permutation (wrapper method), two learning curves (one based on the number of attributes and the other based on the number of observations). To avoid cluttering, the number of displayed attributes is limited to the 20 that score the highest.

Sensitivity analysis: This section visualizes the effects of a single attribute on the model using the technique described in Wojtusiak et al. study. After selecting an attribute, the dashboard shows its distribution, and mean predicted values for training, testing, and random data, as well as means of fixed values for the attribute to check its effect in the model. Finally, two scatter plots are displayed to compare the original predictions and predictions when the attribute values change slightly. For categorical attributes, the distribution of predicted values is displayed for each category instead of the mean.

Results
Medicare claims, COVID-19, and heat disease prediction data from UCI repository were used to test the visualization. For claims data, the purpose was to predict if the patient will be a high utilizer in the next six months, while COVID-19 data were used to predict covid-19. Figure 1 shows the dashboard for predicting high utilizers using claims patients.

Discussion
Visualizing the model results help both the analysts and the clinicians to evaluate the model results. Based on the problem, different ways of evaluation are needed. However, this dashboard visuals are applicable to any type of classification problem. The next step of this project is to visualize the difference between multiple models.

Use of Geomapping and Data-driven Personas to Target Intervention for At-risk Patients with Diabetes

Adarsha S Bajracharya, MD, MMSc1,2, Soussan Djamasbi PhD,MS,3 Gaayathri Sankar BA,3 Qiming Shi, MS1 Daniel J Amante PhD, MPH,1

1. Dept of Population and Quantitative Health Sciences, University of Massachusetts Medical School, Worcester, MA 2. Dept of Medicine, University of Massachusetts Medical School, Worcester, MA, Worcester, MA 3. User Experience and Decision Making Lab, Worcester Polytechnic Institute, Worcester, MA

Introduction:

Diabetes is a major health concern in the US with over 25 million Americans having type 2 diabetes (T2D). Adherence to guideline recommended care has shown to improve health outcomes in diabetic patients, including decreased rates of complications, less hospitalizations and improved quality of life. Yet, adherence to guideline recommended diabetes care plan is a challenge for many patients due to physical and socio-economic barriers. Persona development refers to the process of creating representations of patients via fictional yet realistic characters (personas). This has been shown to be important in identifying common needs, allowing for development of personalized interventions. We sought to use select demographic and clinical data of diabetic patients from an institutional electronic health record (EHR) system to geemap and create patient personas to identify groups of patients with common characteristics. This works allows us to better understand a diverse patient population and their corresponding needs.

Methods:

UMass Memorial Healthcare (UMMHC) is a large academic health care system caring for patients in central Massachusetts. Institutional patient data from its diabetes registry were used for geomapping the patient population and for cluster analysis to create data driven patient personas. Patient home addresses, including street address, city, state, and zip code, were extracted from EHR system and ArcGIS application was utilized to geocode and transform patient home addresses into latitude and longitude enabling spatial cluster analysis. Two-step clustering technique using SPSS was employed to analyze categorical EHR data to identify representative patient groups.

Results:

Among 53,675 deidentified patient records, analysis of the geocoded data revealed 10 zip codes with highest burden of disease. These 10 zip codes accounted for 48% of the patient population.

The two-step cluster analysis was run for this target population of 26,349 patients and three clusters of patients with important similarities and differences were identified. Common features included being white, obese, with moderate LACE+ comorbidity score, having access to phone and an email address (suggestive of access to Internet) but were not active patient portal users. Important differences noted in the 3 clusters were one cluster of younger, single females of Hispanic/Latinx ethnicity with state-sponsored insurance and two other clusters consisting of older married males not of Hispanic/Latinx ethnicity who had either Medicare or commercial insurance.

Conclusion:

Early results show that geomapping and cluster analysis can be used to identify different subgroups from a larger patient population and help to understand their group characteristics. In our work, we identified communities with highest burden of diabetes. Next steps include gaining further understanding of the barriers and facilitators to guideline-concordant care for each subgroup of patients within the population. This will help us better understand specific clinical and social determinants of health, allowing for tailored development of patient engagement strategies and support services that better meet the needs of the patients.
Electronic Health Record Use for Improving Patient Outcomes for School-Aged Children with Chronic Conditions

Christina Baker, MS, RN-BC¹, Figaro B. Loresto Jr., PhD, RN²
¹University of Colorado | Anschutz Medical Campus, Aurora, CO, USA, ²Children’s Hospital Colorado, Aurora, CO, USA

Introduction

Electronic health records (EHRs) have become the standard of communication and documentation for healthcare systems. Still, full functionality is not yet realized for health information exchange (HIE) between healthcare systems and community partners such as school nurses. One barrier to HIE includes misunderstanding of Federal guidelines, the Health Insurance Portability and Accountability Act of 1996 (HIPAA) and the Family Educational Rights and Privacy Act of 1974 (FERPA) (1). One pilot study gave EHR access to school nurses: results showed decreased hospitalizations pre and post school nurse EHR access for 33 school-aged pediatric asthma patients (2).

An innovative program at a Rocky Mountain area Children’s Hospital provides school nurses based in local urban area schools access to a view-only version of the hospital-based EHR, EpicCare Link (Epic Systems, Verona, WI). With Internet access, the school nurses log into EpicCare Link and view the student's chart, including the longitudinal plan of care, current medications, school health care plans, immunizations, and encounter notes. Access process includes school district and hospital signing a Health Information Sharing Agreement. School nurses complete an online EHR training, sign a Security User Agreement, and complete an in-person privacy and technical training.

Objective/Methods

The study aimed to analyze the effect of school nurse access to medical records in a hospital-based EHR on patient outcomes. We hypothesized that EHR access would decrease emergency department (E.D.) visits and hospital inpatient admissions and that EHR access would be utilized more for patients with chronic conditions.

This retrospective secondary data analysis was conducted in 2020 using EHR data six months pre- and post-school nurse access to students’ hospital-based EHR. The main outcome measures were the E.D. visits and hospital admissions. Descriptive analysis was conducted on demographic variables. ED visits and hospital admissions were not normally distributed by the Shapiro-Wilks test (W = 0.52, p < 0.0001; W = 0.52, p < 0.0001). Unadjusted matched Wilcoxon Rank Sum tests were conducted to compare outcomes between the pre-and post-access time periods for each subject. A multivariate mixed Poisson regression was conducted to estimate the impact of EHR access for school nurses on outcomes adjusting for covariates listed in the demographic and covariate section.

Results

For the sample of 336 students in the study, there was a 33% decrease in E.D. visits from 190 visits before access to 126 ED visits after access. Hospital admissions decreased by 44% from 176 hospital admissions before access to 99 hospital admissions after access. Poisson Regression analysis found a significant (p<.001) 34% reduction in E.D. visits and 44% reduction (p<.01) in inpatient visits post-access compared to pre-access. EHR access was utilized by school nurses more for patients with higher complexity and chronic conditions.

Discussion/Conclusion

HIE between hospital systems and community partners was established. School nurse access to medical records through a hospital-based EHR may improve patient outcomes with access to real-time, accurate medical records. Further research of feasibility, improved functionality, and confounding variables is warranted.

Planning Change Using the ADKAR Model: Establishing a Data Governance Program in the VHA Office of Community Care

Gina Baker, CCP, Francine Sandrow, MD, Katharine Miller, MHA/MPM, Jianji Yang, PhD, Darby McKnight, MBA, Natalie Ngu, MS
Department of Veterans Affairs, Veterans Health Administration, Office of Community Care

Introduction
Veterans Health Administration (VHA) provides access to timely, high-quality, cost-efficient, and well-coordinated community care for Veterans and VA beneficiaries based on certain conditions and eligibility requirements. The VHA Office of Community Care (OCC) is the national office in charge of community care delivery and revenue operations. Data management and analytics are critical to support OCC administration, planning, and oversight functions.

The evolution of VA Community Care operations and implementation of third-party software to manage referrals, claims and payments, has contributed to OCC data systems becoming overly complex and disjointed. Subsequently, OCC established a Data Governance (DG) Program to manage data as a strategic asset and formalize behavior and control over how data assets are managed. The DG program will establish Data Stewardship practices from data capture to disposition, to ensure data is consistent and of the highest quality with the goal of improving care quality and Veteran satisfaction informed by data analytics.

Methods
The DG program imposes significant changes on staff and current processes. OCC has executed a methodical way to manage change, using the Prosci ADKAR Model to guide staff through the transition. ADKAR stands for the 5 elements for a successful change: Awareness of the need for change; Desire to support and participate in the change; Knowledge of how to change; Ability to implement required skills and behaviors; and Reinforcement to sustain the change.

A DG project team was assembled by the OCC Chief Health Informatics Officer and the change management component is led by a Certified Change Practitioner. The team conducted a baseline assessment using Prosci tools. Through interviews and observations, project health and the Impact Index for 33 groups of staff were assessed in line with the 5 elements. Based on the insights gained from the assessment, the team created an organizational change management plan with mitigation strategies tailored for each group to address the risk and barriers. In accordance with the organizational change management plan, the following plans will be developed in support of ADKAR: sponsor roadmap, coaching plan, communications plan, resistance management plan and training plan.

Results
After analysis of the project and group impact results, a change management plan based on the ADKAR Model is created with strategies for each step in the lifecycle of the project (Figure 1).

Conclusion
Change management plays a crucial role in project success, especially for high impact projects like the DG Program. Using the ADKAR change framework, leadership has a better understanding of the risks and resistance to the adoption of the Data Governance strategy in OCC and is developing plans to mitigate the risks and ensured project success.

Evaluating HL7 FHIR Resources for Sharing Research Consent Data

M Katie Banasiewicz; Mark McEver; Douglas Conway, MS; Alex C Cheng, PhD, MEM; Colleen Lawrence, PhD; Leah Dunkel, MPH; Paul A Harris, PhD; Stephany N Duda, PhD
Vanderbilt University Medical Center, Nashville, TN, USA

Introduction
The HL7 Fast Healthcare Interoperability Resources® (FHIR®) specification was originally developed to facilitate the exchange of clinical care data from the electronic health record, but is increasingly used to share research data. We evaluated the capacity of FHIR Release 4 to represent the elements of informed consent for research.

Methods
With researcher input, we identified the data and metadata elements needed to describe different types of research informed consent, reviewed HL7 FHIR Resources for appropriate mappings, and identified gaps.

Results
We identified 21 data elements to represent research consent and associated documents (e.g., child assent), of which 17 (81%) mapped to existing FHIR Resources (Table). No FHIR elements aligned with data for consent version, language or mode of administration (e.g., in-person, mail, electronic), or copy of the signature image (for eConsent).

Table. Research consent data elements and their mappings to HL7 FHIR Resources.

</table>

Discussion
FHIR Resources, particularly Consent and DocumentReference, currently cannot capture the full data structure of research consents, but hold promise for representing research consents via extensions or future versions. Limitations include our focus on US-based research consents or unrecognized consent fields. We are developing a proof-of-concept Consent FHIR payload module built into the REDCap data collection platform to implement this mapping.

Patient Perspectives on ‘FH Family Share,’ a Tool to Increase Uptake of Cascade Testing for Familial Hypercholesterolemia

Hana Bangash¹, MBBS, Ahmed Makkawy², BSc, Justin H. Gundelach¹, MSc, Alexandra Miller¹, BSc, Aaron Leppin³, MD, Iftikhar J. Kullo¹*, MD.

¹Department of Cardiovascular Medicine, Mayo Clinic, Rochester, MN; ²User Experience Research, Saharafox Creative Agency, Rochester, MN; ³Health Care Delivery Research, Mayo Clinic, Rochester, MN, USA.

Introduction

Familial hypercholesterolemia (FH), a prevalent genomic disorder, significantly increases risk of early onset coronary heart disease. Cascade testing for FH is a cost effective method of identifying at-risk family members of a diagnosed proband, however it has low uptake in the U.S.¹ Digital tools may increase uptake by facilitating the sharing of FH-related risk information between probands and family members.

Methods

‘FH Family Share’ is a web-based tool designed to promote cascade testing for FH by enabling probands to share their diagnosis with family members via templated ‘letter to family members’ emails. To evaluate FH Family Share we conducted usability testing with FH patients over a 3-month period. Patients with a confirmed pathogenic/likely pathogenic variant were asked to participate. Due to Covid-19, sessions were conducted virtually, lasted 1 hour, were audio recorded and transcribed. Patients navigated a prototype of the tool, applied the ‘Think Aloud’ usability technique and shared insights on interface design, content and user experience. Patients also completed a survey.

Results

Nine patients participated in the usability testing sessions. Feedback highlighted the need to address the implications of FH for children in the tool, including age of screening and treatment, and implications for FH patients who were family planning. Children and grandchildren were identified as the greatest motivators for patients to get tested and share their diagnosis. Feedback on interface design included need for larger, clearer font and making the content easier to read. Patient feedback led to iterative refinement of the tool. Survey results are summarized in Table 1.

Table 1: Satisfaction survey responses from FH patients (n=9).

Assessing the Use of Prescription Drugs in Obese Respondents in the National Health and Nutrition Examination Survey

Laura A. Barrett, MS¹, Aiwen Xing¹, Elizabeth Steidley¹, Terrance J. Adam, RPh, MD, PhD², Rui Zhang, PhD², Zhe He, PhD¹*  
¹Florida State University, Tallahassee, FL; ²University of Minnesota, Minneapolis, MN

Introduction

Obesity is a complex, multifactorial, and largely preventable disease commonly defined as having an excess of body weight for an individual’s height. As a major health and economic crisis affecting the modern world, much progress has been made in identifying and developing strategies for preventing and treating obesity. It is important to understand the patterns of RXD use among people with obesity, who often have other chronic conditions, in order to inform both clinical practice and research. In this project, we aim to gain an in-depth understanding of both the relationship between obesity and RXD use, as well as the correlations between specific RXD and DS use in the obese population using National Health and Nutrition Examination Survey. We would like to understand: 1) what are the correlations between reported dietary supplement use, reported prescription drug use, and demographics? 2) Are prescription drugs or dietary supplements used more by the obese population than in the non-obese population? 3) Can demographic variables and obesity status predict prescription drug or dietary supplements use?

Methods

Demographic, physical examination, prescription drug (RXD) and dietary supplement (DS) use, and health insurance information were extracted from NHANES for survey years 2003 – 2014 (6 survey cycles). We used the sample weight provided by NHANES to combine the samples from different survey cycles. We conducted multivariate logistic regression analyses, performed two separate logistic regression analyses and evaluated different machine learning models to answer our research questions.

Results

The obese group has a higher reported use of RXD. Use of CV agents and metabolic agents was higher in the obese group. The highest average number of RXDs used can be found among people with BMI from 63-67 kg/m². Figure 1 illustrates the correlation between the number of RXDs/DSs used and BMI. People take higher numbers of RXDs than DSs. The largest maximum number of DSs used (24) can be found among people with BMI from 18 to 22 kg/m², the healthiest group, compared with other BMI groups. Regarding the prediction results, we discovered that adding the extra predictor (of RXD/DS use) did not make a significant contribution to the predictions for RXD or DS use. For RXD prediction, insurance status, DS use, and age were the top three important features.

Conclusions

We found that there are demographics that show higher DS and RXD use; and that obesity can be a factor in the types of RXD that are used. Further knowledge on the association between obesity, DS, and RXD can inform patient education with the help of informatics tools such as data dashboards.

Asthmatic Patient Portal Messaging and Pollution

Marily Barron, BS, Matthew D. Zaragoza-Watkins, PhD, Melissa L. McPheeters, PhD MPH, S. Trent Rosenbloom, MD MPH FACMI FAMIA
Vanderbilt University, Nashville, TN, USA

Introduction

Air pollution is the most common allergen to trigger asthma exacerbations or asthma attacks1 and this is well established in scientific literature2. Self-management is a hallmark of asthma treatment, and includes symptom tracking, trigger awareness, medications, and health-seeking when risk of exacerbation increases.

This study will evaluate disparities in health seeking behavior among adult asthmatic patients during spikes in ambient air pollution. Broadly defined, health seeking behaviors are attempts to access health-related knowledge and resources, including healthcare providers and health systems, with the goal of improving health status3. This study will measure health seeking behavior using the frequency of patient portal messages sent from patients to physicians. The use of patient portals to communicate with healthcare providers is a potentially important form of health seeking behavior4, which may vary in diverse populations. We are not aware of prior research evaluating the health seeking behavior of asthma patients through patient portals when exposed to unfavorable environmental circumstances.

Methods

This retrospective study will be performed at Vanderbilt University Medical Center (VUMC), a large academic medical center located in Nashville Tennessee that serves primary-care and referral patients from across the Southeast. Subjects will include all adult asthmatic outpatients who visited a VUMC clinical from 2012 to 2015. Portal messaging of included patients will be measured from their initial visit until 2017, providing at least 2 years of longitudinal data for each outpatient. We follow, a recent study of adult asthmatic patients in Chicago4, identifying asthma patients as individuals who are assigned an ICD9 code for asthma (493.*) in their first observed visit to a VUMC clinic and are assigned either the asthma ICD9 code or a medication related to asthma on a subsequent visit5.

Data for this study will be collected from VUMC’s Electronic Health Record (EHR), My Health at Vanderbilt (MHAV), and Vanderbilt’s pollution data bank. Patient message counts will be collected from MHAV, VUMC’s patient portal. Medical (presence of asthma) and demographic (age, race and residence) variables will be extracted from the EHR. Ambient concentrations of various air pollutants (e.g., fine particulate matter) will be collected from the Vanderbilt Air Pollution Data Bank. This ensemble will be used to generate a categorical variable, Air Quality Index (AQI), aggregated by Zip-code-date.

To model the relationship between health seeking behavior and air quality, we will estimate a linear probability model via a panel fixed effects research design. Fixed-effects regression avoids potential confounding due to unobserved socioeconomic factors that covary with AQI and affect health seeking behavior at the level of Zip code or date. These statistical models will be used to determine if there is a significant increase in messaging frequency during episodes of high air pollution levels compared to those with low air pollution levels. Using EHR data, we will also estimate models that test whether the magnitude of this effect is mediated by socioeconomic factors such as race and income.

Conclusion

Our findings may reflect differences in the hesitancy of different demographic groups to use the patient portal to communicate with their clinician, differences in familiarity with technology or differences in asthma exacerbation.

Towards effect estimation of COVID-19 Non-pharmaceutical Interventions

Vesna Barros, MS¹, Victor Akinwande, MS², Itay Manes, BS¹, Osnat Bar-Shira, PhD¹,
Celia Cintas, PhD², Yishai Shimoni, PhD¹, Michal Rosen-Zvi, PhD¹
¹ IBM Research, Mount Carmel Haifa, Israel; ²IBM Research Africa, Nairobi, Kenya;

Introduction There still remains uncertainty about the relative effectiveness of multiple Non-pharmaceutical Interventions (NPIs) applied by different countries against COVID-19 transmission. We aim to estimate the effect of these NPIs on reducing the spread of the pandemic using a causal inference approach.

Methods We used Google mobility data¹ and a subset of socioeconomic and health covariates from World Development Indicators² as covariates in our causal analysis. We obtained comprehensive NPI data provided in WNTRAC¹ and the number of COVID-19 confirmed cases were extracted from the World Health Organization³.

To estimate the causal effect of a given NPI, we defined the outcome of the causal model \( Y \) as the reproduction number’s \( R_t \) slope two weeks after the NPI was imposed, where \( R_t \), i.e., the rate by which the pandemic spreads, was calculated using EpiEstim². Treatment was defined based on the imposition \( A = 1 \) or lifting \( A = 0 \) of the NPI. Using this problem setup, Inverse Probability Weighting (IPW)³ and Adversarial Balancing (AB)⁴ were used to calculate the weighted population outcome for each subgroup, stratified by treatment assignment. Using the weighted population, the average treatment effect (ATE), i.e., \( E[Y_{a=1}] - E[Y_{a=0}] \) was calculated, where it was assumed that the null hypothesis is that not imposing any NPIs would result in an ATE=0.

Preliminary Results We selected the ten most frequently imposed NPIs across 115 countries and 50 US states from the beginning of the pandemic until May 2021. For each NPI, we adjusted for confounding bias by balancing the distribution of the covariates between the groups with that NPI imposed and not imposed. Based on the evaluation framework proposed by Shimoni et al.⁵ we observed improved balancing after applying IPW for NPIs corresponding to Confinement (C), School Closure (S), Mass gatherings (MG), Mask wearing (MW), and Work restrictions (W). The population average treatment effect of these NPIs on \( R_t \) slope are reported in Table 1 with the 95% CI. We observed an overall null effect of these NPIs when multiple countries and US states are aggregated.

Discussion Given the heterogeneity of different countries, finding valid causal effects is challenging. Not only the covariates are noisy and uncertain, but unobserved factors may also confound the results. Additionally, the outcome, \( R_t \) slope, is itself an estimate with some degree of uncertainty. We recommend that any appropriate data-driven NPI effectiveness model must be accompanied by extensive validation and sensitivity analyses. As future work, we will do an individual evaluation for the US states only, and redefine the treatment and control groups of our causal model.

Text Mining on COVID-19 Publications  
Mrigendra M. Bastola¹, MD, MS, Paul Fontelo¹, MD, MPH.  
¹NIH/NLM/LHC, Bethesda, MD, USA.

Abstract:  
The unprecedented number of publications on COVID-19 has created a challenge for physicians, researchers and consumers to get reliable health information. We deployed text mining tools (PyTorch) on selected PubMed articles to answer context-specific COVID-19 related questions, aiming to develop an askMEDLINE like tool.

Introduction:  
COVID-19 has generated unprecedented numbers of publications, challenging health professionals and consumers seeking trusted, reliable information from the internet. Text mining tools that accurately mine a reliable publications portal (e.g., PubMed) can better answer COVID-19 questions. This study aims to develop a text mining tool similar to askMEDLINE using Natural Language Processing to find PubMed resources.¹

Methods:  
Selected publications were searched in PubMed and resulting PubMed IDs were recorded. Using PyTorch, queries were modeled after the PICO (patient, intervention, comparison, outcome) for context-specific clinical questions about COVID-19 (outcome, prognosis, laboratory tests, age, and comorbidities). Query methods included CORD-19 and BERT models. Word vector analyses were performed, heat maps using RoBERTa models were generated. Search sequences were generated in PyTorch, using pre-trained models from a “transformers” model.

Results:  
Text mining tools deployed retrieved relevant material from selected PubMed publications. The results of the query varied for PICO query type and vocabulary (Figure 1). Results showed high association of sample query outputs to commonly used COVID-19 medical terms and phrases (0.7 to 1.0) (Figure 1 & Table 1). Overall, vector similarity analysis on the query output showed 0.67 similarities within words with similar meanings and 0.49 for words with different meanings. The average cosine distance was 0.03 between search words and output.

Conclusion:  
Text mining methods may provide a useful tool for healthcare givers and consumers looking for reliable information on COVID-19. Natural language queries from healthcare consumers, supported by healthcare givers, could improve access to their health information needs and make better medical decisions. This method can also be applied to other reliable sources (e.g., medRxiv), while also addressing the quality of published evidence.

Acknowledgments: This research was supported by the Intramural Research Program of the NLM/NIH.

INTRODUCTION
Hospitalized SARS CoV-2 coronavirus disease (COVID-19) patients are susceptible to a dysregulated immune system response giving rise to significant deterioration, days after admission. Among COVID-19 patients, reports indicate that age and comorbidity correlate with mortality risk. Our work evaluates the relationship between impairment and subsequent in-hospital deterioration by explicitly measuring physiologic acuity at admission using the Rothman Index (RI), an extensively validated, commercially available patient condition score (PeraHealth, Inc.; Charlotte NC). We evaluate the ability of the RI model at the time of hospital admission to stratify patients into high or low risk of subsequent severe deterioration with an emphasis on opportunities to support risk stratification in the COVID-19 population.

METHODS
Data - We analyzed data from LifeBridge Health System’s Sinai Hospital of Baltimore, in Baltimore, MD and from three Yale New Haven Health System (YNHHS) hospitals in New Haven, Bridgeport, and Greenwich CT. These include urban and suburban community hospitals and an academic medical center. The data included 3,499 COVID-19 patients and 14,658 non-COVID-19 patients from January 2020 – June 2020.

RI at Admission as a Predictor of Risk
To evaluate differences in deterioration risk between COVID-19 and non-COVID-19 patients, we compared RI at the time of inpatient admission with in-hospital mortality rates for COVID-19 and non-COVID-19 populations. We validated the use of the RI with COVID-19 patients by using a single-variable logistic regression model to compare the first RI score in predicting in-hospital mortality.

RESULTS
RI at Admission as a Predictor of Risk
Evaluation of in-hospital mortality as a function of acuity as measured by the RI at admission reveals that COVID-19 patients have a significantly higher mortality risk than non-COVID-19 patients for a given acuity. For both COVID-19 and non-COVID-19 patients, performance at all hospitals using the initial RI on admission ranges from good to excellent for discriminating in-hospital mortality (AUC of 0.81–0.84 for COVID-19 and 0.90–0.92 for non-COVID-19). The RI model is found to be well calibrated.

Operating Thresholds for Risk Stratification
Fewer than a third of COVID-19 patients meet the high-risk RI criteria (RI<50); they have a 34–45% mortality rate. Approximately half the COVID-19 population meet the low-risk RI criteria (RI>70); they have a mortality rate of 2–5%.

DISCUSSION
A direct measure of acuity is an effective predictor of physiological susceptibility to decline as shown in reported AUCs. Importantly, we also see that for a given level of acuity at admission, as measured by the RI, mortality rates for COVID-19 patients are higher than for the non-COVID-19 medical population; this difference holds even when comparing COVID-19 to a sub-population of non-COVID-19 medical patients with respiratory-related diagnoses. These findings imply that a clinician’s sense of how to treat a COVID-19 patient may be led astray by how he or she would treat a non-COVID-19 patient. Especially during surge situations, an objective measure may help ensure that resources, supplies, and bed capacity are allocated efficiently. These findings are also important for high-risk patients who may benefit from closer monitoring or more intensive therapies, and for low-risk patients, some of whom may not need high levels of care, or indeed hospitalization at all. In conjunction with the Biomedical Advanced Research and Development Authority we have developed a mobile app which we are currently testing for risk stratification in the Emergency Department to assist clinicians in admission and level-of-care decisions.
A Process for Multi-Stakeholder Governance of Patient Data Releases

Douglas S. Bell, MD PhD1,2,3, Marianne Zachariah1, Amanda L. Do1, Carina V. Hampp1, Karen V. Lopez1, Michael Pfeffer, MD1,2,3

1UCLA Clinical & Translational Science Institute, Los Angeles, CA; 2Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3UCLA Health, Division of Information Services and Solutions, Los Angeles, CA.

Introduction

Data derived from patient care is needed for a growing number of applications, particularly for machine learning. Investigators often collaborate with external entities and request that patient data be shared with organizations outside of UCLA Health. We report an approach to governing the release of patient data to third-party organizations.

Methods

The Figure shows an overview of our process. Staff work with submitting investigators to ensure that complete information is elicited for each release. Next, a Data Release Subcommittee, consisting of CTSI and UCLA Health representatives, reviews the request’s potential risk, including data security, the use of sensitive data such as drug use, and consistency with any IRB approvals. Next, UCLA’s Technology Development Group develops a contract with the third party, which must meet 16 mandated terms, the first of which is “Purpose must advance public benefit.” The request and the terms are then reviewed by the Health Data Oversight Committee, which consists of 12 members including the CIO, Chief Counsel, and CTSI Director. Finally, the agreement is approved or rejected by the Vice Chancellor for the Health Sciences, who oversees both the David Geffen School of Medicine and UCLA Health.

Results

In the first 18 months (9/2019 to 2/2021), investigators submitted 109 requests for external data releases. The rate of submittal has varied from 2 to 12 per month, with no distinct uptrend. Of the requests submitted, 33 were withdrawn by the investigator, 20 are actively in process and 29 are suspended due to non-response from investigators. For 27 requests, the review process has been completed by both committees and the Vice Chancellor, with 23 requests (85%) having been approved and 4 (15%) not approved. The poster will review examples in specific categories.

Conclusion

Our review process, which involves a risk assessment, followed by a value assessment with mandated contract terms, has resulted in 27 well-justified data releases over 18 months. Only 15% of requests completing the review process were not approved, but almost half of requests were withdrawn or suspended, suggesting that the process often leads investigators to decide on their own that the value-to-risk ratio is not sufficient to justify their request.
Supporting EHR-based Cohort Discovery Through User-centered Design: Results of an Early Formative Usability Study

Natalie C. Benda, PhD1, Pascal S. Brandt, MSc2, Jessica S. Ancker, MPH, PhD1, Jennifer A. Pacheco, MS3, Prakash Adekkanattu, PhD4, Guoqian Jiang, MD PhD4, Jyotishman Pathak, PhD1, Luke V. Rasmussen, MS3

1Weill Cornell Medicine, New York City, NY1; 2University of Washington, Seattle, WA; 3Northwestern University, Chicago, IL; 4Mayo Clinic, Rochester, MN

Introduction
Cohort discovery is a critical step in clinical and biomedical research studies. Computational electronic health record (EHR)-based phenotyping provides a means for cohort identification that limits the need for exhaustive chart review. Creating portable phenotypes that may be implemented and validated in different institutions presents a challenge in this space. One aim of the ongoing Phenotype Execution and Modeling Architecture (PhEMA) initiative is to develop an authoring tool for creating and executing portable phenotypes.1 To create a useful, usable tool, we have taken a user-centered design approach for system development. Here, we present initial results from a formative usability study to explicate user needs for supporting authoring and execution of phenotypes across institutions.

Methods
We first created a wireframe interface of our phenotype “workbench” through iterative task analyses and design cycles with the PhEMA team that has expertise in phenotyping and user-centered design (examples in Figure 1). The wireframes were pre-populated with sample phenotype algorithms, and we completed formative usability assessment interviews with representative end users who had experience analyzing EHR data. Participants granted written informed consent and were reimbursed for their time. Each participant was assigned the task of executing two phenotype algorithms without any formal instruction and as little help as possible. After working through the execution, a brief semi-structured interview was conducted to elicit additional suggestions and feedback. The Weill Cornell IRB approved this project.

Results
Five expert phenotype author participants found the textual summary generally useful, and noted that the graphical phenotype summary may be helpful for data requesters. Participants also expressed the utility of the results summary view. However, participants had design critiques for each interface component. Specifically, participants wanted the ability to link to terminologies presented in the textual phenotype summary and a means for drilling down to demographics in the results summary. The phenotypes in the study came “pre-loaded”, and participants further described that they would want the ability to load and edit additional phenotypes.

Discussion and Conclusion
The results of our formative usability assessments directed our efforts to implement two new features in our phenotype workbench 1) connection of the textual summary to standardized terminologies through the Value Set Authority Center and 2) the ability to directly load and edit phenotypes from the Phenotype Knowledge Base. Future efforts will involve cognitive task analytic approaches to gain a deeper understanding of phenotyping activities to provide enhanced visualization for phenotypes and their outputs for authors and their collaborators.

Problem to be Addressed
Although several risk factors have been associated with colorectal adenomas, precursors to colorectal cancer, risk factors for less-studied polyp subtypes, including the more aggressive serrated polyps, are unknown (1,2). Identifying risk factors for these polyp subtypes is critical to developing evidence-based personalized screening strategies. However, studying the risk factors for these polyps is often cost- and resource intensive as polyp features are embedded within unstructured pathology reports. Consequently, Natural Language Processing (NLP) could serve as an effective tool to extract large amounts of unstructured data from pathology reports and enable construction of epidemiologic datasets to study risk factors for colorectal polyps.

Methods
Using pathology reports (n=12,515) from the University of Utah Enterprise Data Warehouse, we developed a rule-based NLP pipeline to extract colorectal polyp diagnoses and related features (number, site, shape, and size of colorectal polyps) for all colonoscopies at the Gastroenterology clinic at the University of Utah from 2013-2018. To develop and refine our annotation scheme and determine interrater agreement, two authors manually annotated 200 pathology reports for histopathologic features of colorectal polyps. Once a strong level of agreement was achieved and maintained (i.e., Cohen’s κ > 0.8), the same authors annotated a validation set of 150 pathology reports to serve as a reference standard for calculating performance metrics of our pipeline.

Results
We extracted the histopathologic features of 11,269 polyps across 6,323 patients with a colorectal polyp diagnosis (2,367 individuals were polyp-free) using our NLP pipeline. On average, patients had 1.7 colorectal polyps resected with an average largest polyp size of 0.54 cm. Our pipeline extracted 6,688 adenomas (98.2%, 1.7%, 0.03%, specified as a tubular, tubulovillous, or villous pathology, respectively), 1,208 serrated polyps, and 3,104 hyperplastic polyps. Of the adenomas, 5.6% were classified as advanced adenomas (i.e., polyps > 1 cm. in size or containing a villous or tubulovillous pathology), and 1.8% of polyps displayed dysplasia. Overall, our NLP pipeline achieved a precision of 98%, a recall of 91%, and an F1-score of 94% in extracting all colorectal polyp variables of interest.

Conclusions
We developed an NLP pipeline that accurately extracted the diagnosis of 6,688 adenomas, 1,208 serrated polyps, and 3,104 hyperplastic polyps and their clinically relevant features from unstructured pathology reports from 6,323 individuals undergoing colonoscopy at the University of Utah Gastroenterology clinic between 2013-2018. We have successfully demonstrated the utility of NLP techniques to create unique datasets for the epidemiologic research of colorectal polyp risk factors.

Parent and Paraprofessional Use of Commercial Augmentative and Alternative Communication Devices with Non-verbal Autistic Young People

Ariana Bernstein, MS, Jina Huh-Yoo, MHCI, PhD, Andrea Forte, MS, PhD
Drexel University, Philadelphia, PA, USA

Introduction
In a report published in 2020, autism spectrum disorder affects 1 in 54 children as of 2016, a move from 1 in 60 in 2014 [1]. Approximately 30 percent of children with autism are minimally verbal [2], meaning they communicate using little or no spoken language. Novel technologies have introduced new communicative possibilities for minimally verbal individuals and the people close to them. We conducted semi-structured interviews to explore the experiences of people who use commercially available communication technologies to interact with minimally verbal autistic children. Our goals are to understand the experiences of teachers and parents who use these technologies, to learn from them about the experiences of their minimally verbal students and children, and to derive insights about future design and use of aided augmented and alternative communication (AAC) devices and software.

Methods
We conducted six semi-structured interviews recruited using convenience sampling to encourage parents and speech-pathologists of non-verbal individuals to raise relevant issues that we may not have anticipated and to allow for storytelling and rich descriptions of their general technology use and retrospective reflections on interactions with others using AAC devices. The team iteratively coded transcribed interviews beginning with open codes grounded in data, and gradually grouping and thematizing the codes to generate the findings. We received an IRB approval for in-person and remote interviews. Participants included three professionals who have and currently work with non-verbal individuals as aides and speech-pathologists (referred to as ‘‘aides’’ or ‘‘paraprofessionals’’) and three parents of non-verbal children. The interviewer asked for examples of people who stood out in participants’ minds and asked how communication happened with those individuals and probed the details about any technologies that were used.

Results
Common dedicated devices among the participants included: Accent Program with Unity, Bigmack, LAMP Words For Life, Proloquo2Go. We found four major themes regarding participants’ experiences with AAC and a methodological insight. (1) Customization: It was critical to choose what devices and strategies work for non-verbal individuals, as one participant explained: “We say their voice, their choice.” (2) Maintenance: When a dedicated device breaks, it needs to be sent back to the company and can take weeks to be returned to the individual. The severity of disruption associated with inconsistent access was detrimental to user experience. (3) Two-way Communication: Caretakers reflected that they, too, not just non-verbal individuals, need to learn how to communicate effectively with the devices. There was a lack of resources available for caretakers to learn how to use the device(s). (4) Usability: Low frustration tolerance is common among people on the spectrum and can lead to distress, which makes choice overload an egregious design problem that can erect critical barriers to use. Usability problems such as labeling issues and communication symbol sets contributed to this frustration. Lastly, we learned that the participants who work with non-verbal individuals closely in a 1:1 relationship and their concerted efforts to achieve intersubjective understanding with learners linked their experiences in a way that is uniquely powerful among informants in qualitative research.

Conclusion
In addition to the experiences we identified regarding commercial AAC devices, we discovered a methodological insight of how caretakers’ reports of their own experiences and concerns were entangled with those of the young people they taught and cared for. We elucidate the role of what we call intersubjective entanglement in the reported experiences of people who serve as caretakers and catalysts for the learning of others. This concept expands on the idea of key informants as individuals with access to a wide range of cultural roles and representations by virtue of their social relationships or position within an organization. We suggest that intersubjective entanglement is a useful concept to explain the role of key informants in interview-based work that seeks to extrapolate understanding or design implications for supporting a vulnerable population alongside data collection from vulnerable populations themselves.

Understand the Role of Health Literacy in Relation to Social Determinants of Health: A Systematic Review

Shwetha S. Bindhu1, Anunita Nattam1, Catherine T. Xu1, Tiffany Grant, PhD1, Hexuan Liu, PhD1, Danny T.Y. Wu, PhD, MSI1
1University of Cincinnati, Cincinnati, OH;

Introduction

In recent years, clinical note sharing has expanded patients’ abilities to understand and control their own health, especially for patients from vulnerable populations. Addressing low levels of health literacy (HL) is an important factor in improving the benefits of clinical note sharing, as high HL helps improve shared decision-making1. While causes of low HL have been extensively researched, the nature of health literacy as a modifiable social determinant of health (SDoH) is yet to be thoroughly explored. This systematic literature review aims to understand the nature of the modifiable relationship between HL and SDoH and the feasibility of developing interventions to address HL.

Method

The study systematically reviewed literature following PRISMA guidelines2. Literature in PubMed and Scopus databases were searched according to the eligibility criteria. The search criteria used were “health literacy” AND “social determinants of health.” Two researchers separately screened the papers by title and abstract. Disagreements were resolved by a third researcher after the initial screening. The process was repeated for full article eligibility. Papers that were included for the full article review were assessed for quality using AHRQ-informed assessments. After excluding articles with a “poor” quality rating, a team of four researchers extracted information from the remaining articles based on PRISMA guidelines and the articles’ SDoH and HL of focus2.

Results

A total of 146 articles from PubMed and 243 articles from Scopus were found through the search criteria, and 49 articles will be assessed in the narrative synthesis. Figure 1 shows the totals after each step of screening, eligibility, and quality assessment were conducted. Figure 2 shows the study design totals after the information extraction was completed.

Discussion

Current progress on the systematic literature review indicates that there has been substantial research into the multidimensional nature of the relationship between HL and SDoH and that significant consideration has been taken on the implications for intervention procedures. We will continue to conduct the narrative synthesis to summarize the large-scale impacts and relationships between these multiple factors and in improving clinical note sharing for patients with low HL.

Case study in the development of a framework for quality and reproducibility in inner-sourced packages and self-service analytic dashboards to accelerate common study types

James A. Black, PhD\textsuperscript{1}, Nayan Chaudhary, MSc\textsuperscript{2}, Adam J. Fory, PhD\textsuperscript{3}, Sriraman Madhavan, MSc\textsuperscript{3}, Matthew Secrest, MSc\textsuperscript{3}, Kamil Wais, PhD\textsuperscript{2}  
\textsuperscript{1}PD Data Science, Roche, Switzerland; \textsuperscript{2}7N Consulting, Poland; \textsuperscript{3}PD Data Science, Genentech, United States. All authors contributed equally.

Introduction and Principles

Reproducibility of a research question and reproducibility of individual studies are hampered in studies due to the diversity in the code that sits between a statistical analysis plan and a result. We propose a set principles that can be immediately implemented to boost efficiency.

Code has value: The use of ad hoc code within a study should be minimised, and a culture promoted of collaboration on pan-study code in documented packages for reuse. Unit tests are ideally written at function creation, and reviewed and expanded with new use cases.

Democratise access to analytics: Aided by the consolidation of code into packages, less technical users should be given access to well documented packages to promote guided analyses, as well as dashboards considered for fully self-service interaction.

Be verbose and specific on input cohorts: Publish cohort derivation code as user readable markdown vignettes with descriptive statistics and assumption checks.

Assertively limit user inputs in dashboards: Developers should ensure that variables exposed for manipulation in the app can be varied without compromising validation.

Separate logic from the user interface: As shown in , scientific logic should be separated from visualisation code. This loosely coupled approach improves the robustness of the system by making it easier to isolate, test and document any logic applied to the data.

Case study

By applying these principles to a common study data type, the estimation of duration of treatment in real world settings using routinely collected data, we were able to accelerate time to deliver study results from months to days, while improving robustness and standardisation via well documented and tested code.

In this case study we wrapped repeated study code into a robust and unit tested R package (Code has value), which contained all scientific business logic (Separate logic from the user interface). When then created a de-coupled interactive user interface via Shiny (Democratise access to analytics). Within Shiny we controlled inputs, to ensure the underlying R package was used within a valid scope (Assertively limit user inputs in dashboards). In addition to logic required for the final app, the R package contained vignettes that defined and provided documentation metadata for versioned cohorts. These versioned cohorts, and the accompanying metadata, were then ingested by the app (Be verbose and specific on input cohorts).

Discussion

These principles provided a mechanism to improve the reliability of our code, and had an important secondary effect of providing a clear framework to communicate with stakeholders and between data scientists steps taken to improve quality and reproducibility of internal study dashboards.
Challenges in Designing A Notification System for Electronic Medical Records: An Exploration of User Expectations

Katherine Blondon, MD, PhD
University Hospitals of Geneva, Geneva, Switzerland

Introduction
Information overload can occur in electronic medical records (EMRs). A notification system can help draw attention to the arrival of new data in a chart (notifications) or to abnormal or critical values (alerts). The aim of this paper was to explore what clinicians expect to be notified about when managing their patients and how they expect to be informed. We hypothesized an association between the perceived importance of a result and the alert mode.

Method
We recruited 9 doctors (7 supervisors, 2 residents) from different medical specialties of our hospital to participate in a focus group. Participants were asked to individually estimate the importance of incoming information in 9 vignettes, and to report how they wanted to receive this information (smartphone message, patient’s chart or multi-patient view on the computer). They discussed their answers and explored approaches to avoid alert fatigue. Vignette responses and notes during the session were analyzed qualitatively, comparing and contrasting findings to find common themes and design implications.

Results
Although participants perceived the importance of incoming information similarly, and expected similar communication modes, there was no clear consensus. Context and acuity of response were used to interpret the new results. Low urgency was more often associated with EMR alerts and high urgency with smartphone alerts. For outpatients, doctors underlined the need for alerts because test results are often not seen until the patient’s following appointment. Participants also suggested notifications for emergency department patients’ tests to help decrease consultation times. Participants agreed that targeting the patient’s doctor was a good way to avoid alert fatigue, but recognized the difficulty to reliably identify the proper target for each patient. Another approach to avoid alert fatigue was to be able to adjust alert thresholds for a division and/or according to individual preferences.

Design implications from the focus groups results are reported below (Table 1).

Table 1. Design implications for a notification system with a default setting and possibility of customization

<td>Interruptive</td>
<td>Interruptive</td>
<td>Text</td>
</tr>
<tr>
<td>Critical</td>
<td>Urgent</td>
<td>Interruptive</td>
<td>Text with snooze</td>
<td>No</td>
</tr>
</tbody>
</table>

Conclusion
To address user expectations, alert systems need a default setting that allows some customization (by division, and by personal preferences) for non-critical events. Targeting alert receivers to help avoid fatigue requires being able to reliably identify the right person.

Comparing Performance of Hip-worn and Wrist-worn Research-Grade Activity Monitors for Daily Activities

Katrina Boles, MS¹, Malaika R. Gallimore, RN, MPH¹, Chuka Emezue, PhD, MPH, MPA¹, Chelsea Howland, MSN¹, Amy Grimsley, MSN, RN, CCRN-K¹, Jo-Ana D. Chase, PhD¹, Allison B. Anbari, PhD, RN¹, LeeAnne B. Sherwin, PhD, MS, FNP-BC¹, Blaine Reeder, PhD¹

¹University of Missouri, Columbia, MO

Abstract
Increasingly available consumer-grade wearable devices represent great opportunities for their inclusion in research. Measuring the usability, function, and accuracy of wrist-worn smart watches helps inform best choices for device selection for participant studies. Researchers often test consumer-grade devices against a “gold standard” device such as the hip-worn ActiGraph wGT3X-BT (GT3X). The ActiGraph GT9X-Link (GT9X) is a newer research-grade device designed for wear on the wrist. However, there are known differences in the accuracy of wearable devices based on wear location. Therefore, it cannot be automatically assumed that data from hip- and wrist-worn research-grade devices are comparable for measuring activity. We compared the hip-worn GT3X to wrist-worn GT9X in two different week-long test sessions with adult testers (session 1: n=4 participants; session 2: n=5 participants) for daily free-living activities, segmented on high versus low activity, using the GT3X as a gold standard.

Introduction
In the Precision Smart Technologies and Applications for Rapid Translation (START) laboratory, we use a step-wise methodology to evaluate consumer-grade devices for function and usability. We capture activity data with multiple devices worn concurrently and make performance comparisons with the GT3X as the accepted standard. We use these early comparisons to identify which devices to test activity levels with more evaluators in the next phase. ActiGraph devices are the most used accelerometers in physical activity research studies and are accepted as the gold standard. The purpose of this study is to compare daily activity step counts from the hip-worn GT3X and the wrist-worn GT9X.

Methods
Evaluation data were collected during two one-week sessions. In the first test session, four evaluators concurrently wore the GT3X on the dominant hip and the GT9X on the non-dominant wrist, set to the default sampling frequency of 30 Hz. In the second session, five evaluators concurrently wore both devices in the same locations. Evaluators logged two days of daily activities in each session using an open write-in method for activity description, start and stop times. Using a 60-second epoch for each device, we calculated the sums of total steps for the timeframe of each activity tracked. We identified key terms in the descriptions for high activity - such as walk, exercise, and move - versus low activity - including sit, nap, sleep, and drive. Ambiguous activities were left unidentified. We calculated the absolute percent error using GT3X as the accepted and GT9X as the experimental values for each activity:%

\[
\text{% error} = \left| \frac{\text{accepted} - \text{experimental}}{\text{accepted}} \right| \times 100.
\]

Results
A scatterplot of step count comparisons shows the GT9X captured more steps per GT3X steps (Figure 1). It is difficult to tell from the visual whether high or low activity levels account for larger differences in step counts. The median absolute percent error for low activity (n=107) was significantly higher at 195.2% versus 82.8% for high activity (n=51). The wrist-worn GT9X identified movement as steps more frequently during times of low activity.

Discussion
We identified that the GT9X has a higher error rate for step tracking during low-level activity. Therefore, the ActiGraph GT9X-Link is not a substitute for the hip-worn ActiGraph wGT3X-BT as a gold standard research device. Future studies could compare the GT9X and GT3X while worn in the same place (either hip or wrist) though this endeavor may be of limited utility since the GT9X was designed as a smart watch device.

Quantifying the Period Prevalence of Autoimmune Diseases Across the United States

Gagana Borra¹, Joshua M. Landman, MS²,³, Randi Foraker, PhD, MA, FAHA²
¹College of Arts and Sciences at Washington University, St Louis, MO, USA; ²Institute for Informatics at Washington University School of Medicine, St. Louis, MO, USA, ³Division of Computational and Data Sciences at Washington University, St. Louis, MO, USA

Introduction

Millions of individuals across the United States (US) have an autoimmune disease (AD) and it is difficult to diagnose an AD as there are various symptoms. We hypothesize that we can aid patients in obtaining a quicker diagnosis by quantifying the prevalence of ADs; allowing physicians to make more efficient, accurate diagnoses. To establish estimates of the baseline prevalence of ADs in the US, we conducted a literature review (LR) to characterize the prevalence of over 160 ADs. From these baseline rates, we identified the top ten most prevalent ADs in the US and used current electronic health record (EHR) data to calculate prevalence estimates for ADs.

Methods

A list of ADs¹ was compared with a table of ADs compiled by the LR and via consultations with physician experts at our institution. We added 57 diseases to the list, resulting in a total of 166 diseases, of which 109 of 166 diseases were verified as ADs in our healthcare system. Search criteria for ADs since 2010 included “disease name” and “prevalence rate” (PR). Based on the LR, the top ten most prevalent ADs were identified. We extracted EHR data from our health system, using International Classification of Diseases Version 10 (ICD-10) codes and capturing cases diagnosed from 2010 to 2019 inclusive (n=6,494). We estimated the period PR as cases/100,000 persons. Using R statistical software², we age-standardized these rates to the US population and described the demographic distributions for all 109 ADs in our system’s EHR data during this timeframe (n=19,336).

Results

Rheumatoid arthritis had the greatest number of cases (n=2,925). Its PR in our health system was 170.5 (US 163.4). Lichen sclerosus had the fewest number of cases (n=71). Its PR in our health system was 4.1 (US it was 3.9). Patients with polymyalgia rheumatica had the oldest average age (80 years). Patients with urticaria had the highest variation in age (+/- 26 years). The top ten prevalent conditions were most likely to be diagnosed in women than men. The PRs for the top ten ADs in the US are seen in Figure 1. The blue bar shows age-standardized US rates. The red bar shows the published PR. *Psoriasis exceeds 1000 with a PR of 2328.

Figure 1. Top Ten Prevalent Autoimmune Diseases in the US

Conclusion

Quantifying the prevalence of ADs from 2010 to 2019 can serve as a reference point for future studies. By age-standardizing our locally estimated rates to that of the US population, we can observe how the PRs of these conditions may vary. Future research can update these rates, quantify the PRs of rare ADs which were missing from our analysis, and compare PRs across healthcare systems to assess the robustness of our prevalence estimates.

A comprehensive platform for induced pluripotent stem cell research data

Kirill Borziak, PhD¹, Irena Parvanova, PhD¹, Joseph Finkelstein, MD PhD¹
¹Icahn School of Medicine at Mount Sinai, New York, New York, USA

Introduction

Stem cell therapies, particularly those involving induced pluripotent stem cells (iPSCs), are a growing new therapeutic field for treating, repairing, or replacing patient cells, with the aim of addressing physical damage or disease. Our previous work examined how the voluminous amount of data generated by stem cell research is maintained across the many publically-available stem cell databases¹. However, the diverse forms of data resulting from stem cell research are not consolidated, stored, and available for access by researchers in a centralized and harmonized manner. Based on this necessity to homogenously organize and visualize stem cell data, we developed the Regenerative Medicine Data Repository (ReMeDy). The ReMeDy platform provides a unique solution by allowing the systematic aggregation of data by using a multi-modal common data elements (CDE) framework. The potential users of ReMeDy include clinical and pre-clinical researchers interested in understanding the similarities and trends in the derivation of iPSC products across different applications. The feasibility of ReMeDy has been tested using over 50 diverse, published iPSC projects. It is publically accessible at https://remedy.mssm.edu/.

ReMeDy platform and multi-modal CDE framework

ReMeDy is designed to be a user-friendly database, providing comprehensive and detailed information on iPSC projects. It is an implementation of the Signature Commons², available at https://github.com/MaayanLab/signature-commons. ReMeDy uses the data storage framework of Signature Commons, which is designed to store and search diverse metadata in an agile and flexible manner, using PostgreSQL for data storage. To further improve the usability of Signature Commons, an automated upload interface was developed using ReactJS and Spring Boot, which allows for public data upload and aims to promote crowdsourced uploading of published iPSC data into ReMeDy. To ensure strict quality control of the ingested data, all CDE values are submitted for validation prior to upload, using validator schemas against existing ontologies. The landing page provides easy access to the available functionalities of the platform: search, visualization, and API. Filtering schemas implemented in the search functionality allow users to incrementally refine their search query and provide statistical information on the distribution of CDE values. The API functionality allows researchers to download the data stored within ReMeDy as structured JSON format data.

To facilitate data collection and promote standardized data organization within ReMeDy, we have developed a multi-modal CDE framework that describes the full range of data generated by iPSC studies. Our framework aims to flexibly and comprehensively organize iPSC data, integrating iPSC and stem cell product characteristics, with patient and animal model information, omics data, and project findings and outcomes, to create a comprehensive framework of stem cell research data. The framework is organized into 5 modules: Project, Research System (patient and animal model CDEs), Manufacturing/Production (iPSC derivation and characteristics CDEs), In-depth Product Characterization (omics CDEs) and Outcomes/Findings.

The feasibility of the ReMeDy platform and the multi-modal CDE framework was tested by abstracting data from over 50 published iPSC projects manually by trained abstractors with experience in stem cell research. The abstraction focused on iPSC characteristics, patients or animal model and the research finding and outcomes. Our results indicate that ReMeDy is able to successfully accommodate in vitro, preclinical and clinical projects; data from both stem cell product and tissue engineered medical products; and mouse, rat, pig and rhesus monkey animal models.

Conclusion

ReMeDy provides a comprehensive, centralized and unified platform for data generated by iPSC research, as seen in our feasibility study. The improved access to aggregated CDE values and statistics has the potential to drive knowledge discovery. Future plans include automation of abstraction using natural language processing functionalities.

Challenges of comprehensive automatic coding of presenting complaints
Annie E Bowles, MS,1,2 Hannah Eyre, MS,1,2, Scott L DuVall, PhD1,2, Olga V Patterson, PhD1,2
1VA Salt Lake City Health Care System; 2University of Utah, Salt Lake City, UT, USA

Introduction
The Department of Veterans Affairs (VA) Informatics and Computing Infrastructure (VINCI) aims to improve access to VA clinical data and to facilitate their analysis. The VA research and operational efforts related to COVID-19 are supported through the VINCI COVID-19 Shared Data Resource (SDR)*. Emergency department (ED) presenting symptoms and chief complaints (CCs) have been identified as important in studying onset and progression of COVID-19 infection. An automatic coding algorithm that utilized the cTAKES dictionary annotator had been implemented to map the CCs as the primary reason for ED visit and admitting diagnosis to the UMLS 2020AA standard terminology. The output data is available in the COVID-19 SDR. While sufficiently accurate for coding the primary set of symptoms relevant for COVID-19 research, the complete set of collected mappings (referred to as CUIs) provided a valuable opportunity to evaluate mapping accuracy and clinical applicability of an existing algorithm on a large dataset.

Methods
As of March 1, 2021, the SDR has collected data for 1,242,560 patients and 601,622 ED visits, which resulted in 287,881 admissions. Processing 971,607 non-empty ED presenting symptoms, 77,592 ED discharge diagnoses, and 486,438 admit diagnoses, the mapping algorithm produced 1,682,270, 106,840, and 715,506 CUI mappings respectively. Validation was performed in three steps. First, we evaluated mapping accuracy against 1,000 manually mapped distinct CCs entries (100 most frequent and 900 randomly selected CCs). Second, we evaluated context of the mapped concepts on 400 CCs for negation, temporality, and certainty. Lastly, using the complete set of acquired mappings, we evaluated frequency of specific CUIs and semantic types to identify systematic errors of the mapping algorithm. ED presenting symptoms, ED discharge diagnoses, and inpatient admit diagnoses were evaluated separately.

Results and Discussion
Across the three evaluated datasets, the algorithm achieved 89.3-94.6% precision and 83.9-90.3% recall in identifying the correct CUIs. For the correctly mapped concepts, accuracy of context was measured as 80-89.7%. Misspellings, acronyms, concepts being mapped to multiple CUIs, and systematic mapping errors were the most frequent causes of errors. Due to the inherent ambiguity of short CCs statements, the mapping algorithm produces multiple CUIs that may or may not be related. For example, the concept “liver cancer” is double mapped to related CUIs: “Malignant neoplasm of liver” and “Liver and intrahepatic biliary tract carcinoma”. In contrast, the acronym “LBP” is mapped to both “lower back pain” and “low blood pressure”. Since the generic mapping algorithm attempts to map every possible concept, some CUIs may not carry clinical information such as “test” or “screen”. Varying concept granularity made accuracy comparison challenging. For example, did the algorithm fail if it mapped “acute” and “[disease]” as two CUIs, when a single CUI for “acute [disease]” exists? Context labeling evaluation showed concept variation that can only be differentiated through targeted processing. For example, “CUI=[test] context=[negated]” was identified for both statements test is negative and patient refused to be tested, even though the meanings of these statements are not identical. Manual review of most frequent CUIs on the complete dataset revealed a number of systematic mapping errors. ”ICD” as in ”ICD-10” was consistently mapped to an unrelated concept, and general use modifiers such as ”upper”, ”lower”, ”low”, ”high” were consistently mapped to CUIs related to specific diseases. Also, the vast majority of CUIs that had ”Nucleic Acid, Nucleoside, or Nucleotide” and ”Amino Acid, Peptide, or Protein” semantic types were erroneous. Systematic errors also affected recall. For example, a phrase ”failure to thrive” was never mapped to the CUI of the exactly identical UMLS concept. Once we identified a set of CUIs that were consistently erroneous, we implemented a post-processing step to remove them from the shared dataset, thus increasing its precision.

Conclusion
Ensuring data quality is a vital step in any study. By providing automatically extracted mappings and performing data cleaning on a common data set, VINCI has made a major step from facilitating access to existing data to providing previously inaccessible high quality variables to research groups.

An Open-Source Engine for Decision Support and Workflow Automation
Aziz A. Boxwala, MD, PhD, Mariano De Maio, Hank Wallace
Elimu Informatics, Inc., La Jolla, CA

Introduction
New health interoperability standards such as FHIR and CDS Hooks enable development of applications and services that can integrate with the electronic health record (EHR) and other clinical information systems. This integration allows healthcare organizations to extend the capabilities of the EHR to provide clinical decision support (CDS) and workflow tools to their staff and patients using apps and services that are internally developed or licensed from CDS vendors. While these new standards make it easier to integrate such applications, the development of the applications with complex logic and workflows still requires significant effort. Thus, in practice, few applications have been deployed for clinical use. To expedite the creation of interoperable applications, we developed a2d2, an open-source engine for implementing interoperable clinical automation services for CDS and workflow execution. The OpenCDS project provides open-source software for implementing CDS services.

Architecture and Implementation
An a2d2 server hosts and executes microservices for clinical automation. A microservice provides a well-defined interface and typically implements a single function as a module, e.g., a CDS Hooks service for computing pharmacogenomic interactions for a medication being prescribed. In a2d2, the work to be done by the microservice is specified in a process diagram in the standard Business Process Model and Notation. A process diagram is a set of tasks organized in a graph. The a2d2 software provides built-in tasks for querying and writing to FHIR APIs (of the EHR or other FHIR servers), calling non-FHIR APIs, parsing CDS Hooks requests and creating CDS Hooks cards, evaluating data against rules, sending text messages, transforming data into different models, and calling FHIR terminology services. The a2d2 software is implemented in Java. It uses JBoss’s jBPM Suite for the business process engine and JBoss Drools engine for rules evaluation. Process diagrams can be created using a web-based authoring workbench from JBoss. In our experience, the performance of the microservices is limited primarily by the response time of the FHIR APIs. For larger workloads, the a2d2 server can be horizontally scaled.

Results and Discussion
We have used a2d2 to create a variety of applications for different care settings that integrate with diverse EHR systems: (1) In an application for obtaining patient-reported outcomes (PROs), an a2d2 service was used for sending text messages to patients to complete the PROs at a physician-specified schedule. Another service received completed PROs, transformed them into documents, and wrote them into the patient’s chart in the EHR. (2) In an intraoperative CDS application integrated with the EHR, a2d2 services received asynchronous events such as intraoperative labs, and if needed generated alerts, and displayed them on the anesthesiologist’s monitor. Additional services provided drug dosing information and drug interaction alerts synchronously when medications were scanned for administration. (3) A SMART on FHIR application used in the ICU leverages an a2d2 service to prefill a form for the Sequential Organ Failure Assessment (SOFA) score with data from the EHR and another a2d2 service to calculate the SOFA score and perform risk stratification. (4) A pain management app used post-operatively in an acute care setting by surgeons, calls on a2d2 to compute from FHIR MedicationAdministration resources the dosage of opioids administered daily to a patient as morphine milligram equivalent. (5) An app for hypertension CDS uses a2d2 to obtain blood pressure data from a consumer health device and display the trends graphically. (6) A pharmacogenomic CDS application uses a2d2 to perform drug-gene interaction checking by querying specific regions of a patient’s whole genome sequence data, normalizing variants, computing genotypes, and creating FHIR DiagnosticReport resources.

Informaticians and analysts in our team have rapidly implemented complex automation logic for the services described above in a2d2. Externalizing this logic from the code of the applications has also allowed us to make and deploy updates to these automation services more frequently. We have found that a small number of built-in tasks described above have been sufficient to create many complex workflows due to the flexibility of the framework. We plan further enhancements to a2d2 to make development of services easier. We also intend to provide more support for standards such as supporting use of rules written in Clinical Quality Language and closer alignment with the work being done by the BPM+Health. The source code for a2d2 is available at https://github.com/elimuinformatics/a2d2.

Expanding the secondary use of prostate cancer real world data: Automated Classifiers for Clinical and Pathological Stage

Selen Bozkurt, PhD\(^1\), Tina Hernandez-Boussard, PhD\(^1\)

\(^1\) Department of Medicine, Stanford University, Stanford CA, USA;

Abstract

Cancer stage is essential to determine prognosis and treatment options, yet often recorded as unstructured text in EHRs. We developed an NLP solution to predict clinical and pathological TNM stages from EHRs from 5461 patients. We trained ML and rule-based algorithms to classify stage. We extracted TNM stages with high accuracy (average precision =90\% and recall = 86\%) and imputed 21\%-71\% of missing stage information in the institute cancer registry. Advanced NLP and ML technologies are necessary to capture staging information embedded in real-world data.

Introduction

Cancer stage is one of the most important parameters for cancer diagnoses, which guides treatment options and prognosis. However, this information is often not recorded in the electronic health record (EHR) as a structured field but instead found within the unstructured text and requires tedious manual effort to make this information available for secondary use. This presents a barrier to leveraging these real-world data sources for clinical research and clinical assertions. Therefore, adoption of advanced informatics methodologies such as machine learning (ML) and natural language processing (NLP) to unlock the vast information embedded in clinical free text and converting it into a usable structured format is essential to holistic use of the EHR.

Methods

We used data collected from a prostate cancer Clinical Data Warehouse (CDW), which links EHRs to the California Cancer Registry.\(^1\) As our primary guideline we used the most widely adopted cancer staging system for prostate cancer maintained by the American Joint Committee on Cancer (AJCC), which includes information on tumor, nodes, and metastasis.\(^2\) We developed two different NLP pipelines: 1) rule based and 2) semi-supervised machine learning. For each of T, N and M stages, we used the key-words based document-level vector representations of the text to train a classifier against the stage labels from the manually annotated set.

Results

There were 5461 prostate cancer patients in our initial cohort whose first line of treatment were completed in our hospital. Clinical stages of the patients were mostly T1 (44\%), N0 (61\%) and M0 (62\%). Likewise most of the patients’ pathological stages were T2 (51\%) and N0 (75\%). Since the number of patients whose pathological M stage is 1 were less than 10, these patients were excluded from the analysis. Overall, more than 20\% of staging information were missing for both clinical and pathological stages. Based on the distribution across all years, the highest number of missing cases were in 2018 (42\%). Manual chart review (‘gold’ standard) of the 1200 patients’ clinical and pathological reports were used for training and testing of the NLP models. For clinical T and N staging, rule based model outperformed the ML model with F1-scores over 0.71. However, for clinical M stage classification ML models reached better results than the rule based model with F1-score 0.98 for M0 and 0.88 for M1. For pathological T stage classification, both models achieved similar results with F1-scores over 0.85. ML model failed to classify N1 stages whereas rule based model reached F1-score of 0.88.

Conclusion

Cancer stage, a critical piece of information necessary to treat and prognosis newly diagnosed patients, is often not available in an easily obtainable format in real world data yet often missing. Our NLP pipeline to extract both clinical and pathological stages from clinical narratives and used this pipeline to augment staging documentation in our cancer registry.

Development of a multi-class deep-learning algorithm capable of diagnosing many histopathologic entities in digital pathology.

G. Thomas Brown¹, MD, PhD; Sudhir Sornapudi², PhD; Paul Fontelo³, MD, MPH
¹Artificial Intelligence Resource, NCI, NIH; ²Corteva Agriscience, Johnston, IA; ³National Library of Medicine, NIH

Introduction

The pathologist’s role in diagnosing cancer and guiding treatment is essential for patient care. As our understanding of cancer improves, the amount of knowledge required is increasing at a rapid pace, making the task of diagnosing tumors increasingly difficult, sometimes requiring expert consultation. Numerous papers have been published regarding digital pathology and machine learning¹⁻⁴, yet digital pathology tools remain primitive and not implemented on a wide scale. Although the practice of pathology covers a broad spectrum of diagnoses and organ systems, many reports have focused on limited specialties or diagnoses.

Methods

We have collected a wide variety of specimens to train a multi-class algorithm (VGG19) capable of assigning a wide range of diagnoses. We curated and digitized 2378 de-identified pathology slides (22 diagnoses). Pathologists digitally annotated regions of interest (ROI) indicating malignancies and patches (224 x 224 pixels) were extracted. Patches were also extracted from 112 benign slides. Three datasets were created at equivalent optical magnifications of 10X, 20X, and 40X. Each dataset was further split into 60% training, 20% for validation, and 20% for independent testing. Patches were only included in one arm of the dataset, i.e., a slide’s patches were not distributed across training, testing, or validation. We trained for over 200 epochs on a DGX-1 GPU server, and evaluated the model from the best epoch.

Results

The best results were generated with 20X magnification (Figure 1). The overall accuracy was 85% across the 22 classes, while the F1 score (micro) and Matthew Correlation Coefficient were 85% and 84%, respectively. When we trained at 40X magnification, the overall accuracy was 53%, while accuracy for training at 10X was 40%. At 20X, we achieved >90% accuracy for classifying clear cell renal carcinoma, mucinous carcinomas, granulosa cell tumors of the ovary, alveolar rhabdomyosarcomas, desmoid fibromatosis, pleomorphic sarcomas, urothelial carcinomas, and ganglioneuromas. Accuracy for angiosarcomas and malignant peripheral nerve sheath tumors was 30% and 25%, respectively. While 56% of lung squamous cell carcinomas were classified correctly, it erroneously labeled 26% of those cases as lung adenocarcinomas. Conversely, the algorithm correctly labeled lung adenocarcinomas 70% of the time, while misclassifying 14% of those cases as lung squamous cell carcinomas. The confusion matrices indicate 20X magnification yields the most accurate results.

Discussion

Current deep-learning algorithms generally focus on limited organ systems or diagnoses categories. We believe this is the first multiclass, deep-learning algorithm capable of diagnosing many histopathologic entities in general surgical pathology, with a resulting overall accuracy of 85% across the 22 classes. Although our algorithm performs well at 20X, it is unable to distinguish between different types of soft tissue tumors (e.g., sarcomas), which correlates with the difficulty human pathologists encounter, who often defer to sub-specialty trained pathologists. The algorithm also did not perform at a sufficient accuracy at differentiating between squamous cell and adenocarcinomas of the lung, corresponding to a major clinical error. The treatment regimens between the two are incompatible and could result in serious injury if the correct diagnosis is not made⁵. Finally, the algorithm misclassified benign nerve tissue into the general category of benign, which is not significantly incorrect clinically, but did count against its overall accuracy. Despite this, the overall accuracy was quite high. We plan to further expand the range of pathologic entities, which we believe will enhance its clinical utility, as well as in biomedical research. In countries where pathologists are in short supply, an algorithm such as this could aid oncologists and guide initial treatment, while waiting for confirmation. Likewise, practicing pathologists may be more confident in their diagnoses with a digital second opinion. Lastly, biomedical researchers could benefit from a “virtual pathologist”, as it can be difficult and/or expensive to solicit pathologist input.
How accurate is the Isabel diagnostic decision support system with patients presenting with acute symptoms of heart disease?

Katherine A. Brown, MSN, RN\textsuperscript{1}, Hamish S. F. Fraser, MBChB, MSc\textsuperscript{1}  
\textsuperscript{1}Brown University, Providence, RI, USA

Introduction

Diagnostic decision support systems have been developed to augment the diagnostic decision making process of clinicians over several decades and are intended to help improve patient safety by reducing diagnostic errors.\textsuperscript{1,2} Even as technology advances, algorithms have to date not been shown to outperform physicians, but when these CDS systems are used alongside the physician, they can improve the diagnostic accuracy of either one on their own. New electronic differential diagnosis (DDx) generators continue to be developed in recent years to augment clinician diagnosis, but more rigorous clinical evaluation based on real patient data and standardized evaluation methods is needed to best characterize their performance, accuracy, and ensure proper use by clinicians.

Methods

The purpose of this study was to measure the diagnostic performance of a well-established stand alone general medical diagnosis program designed for use by clinicians called Isabel Pro DDx Generator.\textsuperscript{3} This study used deidentified patient data from an earlier study that collected data on urgent admissions to cardiac services that obtained a differential diagnosis list from resident physicians and the specialized Heart Disease Program. The diagnostic performance of Isabel was tested from a cardiology perspective and compares its performance against the gold standard to that of resident physicians who collected and entered the data for urgent admissions.\textsuperscript{4,5} Clinical features from 57 patient cases (50\%) were entered into the Isabel Pro DDx Generator using a cardiologist validated protocol. After the checklist was generated, the top 20 diagnoses were recorded and compared to the final diagnoses (or “gold standard”) for each patient case from the original dataset. The performance metrics used for this study included Comprehensiveness (similar to sensitivity or recall), and Relevance (similar to Positive Predictive value or precision).\textsuperscript{6}

Results

Out of the 57 patient cases analyzed, 94.7\% had at least one match to the list of final diagnoses, 85.5\% had at least 2 matches, and 52.1\% contained 3 diagnoses matches by the Isabel generated suggestions. The mean Comprehensiveness and Relevance for the Isabel evaluation was reported for diagnoses generated at top 5, 10, and 20 thresholds. The Comprehensiveness measure is the proportion of correct diagnoses or matches to the total number of final diagnoses (similar to sensitivity or recall). The Comprehensiveness mean for all 57 patent cases was at 41.8\% for the top 5 output of diagnoses. It rose to 56.5\% for the top 10, and to 69.5\% for the top 20 threshold. Relevance is the proportion of matches to the total output list (or threshold maximums). The reported Relevance for all 57 patent cases was at 39.5\%, 28.7\%, and 23.1\% for the top 5, 10, and 20 thresholds respectively.

Discussion and Conclusion

The results show a majority of cases had at least one of the final diagnoses was present somewhere in the top 20 of the Isabel generated checklist of possible diagnoses. Comprehensiveness (top 10) matched those from the heart disease program and was higher than the physician performance from the previous study. This work along with further standardization of protocols, automated diagnosis matching strategies, and use of natural language processing can make strides toward large evaluation studies using real patient data extracted from Electronic Health Records.

Estimating Early Warning System Accuracy Prior to Implementation

Lusha Cao, PhD MS1, Gerald Shaeffer, MHI1, Meghan Galligan, MD1, Fuchiang Tsui, PhD1, Robert Grundmeier, MD1, Vinay Nadkarni MD1, Robert Sutton, MD MSCE1, Christopher Bonafide, MD MSCE 1, Naveen Muthu, MD1

1The Children’s Hospital of Philadelphia, Philadelphia, PA

Introduction

Critical deterioration events (CDEs) are life-threatening patient safety events in inpatient pediatric care that are challenging to recognize1. A pediatric early warning score (EWS) uses patient data such as vital signs to predict deterioration risk aim to help clinicians identify children at risk of deterioration1. While there has been a substantial amount of work to develop novel pediatric EWSs, less effort has been devoted to estimating the value of these scores prior to implementation in clinical care. Clinical care processes are already able to identify these patients (e.g. clinicians at our institution designate patients as “Watchers” when they are concerned), and in order to predict the value of a specific EWS2 for use by a freestanding intensive care rapid response team, we aimed to retrospectively estimate the accuracy of the EWS in addition to existing clinician recognition of at-risk “Watchers”.

Methods

Using data extracted from our institution's clinical data warehouse, we constructed a one-year dataset of inpatient encounters. We estimated EWSs at 4-hour time windows throughout each encounter by using the most recent relevant clinical observation and weighting according to the BedsidePEWS, a previously validated EWS2. This dataset was validated by manual chart review of 5% of CDEs by two authors (NM, MG). Sensitivity and positive predictive value (PPV) of the EWS were calculated based on the identification of CDEs in the 2-24 hours prior to the event.

Results

The cohort included 23,835 pediatric patients hospitalized for at least 4 hours in a medical or surgical ward, with 296 CDEs. High-risk patients identified by clinicians as “Watchers” was 40.9% sensitive for deterioration. When an EWS >=5 is added to clinician recognition (i.e. “Watchers”), 80.7% of CDEs were detected (Figure 1, last column). PPV of clinician “Watcher” identification was 16%, which was higher than either an EWS threshold ≥ 5 (3%) or ≥ 8 (8%). Estimating the predictive value of an “alarm” sent to a clinician every four hours for high-risk patients, we found that 14 Watcher alarms would fire for every one patient who deteriorated. Similarly, if EWS threshold was set at >= 8, then 14 alarms would fire and at >=5 then 33 alarms would fire for every one patient who actually deteriorated.

Figure 1. Proportion of critical deterioration events identified by EWS and/or “Watcher” labeling by clinicians.

Conclusion

Retrospective estimation of EWS accuracy suggests there is added value over clinician recognition, but the number needed to alarm is very high. This suggests that alternative approaches such as informing a proactive critical care outreach team may be a better use of an EWS risk score than sending an alarm to bedside teams. Such retrospective estimation of the value of prediction models should ideally be employed prior to EWS implementation into actual use.

Strategies to Engage Traditionally Marginalized Patients in Patient Portal

Heidi Carpenter1, Jacqueline Antoun1, Roman Gusdorf1, Austin Triana1, Elisa Friedman, MS2, S. Trent Rosenbloom, MD, MPH, FACMI, FAMIA2

1Vanderbilt University School of Medicine, Nashville, TN
2Vanderbilt University Medical Center, Nashville, TN

Description of the Problem: As patient access to electronic health records increases, older patients are often left behind due to less familiarity with computer use1. In addition, disadvantaged patient groups such as low-income, uninsured, non-English speaking, Black, and Hispanic patients are less likely to adopt the use of electronic patient portals2-3. My Health at Vanderbilt (MHAV) is a well-adopted electronic patient portal that has been in use at Vanderbilt University Medical Center since 20044. Patients can use MHAV to make appointments, access laboratory and imaging results and communicate with providers. Utilization of patient portals facilitates direct contact with the health care system and promotes transparency with reduction of errors; in addition, it increased patient connection, satisfaction, and treatment adherence4-5. To address barriers and disparities in MHAV access, a student-run initiative during the Martin Luther King Jr. day of service was created. Our aim was to target historically marginalized groups to improve MHAV adoption among diverse populations in preparation for COVID-19 vaccination opportunities.

Methods: Team members developed a database of all Vanderbilt University Medical Center patients ≥75 years old who did not have MHAV accounts. This patient list was organized by race and ethnicity to allow prioritization of patients from historically underserved populations. For this project, patients prioritized for enrollment were African American or Black race, Native Alaskan, American Indian or Hispanic ethnicity. Participating medical students contacted patients via telephone using a standard pre-approved script. The results of each encounter were categorized by patient contact status and MHAV status. Potential barriers were also coded, including access to hardware, technological literacy, waiting for assistance from children/caregiver, and language/hearing status barrier.

Results: During our student-wide day of service, 573 calls were placed. 86% were to Black or African American patients (n=492), 13% to Hispanic patients (n=76) and 1% to American Indian or Alaskan Native (n=5) patients. Calls answered in each group were 40% (n=196), 35% (n=27) and 75% (n=4) by race, respectively. In total, 3% of calls placed (n=17) resulted in successful sign-ups for MHAV. Of patients that were not successfully signed up (n=194), 18% (n=35) cited technological access or knowledge as the main barrier and 12% (n=24) took information about MHAV to sign up with a caretaker at a later time. Follow-up calls remained low yield.

Discussion of Results: This small pilot program identified that cold-calling older patients in historically marginalized groups has underwhelming efficacy for eliciting sign-ups to patient portal systems. Despite immense effort, most calls were unanswered. Those that did answer were not likely to sign up with lack of interest and lack of technological access as the two most common reasons.

Conclusion: Equal access to personalized health information and communication with providers is an important component of advancing health equity. However, cold-calling patients proved an ineffective method to engage older patients of traditionally marginalized groups in signing up for MHAV in preparation for COVID-19 vaccination efforts. Many cited access to technology and lack of technological literacy as the main barriers. Many planned to rely on others to access MHAV.

Attendee’s Take-away Tool: Cold-calling patients 75 years and older from marginalized groups is an ineffective strategy to elicit sign-ups for online patient portals in preparation for COVID-19 vaccination efforts.

Sepsis Prediction Using Semi-Supervised and Transfer Learning

John R. Caskey, PhD1, Fereshteh S. Bashiri, PhD1, Anoop Mayampurath, PhD2, Nicole Dussault2, Jay Dumanian2, Sivasubramanium V Bhavani, MD3, Kyle A Carey, MPH2, Emily R Gilbert, MD4, Christopher J Winslow, MD5, Nirav S Shah, MD5, Dana P Edelson, MD, MS2, Majid Afshar, MD, MSCR1, Matthew M. Churpek, MD, MPH, PhD1

1University of Wisconsin, Madison, WI; 2University of Chicago, Chicago, IL; 3Emory University, Atlanta, GA; 4Loyola University, Chicago, IL; 5NorthShore University HealthSystem, Evanston, IL

Introduction
Sepsis is a life-threatening response to infection and is a leading cause of in-hospital mortality. Early treatment can improve outcomes, while avoidance of unnecessary antibiotics in non-infected patients can avoid complications. Electronic health record data can be used to identify infected patients, but these data contain discrepancies like antibiotic orders for uninfected patients. Manual chart review can determine infection status but is time-consuming for building large cohorts. Semi-supervised learning methods can take advantages of data without labels, while transfer learning can utilize data labeled with surrogate definitions to improve accuracy. In this study, we compare semi-supervised and deep learning to identify patients who are hospitalized due to an infection.

Methods
We conducted a retrospective cohort study at six hospitals in Illinois between 2006 and 2018. A random selection of 2,724 charts of patients who received either antibiotics or blood cultures were reviewed to determine infection on admission status (labeled), with 819 (30%) of these randomly selected as the test set. The remaining 430,241 admissions not selected remained unlabeled. Data from the first 24 hours were used to predict infection status, with characteristics, vital signs, and laboratory values used as features. XGBoost was utilized for the following semi-supervised methods: (1) self-supervised learning, where predicted probabilities were generated in the unlabeled data using a model fit to the labeled 70% training data, with highly confident predictions relabeled; and (2) cluster-then-label, where the labeled and unlabeled patients were clustered using k-means, then the unlabeled patients were relabeled based on the majority class of the labeled patients. An XGBoost model was also fit by assigning infection status to the unlabeled data based on whether the patient met the Sepsis-3 Task Force definition of suspected infection (antibiotics plus cultures). Next, we constructed combined convolutional neural network and long short-term network (CNN-LSTM) models that (1) used the same Sepsis-3 approach for labeling, and (2) performed transfer learning by fitting to the unlabeled data using the Sepsis-3 outcome and then fine-tuning in the 70% labeled training data. All models were compared to each other and to baseline XGBoost and CNN-LSTM models that only used the 70% labeled training data using the area under the receiver operating characteristic curve (AUC).

Results
The XGBoost baseline model had an AUC of 0.76, and none of the semi-supervised learning methods improved performance (Figure). The CNN-LSTM baseline model performed better (AUC 0.78) than the XGBoost baseline model (0.76) and XGBoost with Sepsis-3 labeling (AUC 0.74). The CNN-LSTM model fit using the Sepsis-3 outcome obtained the highest AUC (0.81), which did not improve when using transfer learning (AUC 0.81).

Conclusion
CNN-LSTM models more accurately identified infection than XGBoost. Semi-supervised methods did not improve performance, nor did transfer learning, with the CNN-LSTM model using Sepsis-3 labels having the highest AUC.
Automatic Detection of Surgical Site Infections Using EHR Data

Arjun Chakraborty, MS, Kevin Lybarger, PhD, Dustin Long, MD, Vikas N. O'Reilly-Shah, MD, Meliha Yetisgen, PhD
University of Washington, Seattle, WA, USA

Introduction

Surgical Site Infections (SSI) cost $3.5-10 billion and affect 160-300 thousand patients per year in the United States. SSI surveillance is usually done through labor intensive manual patient chart review. Automatic SSI detection has been proposed using machine learning with electronic health record (EHR) data. We explore the prediction of SSI in orthopaedic surgeries using a deep learning architecture that utilizes structured data and clinical text data from the EHR. A model which retrospectively predicts SSI could be used to assess the effectiveness of hospital infection control efforts or monitor the rate of surgical site infections at a hospital. The neural SSI predictor achieves high performance, 0.81 F1.

Methods

We use an existing dataset of 2,611 orthopaedic surgeries performed at the University of Washington Medical Center and Harborview Medical Center between 2008-2020. This dataset includes gold standard labels for SSI that were manually assigned to each surgery as part of the ACS National Surgical Quality Improvement Program (ACS NSQIP). The distribution of the SSI labels is imbalanced with 168 SSI-positive (6.4%) and 2,443 SSI-negative (93.6%) cases. We explore two feature sets: structured and text. The structured feature set includes nine laboratory fields from 7 days preceding to 90 days following each surgery. For the structured feature set, missing and outlier values are mean imputed. The text feature set includes all the clinical notes from 7 days preceding to 30 days following each surgery. Clinical text is encoded using term frequency-inverse document frequency (TF-IDF) unigram features. The vocabulary size is 128827. Samples in the dataset were randomly assigned into train, validation (for hyper-parameter tuning), and test sets with 3:1:1 a ratio.

We explore the prediction of SSI, as a binary prediction task, using two machine learning architectures: neural network (NN) and random forest (RF). RF is an apt baseline for this task, as several previous works which attempt the same task have used an RF classifier. For the structured feature set, the NN includes a single output layer (size=1). For the structured+text feature set, the NN includes three hidden layers (sizes=1000, 100, and 15 respectively) and an output layer (size=1). The NN configuration includes the Adam Optimizer, initial learning rate (0.001), number of epochs (10), RELU activation in the hidden layers, and sigmoid activation in the output layer. We experimented with up sampling positive cases and down sampling negative cases to account for class imbalance, but performance did not improve. We implement the RF model as a baseline for the NN architecture. The RF configuration includes the maximum depth (25 for structured, 40 for structured+text), minimum samples per split (4 for structured, 6 structured+text), # estimators (50 for structured, 200 for structured+text), and maximum features (all features).

Results and Conclusion

Table 1 presents the precision (P), recall (R), and F1-score (F1) of RF and NN models on the withheld test set for the structured and text feature set combinations. The NN outperforms the RF for both feature sets. Including the text features improved precision and recall for both models. This indicates that clinical text notes augment the information about SSI contained in structured data fields. The best performing model was the NN model with the structured and text feature sets. As future work, we will perform a detailed error analysis on this data set, investigate ways to improve the performance, and evaluate the generalizability of the proposed approach to other surgery types.

A Generalizable and Scalable Distributed Processing Architecture for Guideline-Based Clinical Decision Support

Justin Chambers, BS\(^1\), Tanya Podchiyska, MS\(^1\), Samson W. Tu, MS\(^{1,2}\), Amy Robinson PharmD\(^1\), Susana Martins MD MSc\(^1\), Michael Ashcraft MD\(^1\), Mary K. Goldstein, MD MS\(^{1,2}\)

Introduction

We developed the Medication Safety (MedSafe) clinical decision support (CDS) system to provide a production platform for integrated population-based clinical quality assessment and guideline-based CDS for individual patients in the domains of hypertension, type-2 diabetes mellitus, and chronic kidney disease. The MedSafe CDS system encodes clinical practice guideline (CPG) recommendations and drug information as knowledge bases (KBs). Applying an encoded guideline KB to individual patient data to generate patient-specific recommendations is a resource intensive task. In the MedSafe context where the clinician-facing performance measure dashboard may request a very large number of patients at once, a one-patient-at-a-time approach would not be able to finish in allowed time window. Therefore, we distributed the workload across multiple execution instances linked through a network engine and decoupled each execution instance into its own environment to avoid threaded conflicts within a process accessing resources. Furthermore, we added means to schedule jobs, accept requests, and report build statuses.

MedSafe Processing Architecture

We developed a component-based architecture that ensures component decoupling and reuse. The components are:

- Dispatcher/Listener service (Swarm API) – A generic client interface, which we implemented as a web server to dispatch processing requests and react to returned events. In response to a request, it partitions the requested workload and then distributes and balances it over the available resources. For recurring tasks, a job scheduler was integrated into the system to trigger maintenance and build operations.
- Resource manager (Hive) – A manager of the local health of drone workers that, over time, terminates drone workers that are not being utilized and refreshing instances when they are needed again. The distributed hives forms a computing cluster of multiple servers that communicate with the Swarm API.
- Worker client (Drone) – A component that encapsulates the execution environment for running any algorithm independently without external interference. In our case, it encapsulates the EON execution engine\(^1\), which loads the encoded-guideline KBs and applies them to the patient cases assigned to them. The drone worker receives processing requests from the dispatching host and communicates its status back during processing.
- Data source – A replaceable component that, in our implementation, uses the VA SQL Field Reporting Enclave (FRE) to accesses VA data and, when processing has completed, returns the resulting recommendations back to the SQL database.

While this architecture has been designed to support batch processing requests from a population-based performance measure dashboard, it can also respond to real-time requests as the client interface, upon receiving a request, may call the Swarm API to dynamically check for availability of a valid existing recommendation, and, if not available, call on the other components to process the single patient case.

This architecture was inspired by distributed computation systems such as Pixar’s Tractor\(^2\), a modern and robust solution for network rendering. The functionalities of this processing architecture are orthogonal and compatible with contemporary CDS standards. For example, the drone workers could be configured for the execution of Arden Syntax modules or Clinical Reasoning artifacts written with Clinical Quality Language. The Swarm Web Server can be adapted to field CDS Hooks requests and return CDS Hooks cards.

emrKBQA: Creating a Clinical Knowledge-Base Question Answering Dataset

Rachita Chandra, MS¹,⁴, Preethi Raghavan, PhD¹,⁴, Jennifer J. Liang, MD²,⁴, Diwakar Mahajan, MS²,⁴, Peter Szolovits, PhD³,⁴

¹IBM Research, Cambridge, MA, United States; ²IBM TJ Watson Research Center, Yorktown Heights, NY; ³Computer Science and Artificial Intelligence Lab, Massachusetts Institute of Technology, Cambridge, MA, ⁴MIT-IBM Watson AI Lab

Introduction

The longitudinal, domain-specific nature of Electronic Health Records (EHRs) along with privacy concerns makes it difficult to develop large-scale annotated datasets for training machine learning models. This motivated the creation of emrQA¹, the first community-shared patient question-answering (QA) dataset, which was developed using a semi-automated process leveraging i2b2 annotations² to answer questions on unstructured clinical notes. Here, we present emrKBQA (complementary to emrQA), a dataset for answering questions on structured EHR data using MIMIC-III.

Methods

We generate emrKBQA by first collecting emrQA question templates and logical forms that were created from questions posed by physicians and subsequently normalized, e.g. “What is the dosage of insulin?” was converted to the question template “What is the dosage of [medication]?” These are then mapped to a corresponding logical form template. Second, question templates not answerable by MIMIC-III structured data are filtered out, and the entities and attributes in the remaining question and logical form templates are then mapped to the MIMIC-III schema. For example, since MIMIC-III does not capture relational information across tables, questions requiring such relations such as “Why did the patient have [treatment]?” are filtered out. Third, each question template is assigned one or more question types (YesNo, Temporal, Factual) depending on the kind of information it is seeking. Finally, question and logical form templates were populated with values from the MIMIC-III data tables, and the answer evidence extracted. The logic for these steps was implemented using SQL and shell scripts. Figure 1 shows an example of this process.

Results

Currently, emrKBQA consists of 940,713 question answer pairs over 100 patients, generated from 389 question templates and 52 question type-specific logical form templates. emrKBQA contains an average of 7.5 paraphrases per question type-specific logical form template (ranging from 1 to 55), where a paraphrase is defined as question templates sharing the same question type that map to the same logical form template. Of the generated question answer pairs, 90.9% are test results, 7.8% relate to medications, 1.2% to conditions, and the remaining to other topics (e.g. allergies, tobacco use).

Conclusion

In this work, we present emrKBQA, a dataset for QA on structured EHR data. emrKBQA is well suited for answering factoid questions since explicit values are well captured in tables, which may be difficult to infer from unstructured data. We believe emrKBQA is a pivotal contribution in the space, as together with emrQA, it provides the opportunity to explore differences between datasets derived from structured and unstructured clinical records, and to work towards a complete EHR QA system that considers data across both structured and unstructured data sources.

Towards Clinically Relevant Explanations for Type-2 Diabetes Risk Prediction with the Explanation Ontology

Shruthi Chari, MS, Prithwish Chakraborty, PhD, Oshani Seneviratne, PhD, Mohamed Ghalwash, PhD, Daniel M. Gruen, PhD, Daby Sow, PhD, Deborah L. McGuinness, PhD
1 RPI, Troy, NY; 2 Center for Computational Health, IBM Research, Yorktown Heights, NY

Clinicians who interact with clinical support systems often seek support beyond the displayed predictions - especially when seeing atypical patients or those who are not responding as expected. Depending on the context, clinicians summon different explanations (rationales) for reasoning, including contrasts, context, and evidence from the literature. Here, we present our vision to support user-centered explainability in a chronic disease comorbidities risk prediction setting where multiple data streams are typically used, leveraging a semantic resource we developed, the Explanation Ontology (EO).

In a type-2 diabetes (T2D) risk prediction use case, we are developing a pipeline to support a variety of explanations with different foci to explain the model predictions in a user-comprehensible manner. For risk prediction, we apply knowledge-infused Recurrent Neural Network models to assess the risk for comorbid complications within 365 days of each claim. Using post-hoc explainers, such as those from AIX 360 toolkit (https://aix360.mybluemix.net), we can generate explanations of such predictions at both model (e.g. global feature importance) and patient-level (e.g. personalized feature importance). In a proof-of-concept (POC) implementation, we contextualized risk prediction of a T2D comorbidity, Chronic Kidney Disease (CKD), through a question-answer approach to answer a pre-canned set of questions via feature importances and domain knowledge from the pharmacological chapter of the T2D guidelines. Building on this POC, we aim to enable user-centered explainability by leveraging the EO to present AI model components and relevant literature in a clinician-friendly manner (Fig. 1). The design allows clinicians to probe individual sections that highlight the different data streams for explanations. For instance, they might want to know “why a low risk for CKD, but a high risk for heart failure?” or probe the guidelines or cohort to understand “what was done for a similar patient case?” In part B of Fig. 1, we show an annotated example of an explanation generated by EO’s schema that elaborates on a risk prediction for a prototypical T2D patient. Such annotations can further help clinicians inspect explanations. We are currently extending the POC to support explanations to a more extensive set of questions for a T2D comorbidities use case.

Abstract

Every month, ~10,000 new articles are added to LitCovid, a literature database of COVID-19 related papers in PubMed; this rapid growth challenges the LitCovid curation pipeline. A primary bottleneck is annotating each article with up to eight possible topics. This study proposes AM2BERT, a transformer-based multi-label classification model. It achieves the highest overall performance (up to 8% higher macro-F1 score) and only requires ~15% of the inference time compared with the current best model.

Introduction

The number of articles in the literature related to COVID-19 is growing by about 10,000 articles per month (1). LitCovid (2, 3), a literature database of COVID-19 related papers in PubMed, has accumulated a total of more than 100,000 articles, with millions of accesses each month by users worldwide. LitCovid is updated daily, and this rapid growth significantly increases the burden of manual curation. In particular, annotating each article with up to eight possible topics, e.g., Treatment and Diagnosis, has been a primary bottleneck in the LitCovid curation pipeline.

Background

Innovative text mining tools have been developed to facilitate biomedical literature curation for over two decades (4). Topic annotation in LitCovid is a standard multi-label classification task, which aims to assign one or more labels to each article (5). To facilitate manual topic annotation, we previously employed the deep learning model Bidirectional Encoder Representations from Transformers (BERT) (6). We used one BERT model per topic, known as binary relevance BERT, and previously demonstrated this method achieved the best performance of the available models for LitCovid topic annotations (3); other studies have reported consistent results (7). However, this method has two primary limitations. First, by training each topic individually, the model ignores the correlation between topics, especially for topics that often co-occur, biasing the predictions and reducing generalization capability. Second, using eight models significantly increases the inference time, causing the LitCovid curation to require significant computational resources.

Method and results

Therefore, this paper proposes an Attention guided and regularized Multi-label classification model via Multi-task training and BERT as the backbone, which we refer to as AM2BERT. AM2BERT shares the BERT representations among the topics but uses a novel multi-channel attention mechanism to learn topic-specific representations. It also regularizes the representations via co-topic attention and auxiliary tasks. We compared AM2BERT to three baseline methods using two sets of evaluation metrics (label-based and example-based) commonly used for multi-label classification (8). It achieved the highest performance on the test set (2% higher macro F1-score and up to an 8% higher F1-score on a single topic than binary relevance BERT), and evaluating its generalization shows that it is much more robust to new articles (over 8% higher macro F1-score). Importantly, it requires only ~15% of the inference time needed for binary relevance BERT, significantly improving efficiency. AM2BERT has been employed in the LitCovid production system, making the curation more sustainable. We also make the datasets publicly available to the community via https://ftp.ncbi.nlm.nih.gov/pub/lu/LitCovid/topic_tagger/.

Localize the implementation of FDA list of confusable drug names with the application of Taiwan National Health Insurance database: a study of text similarity computation with real-world data

Ya-Lin Chen, PharmD1, Hsuan-Chia Yang, MSc, PhD1++, Der-Ming Liou, PhD1++
1Graduate Institute of Biomedical Informatics, College of Medical Science and Technology, Taipei Medical University, Taipei, Taiwan; ++: Yang, H.C. and Liou, D.M. contributed equally to this work

Introduction: Food and Drug Administration List of Established Drug Names Recommended to Use Tall Man Lettering (FDA list) has been widely implemented in Taiwan. However, a report from Taiwan government indicated that incorrect drug prescription due to name confusability is the main reason for patient harms. Drugs with similar names and frequently co-prescribed are at higher risk of contributing to medical errors due to cognitive confusion. We proposed a method to incorporate FDA list, text similarity computation and the real-world data of National Health Insurance database from Ministry of Health and Welfare of Taiwan, to optimize FDA list use in Taiwan by differentiating risk levels of cognitive confusion among drug pairs in the list.

Method: Text similarity of each pair of drugs in the FDA list was calculated by Python Levenshtein package. Drugs in all pairs were then labelled with WHO ATC codes and linked with co-occurrence counts and MMQ [1]. Co-occurrence is defined as the frequency of two drugs appearing in the same prescription; MMQ is defined as the ratio of joint probability of two medications in the database and the multiplication of the respective probabilities of two drugs. The two drugs whose respective probabilities are independent would have MMQ value of 1.

Results: After mapping drug pairs in the FDA list to WHO ATC codes, forty distinct pairs of drugs with administration routes as oral or parenteral were found. The median value of Levenshtein ratio among the pairs was 0.595. Fifteen drug pairs were further matched with co-occurrence and MMQ (Figure 1). Two thresholds were identified for risk categorization: the median value of co-occurrence and the value 1 of MMQ, represented as dotted lines in Figure 1. Four risk levels of cognitive confusion, Group A, B, C, and D, represent potential risk from high to low, based on the two decision thresholds. Drug pairs with red dots represent those with Levenshtein ratio more than 0.595, and the pairs with blue dots represent those with ratio less or equal to 0.595.

Conclusion: More than half of the drugs in FDA list are used in Taiwan, which highlights the importance of FDA list use. The optimization of the list use is valuable in tailoring international guidelines into local needs. This study developed a decision process for such purpose with risk levels of confusion. The study result can be further utilized for pharmacy storage layout adjustment or embedded in clinical decision support systems for prescription evaluation.

Early Prediction of Autism Spectrum Disorder Using Health Claims Data

Yu-Hsin Chen, MS1, Qiushi Chen, PhD1, Lan Kong, PhD2, Guodong Liu, PhD2
1The Pennsylvania State University, Department of Industrial and Manufacturing Engineering, University Park, PA, USA; 2The Pennsylvania State University, Department of Public Health Sciences, Hershey, PA, USA

Introduction

Autism spectrum disorder (ASD) is a lifelong neurodevelopmental disorder that affects every 1 in 54 children in the US.7 Certain medical conditions have found to be associated with ASD prior to the onset of behavioral symptoms, but no study has systematically examined the predictive value of the medical records in young children. Our objective is to explore the feasibility of predicting the ASD diagnosis using claims data in children between age of 18-30 months.

Methods

Using the MarketScan® Commercial Health Claims database from 2005-2016, we retrospectively created a study cohort of children with and without confirmed ASD diagnosis based on ICD-9 and ICD-10 codes (12,743 ASD and 25,833 non-ASD subjects identified in total). Independent predictor variables included demographic variables, number of emergency department visits, and numbers of healthcare encounters for each diagnosis and procedure category grouped by the Clinical Classifications Software. We compared Lasso logistic regression (LR) and random forest (RF) in predicting the ASD diagnosis given all available clinical information up to ages of 18, 24, and 30 months, respectively. We randomly sampled from the identified cohort to create a large balanced training dataset (N=20,000) with 10,000 ASD and non-ASD subjects, respectively, and an independent testing set (N=16,123) with a matched prevalence of ASD (1 in every 54) in the US. We repeated random sampling with 50 replications for model validation.

Results

At the age of 24-month, the LR and RF models showed the area under the receiver operating characteristic curve (AUROC) of 0.758 (95% Confidence Interval [CI]: 0.753-0.762) and 0.773 (0.770-0.777), respectively (Table 1). Compared with the LR model, RF model also showed higher area under precision-recall curve (AUPRC) and F1 score. The RF model achieved higher performance consistently in all other measures compared with the LR model. We also found that the prediction accuracy increased with the age of prediction, as more clinical information was available for model training at an older age. When the predictor variables were separated by outpatient and inpatient visits, the RF model for prediction at age of 24 months achieved a higher performance with an AUROC of 0.837, which translates into a promising improvement in sensitivity (40% vs. 38.8%), specificity (96.6% vs. 94.9%) and positive predictive value (PPV; 18.3% vs. 14.6%) compared with the existing screening tool.

Discussion

To the best of our knowledge, our study is the first to predict the ASD risk in young children based on longitudinal medical information from a large health claims database using machine learning models. Our findings have demonstrated the promise of leveraging real-world health claims data to monitor the risk of ASD among very young children and to identify those at high risk for targeted screening, diagnosis and early interventions.

Data Coordination for Multi-Site Clinical Trials Using the REDCap Application Programming Interface

Alex C. Cheng, Ph.D., MEM, Mark McEver, Francesco Delacqua, Adam Lewis, MS, Patrick Newman, MBA, Paul A. Harris, Ph.D.
Vanderbilt University Medical Center, Nashville, TN

Introduction

Coordinating data collection, transfer, and harmonization is a challenging task for multi-site clinical trials. Data coordinating centers (DCC) devote much effort to making sure data is collected uniformly across sites. Additionally, study sites are often wary of entering data directly into an electronic data capture system at a DCC outside their hospital firewall without first having the opportunity to validate and de-identify the data. Due to these challenges, there has been increased interest among groups such as the NIH Collaboratory and the Trial Innovation network for a decentralized model for multi-site trial data collection. We have designed a framework that gives sites control of their own data collection while addressing some inefficiencies of multi-site clinical trial data coordination using REDCap as an engine for data interoperability. REDCap (Research Electronic Data Capture) is a secure, web-based software platform designed to support data capture for research studies in use at nearly 5000 institutions in 141 countries. Its ubiquity among medical centers conducting clinical research use makes it an ideal platform for coordinating multi-site data collection.

Methods

Figure 1 illustrates the data flow for a multi-site trial that collects EHR data and uses this framework. At each site, REDCap uses the HL7 Fast Healthcare Interoperability Resources (FHIR) application programming interface (API) to extract data from the EHR into REDCap. Sites’ study personnel use REDCap’s Clinical Data Interoperability Services (CDIS) module to map data elements available through their EHR FHIR APIs to data elements in the study data dictionary. An external module called API Sync allows for automatic data pushes between REDCap projects with compatible data fields. An authenticated user generates an API key for the DCC REDCap project, which sites use to push data to the DCC. This allows data to flow automatically and securely from the sites to a DCC at a specified frequency.

Results

We are applying this framework to two ongoing multi-site studies where Vanderbilt University Medical Center (VUMC) is the DCC. These studies have approved waivers of informed consent. So far, for one of these studies, two sites have transferred 883,133 data elements for 972 study participants to VUMC using API Sync. Statisticians are able to analyze, in real-time as data are entered by the sites, every participant record from the sites, with EHR data collected through the FHIR API. All data is de-identified and date shifted by REDCap before being sent to the DCC. Currently, 99 institutions have downloaded API Sync from the REDCap External Module Repository.

Discussion

This data collection and transfer framework offers several advantages over traditional methods for data coordination in multi-site clinical trials. The data dictionary distributed to the sites allows the DCC to provide structure for study data while giving site control over their data collection. Using API Sync to transfer data streamlines the process of having to download, de-identify, reformat, send, merge, and harmonize data at the DCC. These processes can all be done within REDCap and scheduled to occur on a regular frequency. The use of REDCap APIs is enabling an automated data pipeline that reduces study personnel burden and increases the accuracy and efficiency of data collection and coordination.

An eConsent Process Framework to Optimize and Standardize Development, Deployment, and Management of Electronic Informed Consents

Benjamin Chisum, BS¹, Kevin M. Johnson, MBA¹, James Ruesch, MBA, CCRP¹, Patti Spencer, BS¹, Pallavi Ranade-Kharkar, MS, PhD, FAMIA¹
¹Intermountain Healthcare, Salt Lake City, UT

Introduction
Research suggests that the delivery of a research informed consent via electronic means (eConsent) can improve participant’s informed consent experience, ease of access, broaden opportunity to participate in trials, improve enrollment potential, and substantially lower the cost of human capital. However, little guidance is available regarding the development of a successful standardized eConsent delivery system, especially across large research systems where numerous clinical trials are conducted. Guidance regarding deployment and management of each study’s unique eConsent process is equally sparse. The process of developing an effective eConsent tailored to the unique requirements of each study and subsequent deployment is complex and many unforeseen technical, operational, and user-related issues may arise. The objective of this project is to propose a framework to optimize, standardize, and disseminate guidelines and best practices for development, deployment, and management of eConsents.

Method
Intermountain Healthcare has developed and deployed more than 100 eConsents since 2015, utilizing multiple platforms. The primary platform used was REDCap. We applied this experience and lessons learned to develop a generalizable eConsent framework. The framework provides instructions and guidelines for the development, deployment, and management life cycle of an eConsent. Development of the framework occurred over the course of many instances of eConsent development for many research departments. Each department’s input helped further grow the framework. As each eConsent was deployed, the framework was subsequently enhanced, optimized, and standardized. The framework spans the process end-to-end from eConsent platform requirements all the way to archival methodology. This framework is a living application that allows active updates to grow the comprehensive eConsent guidelines, experience, and standardization.

Results and Discussion
The eConsent framework is comprised of multiple sections, including: ‘System/software specification,’ ‘Compliance,’ ‘Development,’ ‘Deployment,’ ‘Management,’ and ‘Study closeout/archival.’ Each section includes sub-sections that further outline sub-processes. For example, sub-sections under ‘Development’ include ‘Deployment method,’ ‘Design,’ ‘Communication modality and language,’ ‘Method for subjects to ask questions,’ ‘Legal certification and verification,’ and ‘Return completed consent to subject.’ We recently applied the framework to two high-enrolling studies. One of the studies with a participant enrollment goal of 9,000 projected that the study would require 20 coordinators to facilitate traditional informed consenting. Strategies from the eConsent framework lead to successful deployment of an eConsent that allowed the study to operate with only three study coordinators. The study is subsequently saving more than $1,000,000 in annual salary and benefit expenses. Another study is on-track to enroll 500,000 subjects over the course of five years. This goal would be unfeasible utilizing traditional coordinator-based consenting. Further, a vended eConsent product for this enrollment goal would cost at least $10,000,000 (at $20 per patient per eConsent). During COVID, the guidelines of the eConsent framework allowed for successful and rapid eConsent development and deployment for extremely fast-moving trials.

Conclusion
Development of an optimized and standardized eConsent framework can enable successful and efficient deployment and management of eConsents. Detailed, actionable, and sharable knowledge regarding the lifecycle of an eConsent can improve growth, efficiency, and success of future eConsents. We would like to further develop a platform that is accessible to the global research community and allows for collaboration towards growth of the body of knowledge.

Usability of Clinical Decision Support System for Nursing Care Planning in Palliative Care: Heuristic Evaluation

Hwayoung Cho, PhD, RN1, Gail Keenan, PhD, RN, FAAN1, Olatunde Madandola, MPH, RN1, Fabiana Dos Santos, MSN1, Tamara Macieira, PhD, RN1, Ragnhildur Bjarnadottir, PhD, MPH, RN1, Karen Priola, MS1, Karen Dunn Lopez, PhD, RN2

Introduction

A clinical decision support system (CDSS) is a persuasive tool aimed at supporting evidence-based practice by providing the right information in the right format at the right time to improve patient outcomes at the point of care. In response to the lack of CDSS tools for nurses in palliative care, our study team developed an electronic nursing Care Planning System (CPS) that facilitates evidence-based decision making for nurses caring for end of life patients.1 Our CPS is an electronic nursing documentation and care planning prototype system that can be interfaced with electronic health records (EHRs). Despite the proliferation of technology (EHRs/CDSS) in today’s health care, many systems have not been rigorously evaluated. We aimed to evaluate the usability of the CPS from expert perspectives, before we test the efficacy of the CPS in a randomized controlled trial (RCT) with a nationally representative sample of 220 registered nurse (RN) subjects.

Methods

We conducted a heuristic evaluation with experts in informatics to identify violations of usability principles. Using purposive sampling, six experts were invited using email. Qualifications of the experts included having a doctorate degree in informatics and training in human-computer interaction. Each expert was provided an orientation (PowerPoint video) about how the CPS worked and two use cases that would require users to adjust the plans to the unfolding context. Each expert was then asked to independently interact with the CPS and to complete a heuristic evaluation checklist based on Nielsen’s 10 heuristics.2 The overall severity for each heuristic item was rated on a scale of 0 (no problem) to 4 (usability catastrophe), and space was provided for experts to add comments. Because our upcoming clinical trial will test evidence-based suggestions using three types of formats (text, table, graph), Aesthetic and Minimalist Design heuristic was evaluated for each format. All experts’ comments about usability problems on the heuristic evaluation checklist were synthesized by two health information technology usability experts (HC&KDL). Discrepancies in coding data according to the usability factors of Nielsen’s 10 heuristics were discussed about usability problems on the heuristic evaluation checklist. The mean scores of the overall severity of the identified heuristic violations ranged from 0.66 (Flexibility and Efficiency of Use) and 2.00 (User Control and Freedom/Error Prevention), in which scores closest to 0 indicate a more usable system. The mean scores and sample comments per heuristic are listed in Table 1. To maintain User Control and Freedom, experts suggested the ‘undo’ function not be limited and to give users the ability to fix both current/expected nursing outcome scores. To improve Recognition Rather than Recall, experts recommended clicking the ‘undo’ button to see what was undone should be recognizable within the CPS. In response to the usability factor Match between System and the Real World, experts pointed to the opposite direction in pain scale scores used in our system when compared with those commonly used in clinical practice.

Results

Mean scores of the overall severity of the identified heuristic violations ranged from 0.66 (Flexibility and Efficiency of Use) and 2.00 (User Control and Freedom/Error Prevention), in which scores closest to 0 indicate a more usable system. The mean scores and sample comments per heuristic are listed in Table 1. To maintain User Control and Freedom, experts suggested the ‘undo’ function not be limited and to give users the ability to fix both current/expected nursing outcome scores. To improve Recognition Rather than Recall, experts recommended clicking the ‘undo’ button to see what was undone should be recognizable within the CPS. In response to the usability factor Match between System and the Real World, experts pointed to the opposite direction in pain scale scores used in our system when compared with those commonly used in clinical practice.

Conclusion

The results of this heuristic evaluation will be used to guide improvements in our CPS design/interface including content, organization and workflow. These refinements will be made in our current RCT with 220 RNs in which we are testing the optimal CPS format and decision time, and evaluating simulated patient outcomes related to the CPS formats. Rigorous testing of the CPS using heuristic evaluations can enhance the likelihood of adoption of the CPS to diverse nurses in real-world practice.

The CPS was synthesized by two health information technology usability experts (HC&KDL).
A Quantitative Exploration of Nurses’ Numeracy and Understanding of Predictive Models

Insook Cho, PhD1*, Mi Ra Song, MS2, Shim So Yun, MS2, Dan So Young, MS2
1Nursing Department, Inha University, Incheon, Republic of Korea; 2Department of Nursing, Samsung Medical Center, Seoul, Republic of Korea

Introduction

The rapid expansion of electronic health-care predictive models stemming from the increasing availability of electronic health-record data is introducing new challenges and opportunities that are not covered by earlier health-care models, algorithms, and tools. One concern is that clinicians may not receive the requisite professional training for utilizing the emerging predictive modeling paradigm in health care. The concerns range from clinicians’ and managers’ poor understanding of concepts in probability, statistics, and heuristics to the health-care professional curricular and training. Given the novelty of predictive models to nurses, this study aimed to quantitatively explore nurses’ understanding and their perceptions about probability-based information of predictive models.

Methods

Sixty nurses working at six medical-surgical nursing units in a tertiary academic hospital located in Seoul were recruited in 2020. We applied a stratification sampling framework to the participating nurses according to their level of experience at the unit: novice (<2 years), junior (2–5 years), and senior (>5 years). The survey instrument included educational modules about predictive models, sensitivity, specificity, and confidence intervals (CIs) [1]. Follow-up questions tested the abilities of the participants to interpret these characteristics with both verbatim and gist knowledge. Each module presented the statistical concept in the context of a weather prediction, which was chosen to remove any potential cognitive or affective influences common in medical decision making. Verbatim knowledge is the ability to interpret specific number associated with the model performance characteristics described in the question stems. Gist knowledge is the ability to discriminate the central meaning qualitatively. Objective numeracy and subjective numeracy were also assessed using the short form of the Numeracy Understanding in Medicine instrument (S-NUMi), the Subjective Numeracy Scale (SNS), and an objective numeracy scale [2].

Results

Among 60 nurses, the mean correct responses were 95.0% for sensitivity, 93.9% for specificity, and 68.9% for CIs. Verbatim interpretation was significantly higher than gist knowledge for sensitivity ($\chi^2=8.57, p=0.0061$), but not for specificity and CIs ($\chi^2=4.90, p=0.0535; \chi^2=0.54, p=0.4642$). Scores on each discrete choice experiment tasks were high in each category (Table 1). The overall knowledge score was 85.9%, which was not associated with the scores of subjective and objective numeracy measures. The scores of S-NUMi, SNS, and objective numeracy scale were 7.00±0.88 (mean±SD), 4.65±0.83, and 6.17±0.92, respectively.

Scores are reported as mean percentages with 95%-confidence intervals. DCE means discrete choice experiment.

Conclusion

These results suggest that nurses can interpret quantitative performance measures of predictive models with high accuracy but have considerably lower when interpreting CIs. Their numeracy scores were moderate-to-high level but was not related to ability to interpret performance measures.

Designing a Data Quality Characterization Tool for Fitness Tracker Data

Sylvia Cho, MHS, MA¹, Karthik Natarajan, PhD¹
¹Department of Biomedical Informatics, Columbia University, New York, NY

Abstract
In this study, design requirements of a data quality (DQ) characterization tool for fitness tracker data was identified through findings from previous studies on DQ challenges and dimensions, literature review to find fitness-for-use measures, and interviews with stakeholders. Two design requirements were identified: (1) the tool should be able to characterize data in terms of DQ dimensions and corresponding measures, and (2) contextual information such as metadata and demographic data should be provided.

Introduction
Lack of trust in the quality of data is a barrier to using electronic health data. As DQA is a time-consuming and difficult task, a tool that supports DQA would facilitate the use of data. DQ is commonly defined as fitness-for-use which means that the quality of data is dependent on users’ needs or a specific task. While existing tools provide descriptive statistics or exploratory data analysis that are independent of any specific use case (e.g., percent missingness in a column), it rarely focuses on fitness-for-use measures that are specific to a research question. The aim of this study was to identify design requirements of a DQ characterization tool for fitness tracker data focusing on fitness-for-use measures specifically for data completeness.

Methods
Design requirements were identified through three methods/sources: (1) findings of previous studies on DQ dimensions and DQ challenges [1,2], (2) literature review to identify fitness-for-use data completeness measures that are commonly used in research studies utilizing fitness tracker data, and (3) semi-structured interviews on the current practices of data completeness assessment and challenges of determining the fitness-for-use of a dataset. Thematic analysis was conducted on the transcript.

Results
Two major informational needs emerged from the methods and sources we used. The results are presented in Table 1.

Table 1. Informational Needs and Design requirements Identified through previous studies, literature review, and interview

<td></td>
<td></td>
</tr>
<tr>
<td>• Time of data collection</td>
<td></td>
<td></td>
</tr>
<tr>
<td>• Demographics</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Based on these findings and the authors’ knowledge on DQA, the prototype of the tool included the following features:
1. **Users can define density completeness that fits their use case**: Based on a previous study, the tool should be able to characterize DQ in terms of breadth and density completeness and its corresponding measures.[2]
2. **A data summary on the cohort that meets the completeness definition**: The tool calculates the total number of subjects meeting the completeness criteria for each data types (e.g., step count, heart rate) and summarizes metadata such as device type and data collection period, and also descriptive statistics on demographics.

Conclusion
In this preliminary study, design requirements of a DQ characterization tool with a goal to support fitness-for-use was investigated and applied to the design of the tool. A future study will be conducted to evaluate whether a DQ characterization tool focusing on fitness-for-use measures is more useful to researchers than an intrinsic DQ characterization tool.

Dynamic Phenotyping of Multi-Modal COVID-19 Endotypes

Sutanay Choudhury\textsuperscript{1}, Khushbu Agarwal\textsuperscript{1}, Colby Ham\textsuperscript{1}, Pritam Mukherjee\textsuperscript{2}, Siyi Tang\textsuperscript{2}, Sindhu Tipirneni\textsuperscript{3}, Chandan Reddy\textsuperscript{3}, Suzanne Tamang\textsuperscript{2}, Robert Rallo\textsuperscript{1}, Veysel Kocaman\textsuperscript{4}
\textsuperscript{1}Pacific Northwest National Laboratory; \textsuperscript{2}Stanford University; \textsuperscript{3}Virginia Tech.; \textsuperscript{4}John Snow Labs

Introduction

We aimed to dynamically characterize different multi-modal endotypes (i.e., subtypes) of COVID-19 patients and the effectiveness of hospital-based treatments, over the course of the pandemic. Our analysis found that among COVID-19 patients that experienced a poor outcome, the average LOS reduced after June, while remaining consistent for admissions that did not experience a poor outcome. Also, that clinicians were able to more effectively treat severe COVID-19 cases – or at least specific endotypes of complex, high utilization cases – as the outbreak progressed.

Methods

We conduct our study using a deidentified version of the STARR-OMOP dataset containing both structured electronic healthcare records and free form clinical notes from Stanford Medicine. We represent each patient stay in the hospital as a sequence of sets over time (subsequently referred to as patient trajectory), in which each set represents a snapshot of the patient state comprising diagnosis codes, drug orders and laboratory measurements aggregated over time. Each admission was assessed to determine if a poor COVID-19 related outcome occurred, which was true in the event of ventilator support, ICU admission or inpatient death. To characterize baseline risk factors, we processed each patient’s clinical notes in the first 24 hours of their visit. We processed the clinical notes using the entity resolver model from SparkNLP framework to translate the clinical notes to another temporal set-based data representation. We used a frequent pattern mining method\textsuperscript{1} to discover frequent endotypes among COVID-19 cases.

Results

We show descriptive statistics for our COVID-19 cohort in Figure 1(a). Figure 1(b) shows the monthly ranking of baseline risk factors extracted with NLP. Figure 1(c) compares the distribution of LOS over time for patients with a poor COVID-19 related outcome to the rest of the cohort.

Title: Using Deep Neural Network Binary Classifiers to Infer MeSH Publication Types

Victor Cid, MS and James Mork, MSc, National Library of Medicine, Applied Clinical Informatics Branch, National Institutes of Health, Bethesda, MD

Introduction: We use Deep Learning (DL) models to label PubMed’s MEDLINE citations using a 59-Publication Type (PT) subset of MeSH Publication Types\(^1\) used by NLM indexers. Our training corpus is limited to metadata in MEDLINE citation records. We trained binary classifiers using modern Transformer-based deep learning models with labeled data from PubMed’s 30 million citations, and combine these classifiers on an application that can process tens of thousands of citations daily. We developed a method to carefully engineer training examples in order to maximize the performance of our DL models.

Methods: We use MEDLINE citations to train BERT and DistilBERT\(^2\) models using transfer learning for binary text classification. Previous efforts have used multi-class classifiers\(^3\). There is great variability in the data available for different PTs, ranging from a few hundred to over a million records. We address data balance in a per-class fashion. The corpus data contains over 20 features, but through experimentation we selected Title, Abstract, Authors and Journal Unique ID as best class predictors. We developed a method to prepare training datasets to maximize model performance. The 59 trained models were combined to produce multiple labels for each document, excluding prohibited co-occurrences, and results with scores over 0.93 (determined experimentally), were included in the final output PT labels.

Results: This work is ongoing. We achieved high recall and F1-scores (both 0.84 to 0.99) for all individual trained models, but the application combining all 59 models achieved only a 61% labeling accuracy. Pruning lower-performing models increased the application performance up to about 80% accuracy. Our data engineering approach proved to enhance the application’s inference accuracy by about 15% compared to random sampling, and reduce false positives by about the same amount. DistilBERT proved to be about 50% faster to train and about 90% faster to perform class inferencing than BERT, while conveying very similar training scores. The inference time is particularly important as the application must process up to about 20,000 citations daily, which even with DistilBERT can take hours to complete in our experimental setup. In an effort to achieve better application accuracy, we are both, enhancing the training of classifiers via varying training parameters, and pruning models from the application that we cannot further improve with the available data when necessary. Furthermore, this work is also providing insight on the value of different MEDLINE data features to predict publication types.

National COVID Cohort Collaborative (N3C) Case-control Buddies

G. Marshall Clark¹, Adam M. Lee, MBA¹, Emily R. Pfaff, PhD¹, Kristin Kostka, MPH² ³, Matvey B. Palchuk, MD⁴, Lora Lingrey, BS⁵, Michele Morris, BA⁵, Robert Miller, MS² ⁶¹University of North Carolina at Chapel Hill, Chapel Hill, NC, ²Real-World Solutions, IQVIA, Cambridge, MA ³The OHDSI Center at The Roux Institute, Northeastern University, Portland, ME ⁴TriNetX, Cambridge, MA, ⁵University of Pittsburgh, Pittsburgh, PA, ⁶Tufts Clinical and Translational Science Institute, Boston, MA

Introduction

The National COVID Cohort Collaborative (N3C) required control matches for COVID-19 cases identified by the N3C Phenotype team. The N3C Phenotype team created a case-control matching system that algorithmically assigns persistent case-controls coined as phenotype buddies for the data submissions to the N3C enclave.

Methods

The N3C phenotype 3.0 introduces specific SQL in multiple code variants that create data structures and match controls to the phenotype cases. The code creates tables locally at each site that hold all cases and controls, specifically a permanent data structure, N3C-CONTROL-MAP, table that houses the cases and control population and variables: age group, sex, race, and ethnicity for cases and their buddies. Ages are grouped in 5-year bins, samples are (0-4), (5-9), (85-89), (90+). This table allows the phenotype to maintain persistent buddies per case, while the phenotyping algorithm dynamically checks both cases and controls for cohort eligibility. Cases that are no longer eligible become potential controls, and controls classified as new cases are removed as buddies, and new buddies are assigned. The phenotype progressively matches controls based on variable sets, with each group achieving a matching level as indicated in Table 1, with level 4 being the best match. The data structure and matched buddies are bundled in each site’s data payload to the N3C enclave providing a back-up to the N3C-CONTROL-MAP in case of data loss or corruption. The phenotype SQL code is publicly available at: https://git.io/JqZHi

Results

The N3C Phenotype team’s case-control buddy system matches 90.87% of cases with viable controls on age group, sex, race, and ethnicity. Exact age is the most unmatched factor of the individual variables, with only 34.62% of all cases matching, but creating the age groups increased that match percentage to 98.22%. The remaining variables checked independently are as follows: sex (99.99%), race (97.00%), and ethnicity (96.96%).

</tr>
</tbody>
</table>

Table 1 Control Buddy percentage by match level

Discussion

The current phenotype version 3.1 supports two buddies per case; revisions are underway to scale the number of buddies to any number of case-control matches as requested by N3C and deliverable by each site. While the current iteration of the N3C Phenotype buddy algorithm matches four variables, the code is extensible to add additional matching variables, such as secondary race, geographical region, co-morbidity, or other suspected confounders. Albeit, the extensibility is not ad hoc or site-specific and is determined by N3C. The N3C phenotype buddy system only provides suitably matched controls of non-exposure patients defined by the N3C phenotype; it does not provide study-specific analysis, odd ratios, or insights into efficiency or collider bias¹.

Conclusion

Overall, the N3C Phenotype team developed and implemented a case-control solution for the advancement of COVID-19 research. This phenotype and the buddy matching algorithm allow N3C and collaborators to analyze controls on the over 900,000 COVID19 positive cases currently in the N3C enclave.

Healthcare System Performance on Unsafe Medication Orders in the 2019 CPOE Evaluation Tool

Zoe Co, BS1, Lisa P. Newmark, BA2, David C. Classen, MD, MSc3, Diane L. Seger, RPh2, Melissa Danforth, BA4, Jessica M. Cole, BS3, David W. Bates, MD, MSc1,2,5

Introduction: Since the HITECH Act was passed in 2009, electronic health record (EHR) implementation has grown widespread.1 Hospitals in the United States use The Leapfrog Group’s CPOE Evaluation Tool to assess the ability of their EHR to alert on common and serious prescriber errors. The tool provides hospitals with an overall percentage score of unsafe orders detected, as well as individual order category scores. Past analyses of the tool have reported that EHR implementation varies greatly within vendors and even between hospitals within the same healthcare system.2 In this study, we report on the variability in performance of hospitals within four healthcare systems in terms of their overall percentage score and individual order checking category scores.

Methods: A dataset containing the 2019 CPOE Evaluation Tool results was extracted for analysis and was linked to the American Hospital Association Annual Survey from 2009 to 2016 to identify hospitals that were part of a healthcare system. Next, we selected four healthcare systems that contained 20 or more hospitals from the dataset and identified them as Systems A-D. Within each of these healthcare systems, all the hospitals used the same combination of EHR vendor and medication reference database. For each healthcare system, we reported on the range of order category scores their hospitals received within in the test, as well as their overall performance.

Results: The complete dataset contained 119 hospitals across four healthcare systems, with two different combinations of EHR vendor and medication databases (Table 1).

There was variability in hospital performance within each healthcare system, with System C having the largest range of overall scores (Table 1). In each system, there were order categories that showed great variability in performance. For example, in System A, the drug laboratory, drug age, and drug diagnosis order category scores ranged from 0% to 100%, suggesting that some hospitals in this healthcare system had these alerts completely turned off. A similar case also occurred in System D, where scores ranged from 0% to 100% in the therapeutic duplication, drug age, and drug monitoring order categories.

The analysis also identified differences in how hospitals within the same healthcare system respond to the same medication test orders they received in the test. For example, 16 hospitals in System A responded differently to the same drug monitoring order that involved tobramycin. Of the 16 hospitals, 8 received an alert to monitor tobramycin levels while the 8 other hospitals did not receive the alert.

Conclusion

The results of these analyses show the variability of EHR implementation at the facility level. By having some areas of clinical decision support completely turned off, there is potential for adverse drug events to occur. This study reveals important areas of improvement and reinforces the importance for healthcare systems to repeatedly assess the performance of their hospitals’ EHRs.

Comparative Analysis of Telemedicine Services Before and During Pandemic

Wanting Cui, MA, Joseph Finkelstein, MD, PhD
Icahn School of Medicine at Mount Sinai, New York, NY

Introduction

Since the start of the COVID-19 pandemic, the number of telemedicine services increased significantly due to the ‘stay at home’ order in New York City. The goal of this study is to identify demographic groups of patients who received telemedicine services, and to analyze how different demographic groups’ telehealth usage patterns change throughout the course of the pandemic.

Method

The dataset was generated by querying electronic health records at the Mount Sinai Health System to identify all patients who used telemedicine services between January 2019 and December 2020. Patients’ demographics, diagnoses and medical history are the variables in the dataset. We calculated patients’ Charlson comorbidity index based on patients’ medical history (ICD10 codes) and age. We divided the dataset into 2 sections: prior to the pandemic (2019/1/2 – 2020/2/28) and during the pandemic (2020/3/1 – 2020/12/31). All analyses were performed in Python (Python version 3.7). We performed T-Tests for numerical variables and Pearson Chi-square tests for categorical variables. All statistical tests were two-sided, with p<0.05 being considered statistically significant.

Result

There were 263,051 telemedicine sessions and 169,178 unique patients in the dataset. There was a drastic increase in telemedicine service starting 03/2020 and reached the peak in 05/2020 (Figure 1). The number of daily telemedicine sessions reached a stable but high level in 07/2020.

Figure 1. Average weekday telemedicine cases by month.

Prior to the pandemic, there were significantly more young patients and female patients using telemedicine services. However, these differences only reflected in adult patients, but not in children. The average age for adults was 42.0 years old and 7.9 years old for children prior to the pandemic. The average age increased to 49.9 years old for adults and remained constant at 7.7 years old for children during the pandemic. In addition, prior to the pandemic, only 33.1% of adult patients were male. The number increased to 39.3% in 2020. Although, the proportion of adult African American telemedicine users increased from 9.2% to 14.1%, there were significantly (p <0.001) more White telemedicine users (58.1%) than African American users. Furthermore, the average adult patients’ comorbidity scores also increased significantly (prior: 0.7, post: 1.4) during the pandemic.

Conclusion

The COVID-19 pandemic changed the landscape of telemedicine drastically. The average age of patients increased since the pandemic and there were significantly more White patients using the service than African American patients. In future studies, we plan to study the accessibility of telemedicine to older adults and the disparities of telemedicine usage between different races. Thus, future analyses of telemedicine are warranted.
Machine Learning for Time to Event Biomedical Research

Ioana Dančiu1,2,*, Greeshma Agasthya1, Janet Tate3,4, Amy Justice3,4,5, Ben McMahon6, Olga Ovchinikova1

1 Oak Ridge National Laboratory, Oak Ridge, TN, USA; 2 Department of Biomedical Informatics, Vanderbilt University, Nashville, TN, USA; 3 Veterans Affairs Connecticut Healthcare System, West Haven, CT, USA; 4 Yale School of Medicine, New Haven, CT, USA; 5 Yale School of Public Health, New Haven, CT, USA; 6 Theoretical Biology Group, Los Alamos National Laboratory, Los Alamos, NM, USA; *Corresponding author

Introduction

In recent years, access to an increasing volume and diversity of biomedical data, as well as advances in computational capabilities have generated significant interest in application of machine learning (ML) for biomedical applications (1). In this abstract, we present a domain aware predictive modeling approach for prostate cancer disease progression using machine learning that considers time-to-event with censoring.

Methods

Data: Our cohort consisted of patients with early-stage prostate cancer at diagnosis from the Department of Veterans Affairs (VA) Corporate Data Warehouse (CDW). This study has been approved by the VA and Oak Ridge National Laboratory (ORNL) Institutional Review Boards (IRB). 64 predictors were measured at or before primary prostate cancer diagnosis, and fell in two categories: (i) A set of independent variables abstracted from the CDW cancer registry characterizing patient demographics (age at diagnosis, race) and disease staging (Gleason score clinical, stage group ajcc and SEER summary stage); (ii) Longitudinal prostate specific antigen (PSA) values, aggregated into minimum, maximum, average, density, standard deviation values across 6 months intervals and also across a 5-year period prior to diagnosis. The outcome was a composite consisting of cancer related death from the National Death Index and registry documentation, PSA> 50, and inpatient and outpatient ICD codes indicative of metastatic disease. We censored all patients one year after their last PSA value.

Computational methods: We used xgboost with accelerated failure time (2) that maximized the log likelihood of a decision tree ensemble to calculated time to event survival in months. The model training used 80% of the dataset set aside at the beginning. The remaining 20% was used solely for independent testing of the trained model to compute the performance metric.

Metric: To determine the performance of our algorithms, we used a slightly modified version of Harrell’s c-statistic (3) that uses the time to event predictions instead of the hazard to generate the list of concordant pairs and ties.

Results

Our dataset consisted of 135,974 patients with early-stage prostate cancer diagnosed between 2002 and 2016, 108,260 in the training dataset and 27,714 in the validation set. 11,781 had the composite outcome before censoring in the training dataset, with 3,011 in the test. The median survival for the training dataset was 94 months 95% CI [94, 94] and 94 months 95% CI [93, 95] in the test. The modified Harrell’s c-statistic on the test dataset was 0.63.

Conclusions

Machine and deep learning methodologies that can capture the full complexities of datasets are both needed and underrepresented in the literature and current biomedical practice. Our research demonstrates that adapting existing machine learning technologies to account for time to event outcomes with censoring is feasible.

Disparities in Coded and Imputed Post-Traumatic Stress Disorder and Self-Harm Among US Veterans

Sharon E. Davis, PhD; Praveen Kumar, MS; Nicolas R. Laune, MS; Sharidan K. Parr, MD; Daniel Park, MS; Michael E. Matheny, MD, PhD; Gerardo Villarreal, MD; George Uhl, MD; Yiliang Zhu, PhD; Mauricio Tohen, MD, DrPH, MBA; Douglas J. Perkins, PhD; Christophe G. Lambert, PhD

1Vanderbilt University Medical Center, Nashville; 2University of New Mexico, Albuquerque, NM; 3VA Tennessee Valley Healthcare System, Nashville, TN; 4VA New Mexico Healthcare System, Albuquerque, NM

Introduction
Incomplete coding of phenotypes in electronic health record (EHR) data poses a major obstacle to generating high-quality data for clinical care and research.1 Post-traumatic stress disorder (PTSD) and self-harm may be documented with diagnostic codes in only 2-19% of cases.2,3 Undocumented conditions impede timely screening, diagnostics, referrals and treatment. Further, lack of coding complicates our understanding of health disparities, especially if accuracy varies across patient groups. In this study, we characterize disparities in PTSD and self-harm among US veterans using coded and imputed phenotypes, exploring how documentation practices impact our understanding.

Methods
We accessed US Department of Veterans Affairs national EHR patient data for 2000-2020. Positive unlabeled learning with XGBoost estimated the probability of PTSD and self-harm for a random sample of veterans born after 1940 and receiving care in the VA system for ≥2 years. We estimated the impact of sociodemographic factors on risk of PTSD and self-harm using coded and imputed phenotypes, as well as on the risk of being a probable but uncoded (i.e., missed) case vs a coded case. Logistic regression models estimated associations with race/ethnicity, decade of birth, sex, homelessness, unemployment, county urbanization, and county socioeconomic deprivation covariates. These models also controlled for major mental health conditions known to be associated with self-harm and PTSD.

Results
Our study included 1,022,102 veterans. PTSD was coded for 24.0%. Imputation identified few patients at high risk without a coded diagnosis, adding only 355 cases. The odds of PTSD were 24%-66% higher among minority veterans compared to Non-Hispanic White (NHW) veterans. Female veterans were slightly less likely than their male counterparts to have PTSD documented in the EHR and unemployment conferred 21% increased risk of PTSD.

Self-harm was coded in 1.9% of the population and imputation identified 25,401 additional patients, raising the self-harm rate to 4.3%. Non-Hispanic Black (NHB) veterans were at 25% increased odds of probable but uncoded self-harm compared to NHW veterans. However, the odds of self-harm were 51% higher among NHW veterans. Odds ratios for self-harm increased from 1.96 [1.89-2.04] to 2.48 [2.42-2.55] for homelessness and from 2.06 [1.98-2.14] to 2.68 [2.61-2.76] for unemployment when modeling with coded and imputed cases, respectively. For other sociodemographic features, imputation did not significantly impact our understanding of health disparities.

Conclusion
Among US veterans, we documented disparities in PTSD and self-harm associated with age, race, sex, and economic indicators. Imputation identified few additional cases of PTSD and did not impact our understanding of disparities. On the other hand, imputation revealed many cases of self-harm and we found analyses relying on coded self-harm significantly underestimated associations with homelessness and unemployment. Correcting disparities analyses with enriched EHR-phenotypes through imputation may provide important insight into screening/diagnostic biases, populations in need of additional resources, and the types of interventions necessary to improve veteran health.

An AI Model to Screen for SARS-CoV-2 in Emergency Department Clinical Notes

John Del Gaizo1, Garett Hayes2, Jihad S Obeid1, MD PhD
1Biomedical Informatics Center, Medical University of South Carolina, Charleston, SC, USA; 2College of Medicine, Medical University of South Carolina, Charleston, SC, USA

Introduction

We present an AI model for the rapid screening of potential COVID-19 (+) patients upon presentation to the ED (emergency department), specifically from physician-authored ED notes. Such a model can provide public health benefits through (1) rapid testing; (2) real-time disease incidence metrics; and (3) automated identification of key symptoms through X-AI (eXplainable Artificial Intelligence) algorithms such as Grad-CAM (Gradient – Class Activation Mapping).

Methods

We extracted 9,597 physician-authored ED notes (2,588 positive, 7,009 negative) from the MUSC RDW (Medical University of South Carolina Research Data Warehouse) from 2 groups (IRB Pro00100990): (1) 2,588 notes from patients with COVID (+) lab tests within 2 weeks of the note; and (2) a demographically-matched control set of 7,009 notes from subjects with negative lab tests and without coronavirus ICD codes. The notes were recorded between 03-01-2020 and 01-14-2021. The data was split on September 15 into 2 groups based on the occurrence of 2 major COVID incidence waves within the time frame.

</table>

Our data processing pipeline consisted of the following steps: (1) regular expressions fine-tuned for medical EHR notes, (2) tokenization, (3) numericizing, (4) word embedding, and (5) a CNN (convolutional neural network) for COVID prediction. We next implemented code that applies Grad-CAM to a text input, and outputs HTML (Figure 1). The rendering enlarges and reddens tokens in accordance with prediction importance.

Results

The hold out set AUC values were .82 and .77 on the models trained on the Wave 1 and Wave 2 data, respectively.

Figure 1. Grad-CAM algorithm. PHI has been blotted out, underscore (0_0…) words are simply padded elements.

Conclusion

The AI model was comparable to the AUC derived from EM doctors2. However, the model AUC decreased over time. One possibility is that increased familiarity of ED physicians with standard COVID presentations led to documentations changes.

We are in the early stages of experimentation with other architectures, such as regression models applied to BERT embeddings3. Of particular interest for X-AI is the HAN (hierarchical attention network)4, which calculates attention weights that are essentially discrete probability distributions for both tokens within a sentence, and sentences within a sample.

Leveraging Ontologies for the Aggregation of Normalized Pharmacy Content
Michael Denton MS, RN, Tosh Kartchner RN, Jonathan Herbert RN, Dean Woolstenhulme MS
3M Health Information Systems, Murray, Utah

Introduction
Multiple variations exist between local and standard pharmacy terminologies, limiting interoperability and the creation of accurate cross terminology datasets (map sets, value sets). By leveraging a relational terminology server with a controlled medical vocabulary, we store, translate, and aggregate both consumer and standard pharmacy terminologies in a unified structure, enabling flexible tooling to create standardized datasets for multiple use cases and in varying structures. The goal of this project is to improve the maintenance and usability of cross-terminology pharmacy content, providing end users with comprehensive coverage and multiple levels of granularity for a given use case.

Methods
The project consists of two phases: translation and attribution. In the translation phase, subject matter experts (SMEs) evaluate standard and consumer terminologies to convert to a normalized structure that can be stored in our relational terminology server. During the translation process, concepts are defined with sets of definitional attributes and where gaps exist, attributes can be newly created. The attribute sets are grouped together in an ontological structure which can be organized and aggregated based on type and granularity, resulting in normalized groups of “like” attributes used to define clinical drugs across terminologies with different levels of specificity, increasing the usability of pharmacy content. In addition to making content more flexible, the structure also improves the ability to maintain datasets, integrate standard updates and consumer requests seamlessly while maintaining concept permanence, and allow content to evolve gracefully once a formal definition is defined. During the attribution phase, SMEs map sets of definitional attributes and relational operators necessary for defining group(s) of content, narrowing clinical drugs to the set of concepts with the level of specificity desired for a given use case. This is done by leveraging the attribute ontology and the relationships between each attribute type. For this project, a “clinical drug” is defined as a concept attributed with an ingredient and one or more definitional attributes: route, form, or packaging. Optional attributes that could be included, but not required to define a clinical drug, are the ingredient strength, brand name, and modifiers. For example, if we wanted to aggregate clinical drugs for “intravenous lidocaine”, we would attribute the ingredient “lidocaine hydrochloride” and additional attributes such as a route (infusion, injection, intravenous) or a form (liquid, solution, suspension). Once attributed, the tooling will aggregate clinical drugs using the forementioned attribute types and any “like” attributes depending on the relational operators. SMEs will continue to evaluate and revise the set of definitional attributes until the correct set of clinical drugs are captured for a given use case.

Results and Discussion
The project has resulted in the successful translation of 32 source terminologies, including First Databank (FDB), Gold Standard Drug Database (GSDD), National Drug Code (NDC) Directory, National Drug File – Reference Terminology (NDF-RT), RxNorm, SNOMED CT, Vaccines Administered (CVX), and other consumer source terminologies. This provides us with 323,636 distinct clinical drug combinations which can be leveraged in our attribution process. The combinations utilize a distinct set of attributes including 37,844 ingredients, 129 routes, 884 forms, 1,148 packages, 76,326 ingredient strengths, 50,603 brand names, and 307 modifiers. We also leverage pharmacological classes from standard terminologies, enabling us to aggregate clinical drugs from 156 hierarchical classes and 1,542 therapeutic classes. This allows us to evaluate attributes from the clinical drugs in a desired class which can be leveraged to include cross-terminology concepts with the same definitional attributes. In addition to the drug hierarchies from standard terminologies, The Drug Ontology (DrOn) was also assessed for feasibility of incorporation into our relational terminology server. DrOn was useful as a reference source, but limitations exist for translating standard and local terminologies beyond RxNorm and would require additional tooling for our use case. In addition, we needed a way to maintain multiple terminology sources and cross-terminology datasets to reduce redundancies and prevent semantic drift, which is beyond the scope of DrOn.

Conclusion
By using a relational terminology server with a controlled medical vocabulary, we are able to store, translate, and aggregate pharmacy content accurately in a normalized structure. Then, additional tooling was created to build accurate cross-terminology data sets that are flexible and maintainable for varied use cases.

Assessing the Use of HL7® FHIR® Among Healthcare Apps

Brian J. Douthit, MSN, RN-BC1, Guilherme Del Fiol, MD, PhD2, Chloe Canon, BM3, Jessica Branski, BS3, Titus Schleyer, DMD, PhD4,5, Rachel L. Richesson, PhD, MPH3
1Duke University, Durham, NC; University of Utah, Salt Lake City, UT; 3University of Michigan, Ann Arbor, MI; 4Regenstrief Institute and 5Indiana University School of Medicine, Indianapolis, IN

Introduction

The Substitutable Medical Applications, Reusable Technologies (SMART) on Fast Healthcare Interoperability Resources (FHIR) is an increasingly popular standard on which to develop and deploy interoperable health apps. The FHIR standard has enabled greater access to electronic health record (EHR) data, but plug-and-play interoperability is still limited. However, FHIR is continuously being modified to maximize interoperability, such as through the development of US Core profiles. This work serves to inform priority areas for FHIR profile development by assessing the data requirements among a representative sample of SMART on FHIR apps and the FHIR resources that were used to meet those requirements.

Methods

FHIR apps were sampled from two sources: the SMART App Gallery (https://apps.smarthealthit.org/) and the yearly AMIA/HL7 FHIR Applications Competition. This was done to ensure the apps 1) were of high quality, 2) included varying purposes and clinical foci, and 3) could be used with multiple EHRs. To gather information regarding resource use, app authors were contacted, and open-source code was analyzed when available. If neither option was successful, app demos were analyzed for data requirements which were subsequently mapped to the appropriate FHIR resource.

Results

Of the 90 apps available on the SMART gallery and the 27 apps submitted to the AMIA FHIR app competition between 2018 and 2020, 51 apps were included in the analysis. Apps were excluded from analysis if resources could not be acquired from open-source coding, app demos, or from contacting the app authors. Table 1 summarizes the findings by reporting the raw count and frequency of FHIR resource use among the sample of apps. Condition was the most frequently used non-normative resource, which may be a priority area for development. MedicationStatement, FamilyMemberHistory, Questionnaire, and QuestionnaireResponse were among the top 12 most used resources without associated US Core profiles.

*Has an associated US Core Profile; **Specific observations (e.g., vital signs) have an associated US Core Profile

Conclusion

Continual assessment of FHIR resource use could help to inform the development of the standard and facilitate the development of US Core profiles. Additional sources of FHIR apps should be considered in future iterations of this work, and app authors should be encouraged to share their FHIR resource usage so analyses such as this may be done more readily.
Development of a Drug Allergy Alert Tiering Algorithm for Penicillins and Cephalosporins

Heba Edrees, PharmD1,2, Diane L Seger, RPh3, Ying-Chih Lo, PhD1, David W Bates, MD, MSc1,4, Li Zhou, MD, PhD1,4

1Brigham and Women’s Hospital, Boston, MA; 2MCPHS University, Boston, MA; 3Mass General Brigham, Somerville, MA; 4Harvard Medical School, Boston, MA

Introduction

Clinical decision support (CDS) has become a useful tool in reducing adverse drug events, including drug allergy interactions. Drug allergy alerts are a common CDS problem because alerts are triggered strictly based on the medication being ordered and the patient’s documented allergy. This results in too many allergy alerts being generated and has resulted in an increase in drug allergy alert overrides. Patient allergy alerts are overridden about 80% of the time and about 96% of them are overridden appropriately. In our institution, antibiotics, specifically penicillins and cephalosporins, were the second highest drug class with allergy alerts overrides (14%), following opioids (30%). Current drug allergy alerting mechanisms can be improved, as they negatively impact physicians’ time and patient safety due to alert fatigue. The objective of this study is to determine the frequency of overrides for penicillin and cephalosporin drug allergy alerts and create a rule-based algorithm to reduce the number of inappropriate drug allergy alerts.

Methods

Drug allergy alert and override data was reviewed for penicillins and cephalosporins, over a one-year period, for patients at a large Massachusetts Healthcare System. The data will be used to develop a rule-based algorithm to classify drug allergy alerts into three groups: no alerts presented to the user, non-interruptive (informational) alerts, and interruptive alerts that require a coded response or action. The rule-based algorithm will include factors such as drug class or cross-sensitivity matches, reaction types with the designated severities (categorized as high, medium, or low), patient comorbidities, and allergy alert history. To date, patients’ drug allergies and reactions, medications that triggered the drug allergy alert, and overrides were reviewed.

Results

Drug allergy alerts for penicillin and cephalosporins were overridden 61.4% of the time. Of the drug allergy alert overrides, 15% were for medications in the same drug class and 85% were for drugs that had a potential for cross sensitivity. Of all the reactions documented, 7% of the overridden alerts had a reaction classified as severe, 20% were medium severity, 38% were low severity, and 35% were unknown severity because a reaction was not documented. The most common high severity reactions were anaphylaxis, angioedema, and shortness of breath. The most common low severity reactions were rash, gastrointestinal upset, and itching. Of the drug allergy alerts with a cross sensitivity match, 28% were for patients with a documented penicillin allergy and a medication order for a first-generation cephalosporin, with a 41% low severity reaction. In addition, 30% of overridden drug allergy alerts were for patients with a penicillin allergy and an order for a third-generation cephalosporin, with a 36% low severity reaction.

Conclusion

Providers frequently overrode drug allergy alerts when the allergy reaction severity was classified as low and the alert was for medications that had a potential for cross sensitivity. This preliminary data shows that the number of drug allergy alerts, shown to the provider, could potentially be reduced by filtering by reaction severity and risk of cross-sensitivity. This data is being used to develop an algorithm to redesign drug allergy alerts that will reduce override rates, minimize clinician interruption, and improve patient safety.

Abstract Summary
This presentation discusses the key components for the successful development and implementation of a federal external information system (ExIS) to interface with the Centers for Disease Control and Prevention (CDC) Vaccine Tracking System (VTrckS), and provides an overview of implementing the technology for ordering COVID-19 vaccines during the pandemic response. This report also highlights opportunities to leverage technologies to enhance the supply chain distribution.

Introduction
The Centers for Disease Control and Prevention (CDC) uses the Vaccine Tracking System (VTrckS), a secure, web-based information technology system, to support ordering and distribution of publicly funded routine vaccines. VTrckS manages and distributes within territories, states, and local health departments, as well as federal entities. The Vaccine Ordering System (VOP), described in this presentation, supports the ordering and distribution of COVID-19 vaccines through the Federal Retail Pharmacy Program, the health center COVID vaccine program, and the Rural Health Clinic COVID Vaccine Distribution Program. Further, following careful consideration and assessment, a federal external information system (federal ExIS) was developed to allow 30 commercial and 7 federal agency partners with more than 40,000 provider locations (pharmacies, dialysis clinics, mobile mass vaccination clinics, and federal clinics) to place and receive COVID-19 vaccine orders. This presentation highlights the key factors leading to a successful development and implementation of a federal ExIS, and opportunities for leveraging technologies to expand federal supply chain capacity.

Methods
CDC reviewed past and current ExIS awardee activities utilized for the routine vaccine program as well leveraging tools and resources developing CDC’s Immunization Services Division Immunization Information Systems Support Branch to support ExIS implementations over the past few years. Examples of tools and resources included the CDC-developed ExIS File Specifications, Processing VTrckS Orders document, and the ExIS Usability Best Practices Catalog. CDC also leveraged subject matter experts (SMEs) actively supporting and providing technical assistance to guide awardees through ExIS implementation and enhancements. By compiling existing resources, tools, and SME expertise, CDC was able to rapidly develop a team to support the planning, analysis, design, implementation, testing, evaluation, and support of a federal pandemic ExIS system called the VTrckS Partner Ordering Portal (VPOP).

Principal Findings
VPOP has been adopted by more than 30 commercial and federal partners for placing COVID vaccine orders and has contributed to the distribution of approximately 1/3 of the total distributed US doses. The primary requirement for successful VPOP implementation was its ability to interface with VTrckS while supporting multiple data sources in order to rapidly expand ordering capacity to a larger provider base to ensure rapid distribution of COVID-19 vaccines.

Table 1. Summary of key drivers for the successful and timely development and deployment of VPOP.

<table>
<thead>
<tr>
<th>Key Factors</th>
<th>Description</th>
<th>Applicability</th>
</tr>
</thead>
<tbody>
<tr>
<td>Standard Specifications Guidelines</td>
<td>ExIS File Specifications document outlined the required data elements and business rules that had to be implemented to interface with CDC VTrckS.</td>
<td>The guide contains file specifications for inbound and outbound interfaces for integration of VTrckS and ExIS systems. The specifications document served as the data dictionary for developing the ExIS and ensuring successful information exchange with VTrckS (i.e., interoperability).</td>
</tr>
<tr>
<td>Usability Best Practices Catalog</td>
<td>Outlined best practices for vaccine ordering and inventory tracking, and described business rules that minimized errors, supported accountability, and were efficient (e.g., in terms of the number of screens, steps, people involved, and time to complete tasks).</td>
<td>The Usability Best Practices Catalog was inspired from design observations of awardee-training materials, ExIS functionality demonstrations, focused workshops, the Modeling of Immunizations Registry Workgroup, IIS Inventory Management Operations Guide, and other published material.</td>
</tr>
<tr>
<td>Agile Development Methodology</td>
<td>The development team adopted the time-boxed project cycles known as sprints to release new application features.</td>
<td>The agile development methodology allowed the team to adapt easily and quickly to change, release features at predictable delivery dates, engage stakeholders and users in testing, and integrate changes to achieve better user satisfaction with every sprint.</td>
</tr>
<tr>
<td>User Acceptance Testing/Test-Driven Development</td>
<td>Application owners worked closely with users in the last environment to gain a clear understanding of business and workflow requirements to meet user needs before every release.</td>
<td>The User Acceptance Testing environment was established, and access was granted to the CDC testing team and to a group of users from several partners interested in testing application features and providing feedback before every release.</td>
</tr>
<tr>
<td>Cloud-Based Development</td>
<td>Cloud concepts and technologies provided ample resources to support software productivity through code development, testing, and code repositories.</td>
<td>Cloud hosting offered predictable server uptime, security, scalability, back-up and business continuity, and location flexibility.</td>
</tr>
<tr>
<td>Security</td>
<td>Cloud service providers protected secured and encrypted solutions, backup recovery, firewalls, identity management, and data isolation and storage segregation.</td>
<td>The application leverages: - Secure cloud-based solution - Authorized access only to authorized users through password protection - Two-factor authentication is required</td>
</tr>
<tr>
<td>User-friendly Interface</td>
<td>Intuitive, easy to access and use application.</td>
<td>The application design offered an one-stop shop for placing COVID vaccine orders or performing other relevant activities on one screen. Most business processes could be completed with only a few clicks.</td>
</tr>
<tr>
<td>Flexible Implementation and Provision</td>
<td>Enrolment and credentialing of providers.</td>
<td>The application design adopted a “hub and spoke” model allowing partners to manage and authorize access to their users. Authorized users are easily granted access to the system once they are added as a contact to a location.</td>
</tr>
<tr>
<td>Stakeholder and Partner Involvement</td>
<td>Partner and stakeholder engagement was conducted throughout project life cycle.</td>
<td>Partners and stakeholders have been motivated to serve and be a part of the project targeted at serving public health during the pandemic.</td>
</tr>
<tr>
<td>Crowdsourcing Platform</td>
<td>Crowdsourcing is a way to collect user’s knowledge or feedback.</td>
<td>The application hosted a crowdsourcing platform for all users to share feedback “on the fly” or suggest features through the feedback or project management features while completing regular ordering or processing activities in the portal. Crowdsourcing tools also provide transparency to requesting end users by allowing them to track/#/enhancement was approved, entered development, and which sprint cycle it would be released in.</td>
</tr>
<tr>
<td>User Guide/Training</td>
<td>User-centric manual providing instructions on the use of the application.</td>
<td>The portal enables users to access the user guide through the Help feature and walk through the steps required to complete an activity. Adopting the “hub and spoke” model saved a lot of training effort and allowed us to meet training needs through the “train the trainer” approach.</td>
</tr>
</tbody>
</table>

Conclusion
By leveraging existing public health system implementations, CDC and partners demonstrated the additional potential in leveraging technologies to expand the supply chain and distribution process. Additional areas of improvement have also been identified including the automation of ExIS systems. CDC plans to continue this initiative to expand across all ExIS systems ordering vaccine to enhance processes and modernize public health data.

Race and Ethnicity Agreement Between Medicaid, Health Information Exchange, and Electronic Health Records

Sarah El-Azab¹, MS, Siu Hui², PhD, Heidi Hosler², BS, Katie S. Allen², BS
University of Michigan, Ann Arbor, Michigan¹, Regenstrief Institute, Indianapolis, Indiana²

Introduction
High quality race and ethnicity data is essential for research that assesses health disparities between populations¹. However, in the observational data sources most frequently utilized by researchers to do so, the quality of these data elements can be subpar. In 2018, the Centers for Medicare and Medicaid Services (CMS) reported that the quality of the Medicaid race and ethnicity data for 20 states was “highly concerning” or unusable². Electronic health records (EHRs) suffer from similar data quality issues, due to the challenges of collecting race and ethnicity in clinical settings¹. These issues are likely to be compounded in health information exchanges (HIEs), which collect data from numerous EHRs. Given these data quality concerns, it is critical for researchers to understand the strengths and weaknesses of each data source or risk unknowingly weakening the validity of their research. This study compares race and ethnicity data between a state HIE, Medicaid, and the EHRs of an academic medical center (AMC) and a federally qualified health center (FQHC) for the same cohort of patients.

Methods
A cohort of adult Medicaid enrollees was linked to a HIE, AMC, and FQHC by using exact matching on demographic data points. Patient identifiers, race, and ethnicity data were extracted from all four data sources. While the AMC and FQHC contribute to the HIE, race and ethnicity data was extracted directly from their respective EHRs. All available race data was categorized as “White”, “Black or African American”, “Asian or Pacific Islander”, “American Indian or Alaska Native”, “Multiracial”, “Other”, or “Unknown”. Ethnicity was similarly categorized as “Hispanic or Latinx”, “Not Hispanic or Latinx”, and “Unknown”. For each data source, race or ethnicity was assigned by taking the mode of all available data per patient. In the case that a patient was multimodal, they were classified as “Unknown.” Pairwise agreement between the data sources was assessed using percent agreement and Cohen’s Kappa statistic.

Results
There was wide variation in the race and ethnicity categories among the data sources. Medicaid did not collect data on Multiracial patients and the two EHRs did not collect data for “Other.” There were also considerable differences in the percentage of White and Black patients across the data sources. For the same cohort, Medicaid had a higher percentage of White patients (70.46%) than the HIE (38.66%), the AMC (52.44%), and the FQHC (44.43%). Medicaid also had a lower percentage of Black patients (20.04%) than the HIE (32.67%), the AMC (38.63%), and the FQHC (38.64%). The pairwise agreements between the data sets are shown in Table 1.

<table>
<thead>
<tr>

<td>79.1%</td>
<td>0.655</td>
<td>43.0%</td>
<td>0.077</td>
</tr>
</tbody>
</table>

Table 1. Pair-wise comparison across data sources with percent agreement and Cohen’s Kappa statistic.

Conclusion
The AMC and FQHC had substantial pairwise agreement with the HIE, likely because they contribute data to it. However, there is poor agreement between Medicaid and the EHR-based data sources. Further research is needed to assess how race and ethnicity is collected in these settings and what is contributing to these differences.

Usability and Accuracy Evaluation of the Fitbit Versa 3 Smart Watch Compared to Research-Grade Devices

Chuka Emezue, PhD, MPH, MPA\textsuperscript{1}, Chelsea Howland, MSN\textsuperscript{1}, Malaika R. Gallimore, RN, MPH\textsuperscript{1}, Katrina Boles, MS\textsuperscript{1}, Amy Grimsley, MSN, RN, CCRN-K\textsuperscript{1}, LeeAnne B. Sherwin, PhD, MS, FNP-BC\textsuperscript{1}, Allison Anbari, PhD, RN\textsuperscript{1}, Blaine Reeder, PhD\textsuperscript{1}, Jo-Ana D. Chase, PhD, APRN-BC\textsuperscript{1}

\textsuperscript{1}University of Missouri, Columbia, MO, USA.

Introduction

Consumer-graded wearable devices continue to enjoy increasing consumer adoption and acceptance. However, studies show a tendency for wearables to underestimate steps in controlled testing and overestimate steps in free-living settings. In addition, rapid technological changes and short product release cycles surpass device testing efforts by skilled evaluators. At the University of Missouri Precision START laboratory, we devised a strategy to inform research and health care decisions using a multi-step methodology involving within-team, lab- and field-based tests to rapidly evaluate the Fitbit Versa 3 for accuracy, usability, and feature availability\textsuperscript{1}. This study reports within-team evaluations of the Fitbit Versa 3 compared to two research-grade control devices.

Methods

In February 2021, a five-person team completed lab-based testing of the Fitbit Versa 3 (Fitbit) smart watch, a research-grade control device - the hip-worn ActiGraph wGT3X-BT (GT3X) - and wrist-worn GT9X-Link (GT9X). Evaluators wore the Fitbit and GT9X on their non-dominant arm and the GT3X control on their dominant hip. During 7 days of continuous wear, participants recorded free-living activities on a weekday (Day 3) and a weekend (Day 6). Scripted tasks for walking and stair-climbing activities were completed on Day 4. For walking activity, participants walked a straight pathway with a 0% incline at three self-paced speeds for an 8-minute each for “very light walking,” “light walking,” and “moderate walking,” followed by 2-minute rest periods. Evaluators completed a series of post-test checklists from our stepwise methodology\textsuperscript{1}, including the 10-item system usability scale (SUS), 12-item user experience checklist and a feature availability survey. The SUS was applied separately to the Fitbit smart watch and mobile app.

Results

We calculated the median absolute percentage error (or MdAPE= median (p1,p2,⋯,pN), where p represents each participant). MdAPE is an outlier- resistant measure and reduces bias in favor of lower scores, thus advantageous over the mean absolute percentage error (MAPE). Overall, the Fitbit vs. hip-worn GT3X control achieved the closest agreement with % error of 54% while the Fitbit vs. GT9X comparison had the widest % error of 94.9% (i.e., least precision). Stair Climbing Activity: The % error for total stair climbing activity between the Fitbit vs. hip-worn GT3X control was 20.5%, and for the Fitbit vs. wrist-worn GT9X, % error was 40.85%; indicating better agreement between the Fitbit and GT3X control. Walking Activity: For self-rated exertion, moderate walking had the lowest % error. With the Fitbit vs. GT3X control, % error was 91% for “very light walking,” 71.1% for “light walking,” and 16.2% for “moderate walking.” For the Fitbit vs. wrist-worn GT9X comparison, % error was 95.2% for “very light walking,” 94.9% for “light walking,” and 93.9% for “moderate walking.” This difference in device accuracy held true for Daily-Living Activity Step Counts: % error for the Fitbit vs. GT3X control was 41.45%, while the Fitbit vs. GT9X % error was 44.55%. The median absolute percentage error was lower in daily living activities. Usability: Average SUS scores for all five evaluators on the Fitbit Watch was 87.0 (82.5, 90, 82.5, 100, 80) or excellent usability, and for the Fitbit Mobile App, the usability score was 92.5 (87.5, 92.5, 90, 97.5, 95), indicating excellent usability.

Conclusion

Our results indicate that the Fitbit Versa 3 smart watch did not accurately measure step counts compared to the hip-worn ActiGraph GT3X in controlled conditions. While SUS results indicated excellent usability for watch and app, device error was higher in some activities (e.g., during “moderate walking”), raising concerns about using the Fitbit alone for research in free-living environments. Differences in home arrangement may be associated with reduced Fitbit accuracy even with controlled tests using zero inclines, defined distances, and explicit test instructions. In addition, the Actigraph wrist-worn GT9X appears to be a less accurate comparison device than the GT3X control device. Next steps will evaluate the Fitbit Versa 3 in comparison in participant field tests.

Observations on Documentation of Alcohol Use in Real-World Data

Emilia Farcas, PhD¹, Michael Hogarth, MD², Alison Moore, MD, MPH³
¹Qualcomm Institute, ²Division of Biomedical Informatics, ³Division of Geriatrics, Gerontology & Palliative Care, University of California San Diego, La Jolla, CA

Introduction
Excessive alcohol use is a leading cause of preventable death in the US, with an average of 95,000 deaths annually. During the pandemic, excessive alcohol use and its harms increased. While screening for excessive alcohol use has many barriers, the rapid adoption of Electronic Health Record (EHR) systems in the US over the past decade has enabled implementation of electronic versions of standardized questions and screening tools to assess for excessive alcohol use. To assess the utility of EHR data for screening and assessment of excessive alcohol use, we examined alcohol use items available in one health system’s EHR over a five-year period. Though one study¹ of 500 records examined alcohol use documentation, it had a different purpose (i.e., reasons for use of free text).

Methods
We conducted a retrospective analysis using deidentified EHRs from the UC San Diego Health Clinical Data Warehouse. The cohort included 486,290 patients 18 years or older with 5,614,732 encounters between 11/2014 – 11/2019. Alcohol data were found in structured fields in three separate data structures: (1) social history, including alcohol use (i.e., yes, no, not currently, never) and the first three items from the Alcohol Use Disorders Identification Test (AUDIT-C): frequency of use (i.e., never, monthly of less, 2-4 times a month, 2-3 times a week, 4 or more times per week), number of drinks per day (i.e., 1-2, 3-4, 5-6, 7-9, 10 or more), frequency of drinking 6+ drinks on an occasion, and comments; (2) the complete 10-item AUDIT; and (3) Alcohol/week, including quantity and type of beverage (i.e., glasses of wine, cans of beer, shots of liquor). Besides paragraphs of free text, some clinical notes (e.g., progress notes, patient instructions) also contain a section that starts with “Alcohol use:” followed by one or more alcohol items, allowing pattern matching. We divided the cohort into two groups based on whether they had their primary care assigned to UC San Diego (i.e., without vs with). We analyzed all encounters and also by department (e.g., emergency and primary care). All encounters include 857,744 encounters with no department assigned.

Results
Most alcohol documentation occurred via the AUDIT-C and clinical notes. Alcohol data were stored in different data fields at different encounters. The AUDIT is collected in primary care departments, whereas the Alcohol/week data are collected in the emergency departments. Compared to patients without primary care assigned to UC San Diego, a larger proportion of patients with primary care assigned had alcohol data documented, even for emergency encounters.

Table 1. The availability of alcohol data in various fields in the EHR

Discussion
Alcohol documentation occurred most frequently in primary care as part of standardized screening questions. Clinical notes were also a common source of alcohol data. In future work, we plan to use natural language processing on free text comments and clinical notes to identify additional alcohol data and analyze inconsistencies between these and the structured fields. While the EHR is a promising means of gathering data on alcohol use and identifying excessive alcohol use, we found that alcohol use data is recorded variably in the EHR and fragmented across multiple encounters. Standardized approaches are needed to reliably gather alcohol use information to drive personalized assessments.

Implications of Clinical Bias When Building Electronic Algorithms for Medical Record Phenotyping: Lessons from Type 2 Diabetes Mellitus

Annika Faucon, BS¹, Megan Shuey, PhD¹, Lea K. Davis, PhD¹, Nancy Cox, PhD¹

¹Vanderbilt University, Nashville, TN, USA

Abstract

The advent of electronic health record systems has made clinical phenotyping paramount. The process of delineating case and control populations, can introduce unexpected bias due to how, why, and from where the data was ascertained. Striking a balance between sensitivity, specificity, and introduced bias is essential for use in genetic and epidemiologic studies. Using three algorithms for type two diabetes mellitus (T2DM), we highlight clinical differences and potential confounding bias due to the modifications made for capture improvement.

Introduction

Genetic and epidemiologic studies require high specificity and large sample sizes to accurately identify correlations. Diabetes, for example, is a complex condition defined clinically by a hemoglobin A1C (HbA1C) value above 6.5%, a fasting blood sugar above 125 mg/dL, or an oral glucose tolerance test two-hour blood sugar above 200 mg/dL. An existing algorithm¹ for T2DM deployed across six eMERGE EHRs successfully identified patients with T2D, but application of the algorithm to present day EHRs leaves a large portion of patients with diagnosed T2DM unclassified (53.9%); limiting statistical power in downstream analyses. In addition to updating the existing algorithm, we evaluated the decision to define controls by their HbA1c or glucose measures. Throughout this process, we evaluated population level changes to characterize the biases introduced by definition change.

Results, Discussion, and Conclusion

The previous algorithm classified case values based on ICD codes, laboratory values, and timing of medications (e.g. insulin should not precede T2DM-specific drugs, like metformin). However, new medications for T2DM have become available in the past decade since eMERGE first published. Because medical science continues to evolve over time, updating useful tools in a sensible fashion is critical to continued building of knowledge.

Over 14% of Americans are estimated to have diabetes², and despite individuals with diabetes being more likely to utilize the EHR, phenotyping strategies fail to capture a similar disease frequency. Using BioVU, a Biobank-Linked EHR, we observed simply updating the algorithm to include ICD10 clinical modification codes results in an improvement to recall such that the prevalence of T2DM is 10.3%. Including newer medications further improved capture by increasing prevalence to 12.6% in individuals of genetically determined African ancestry and 12.2% for European ancestry. Updating the algorithm this way improved capture of T2DM-diagnosed individuals by 15.8%.

While updating the algorithm we used phenome and genome wide association study analyses to characterize cases and controls. We evaluated the value of various decision points that reflected clinical management. For example, by requiring control subjects to have a glucose or HbA1c measurement, which are not routinely measured in healthy patients without underlying comorbidities, we found that the early algorithm enriched the control population for patients with other metabolic dysfunction including a 140% increase in comorbid CKD, a 125% increase in comorbid hypertension, and a 217% increase in comorbid Hypertensive CKD compared to putative controls without a glucose test. Putative controls with a glucose test also had lower median HDL and higher median BMI and Triglyceride values. This inherent bias in lab order procedure could result in confounding bias that, impacts interpretability.

In conclusion, we demonstrate the necessity of updating phenotyping algorithms to improve capture. Additionally, we demonstrate how components of phenotyping algorithms can introduce false associations and diminish real ones.

Cohort Discovery with Unified Medical Language System Query Expansion

Robert J. Fawcett, MS\(^1\), Ahmad S. Halwani, MD\(^1\), Kyle R. Hansen, PhD\(^1\), Vikas V. Patil, MS\(^1\), Kelli M. Rasmussen, MD\(^1\), Daphne R. Friedman, MD\(^2\), Andrew R. Post, MD, PhD\(^1\)

Abstract

To simplify and enhance cancer cohort discovery, query expansion was employed by crawling the Unified Medical Language System’s (UMLS) concept tree to find International Classification of Disease for Oncology (ICDO) codes related to an initial code. Relevant ICDO codes were searched starting from a UMLS concept matched to a free-text query via natural language processing (NLP). We envision using this process to enhance a cancer cohort discovery tool that is under development.

Introduction

There is a strong desire to simplify self-service enterprise data warehouse searching by investigators for cohort discovery in oncology. NLP contributes to this simplification by allowing users to query data with language natural to their domain, but it has limitations. Simple NLP searches for concepts within the UMLS can produce associated medical codes (e.g. ICDO), but semantically related codes may also be useful to the searcher. In this work we used NLP to locate an initial set of ICDO codes, and then we traversed the UMLS concept tree to find related ICDO codes using narrower and broader relationships.

Methods

The UMLS dataset was installed into a MySQL database. QuickUMLS, an NLP Python application programming interface tool provided by the Georgetown University IR Lab, was installed for UMLS concept extraction from natural medical text. A python script accepted natural medical language, employed QuickUMLS to find associated ICDO codes from UMLS, and then queried the UMLS database using a recursive SQL call to traverse the concept tree \(x=2\) levels narrower and \(y=1\) levels broader, where \(x\) and \(y\) are adjustable parameters. The results were filtered to only those concepts associated with ICDO codes. The relevance of the ICDO codes returned were assessed by three domain experts who rated each of the 609 codes returned from a set of 22 initial search terms, with the following binary scale: 0=irrelevant, 1= relevant. For each search term, the rating results were averaged for a final percent relevancy score. Query performance was assessed by tracking the time taken, in milliseconds, to produce the final concept tree for each of the search terms tested.

Results

For the 22 search terms tested, the average percent relevancy score was 52% (max 100%, min 8%) with an average of 9.3 additional relevant codes returned per search term. There was good agreement among the reviewers, kappa = 0.66 (95% CI, 0.61 to 0.73). Query performance averaged 60.5ms from search term to ICDO tree.

Conclusion

The UMLS is composed of a variety of medical coding systems, controlled vocabularies and ontologies providing concept relationships not exhibited by using a single coding system in isolation. This research demonstrated that the UMLS concept tree can enhance cohort discovery by presenting the user with an expanded list of relevant medical codes. The process does produce noise, as only 52% of the results were relevant to the initial search term. More work needs to be done to discover causes of low performing search terms and identify associated UMLS features to increase the average percent relevancy score.

School District COVID-19 Response Policies Across Demographics

Ricky Flores, BS¹, Ellen Kerns, MPH², Russell J. McCulloh, MD², Aubree Honcoop, MPS², Martina A. Clarke, PhD¹,

¹School of Interdisciplinary Informatics, University of Nebraska-Omaha, Omaha, NE, USA; ²Department of Pediatrics, University of Nebraska Medical Center, Omaha, NE, USA

Introduction: With the COVID-19 pandemic, we have seen a rapid adoption of remote schooling practices nationwide which is inferior to in-school learning¹⁻². Children from communities who face disproportionate harm attributed to the pandemic may face even greater disparities due to remote learning; it is therefore important to understand how remote schooling practices align with populations and communities served by public schools nationally. This study’s objective is to evaluate the association between school pandemic response policies for districts in the United States and select publicly available student sociodemographic data.

Method: A cross sectional study design was used to evaluate the association of enrollment demographics and COVID-19 policies. Student demographic in addition to free and reduced lunch enrollment data was downloaded from each states’ respective Department of Education website. Thirty-three of the 50 states (66%) had publicly available demographic data along with the proportion of students from each school or district participating in a free and reduced lunch program or, in some cases, identified to be economically disadvantaged (defined as students and families who participate in federal assistance programs). Demographic data was composed of counts of students who fall into 1 of 8 categories for race/ethnicity: White, Black, Hispanic, Asian, Pacific Islander, American Indian/Alaskan Native, two or more races, or N/A. School District response to COVID-19 data was provided by MCH Strategic Data¹ and was joined to the demographic data via district name and state. MCH school data comes from responses gathered between July 2020 and January 2021. The proportion of students from each school who were identified as being part of a free and reduced lunch program or economically disadvantaged and the proportion identifying as being either Black or Hispanic were placed into 4 quartiles for ease of analysis. Chi-squared tests for association were performed for both sets of quartiles against the different COVID-19 responses.

Results:

Conclusion: Schools with higher proportions of Black, Hispanic, and/or economically disadvantaged students more often offered only remote schooling options for their students. Schools serving more communities of color and economically disadvantaged students should be a target for efforts to increase safe in-person school attendance options.

COVID-19 concerns and interests differ with socioeconomic status: Twitter Analysis

Samah Fodeh,1,4 Aarthi Venkat,2 Yihua Su,1 Yadush Yadav,1 Lisa Puglisi3,4

1Health Informatics Program, Yale School of Public Health, 2Computational Biology and Bioinformatics Program, Yale University, 3Department of Internal Medicine, Yale School of Medicine, 4Department of Emergency Medicine, Yale School of Medicine

Abstract: The emergence of novel coronavirus disease (COVID-19) and its etiologic cause, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has prompted an international effort to limit its morbidity and mortality. We sought to understand how U.S. residents responded to COVID-19 as it emerged, and the extent to which socioeconomic status impacted materials and methods.

Materials and Methods:
We mined and reverse-geocoded 269,556 coronavirus-related tweets from January 23rd to March 25th, 2020. We then linked the tweets to a county-level area deprivation index (ADI) and areas with high initial disease counts (“hotspots”). We applied topic modeling1 to identify chief concerns. We first determined dominant topics and then computed the evolution of topics over time, and analyzed how topic proportions varied based on ADI and between hotspots and non-hotspots.

Results: We identified 45 topics, which shifted from early-outbreak-related content in January, to the presidential election and governmental response in February, to lifestyle changes in March. Highly resourced areas (low ADI) were concerned with stocks, social distancing, and national-level policies, while high ADI areas shared content with negative expression, prayers, and discussion of the CARES Act economic relief package. Topics had significance difference between both groups (p <.05) (see Figure 1). Within hotspots, these differences stand, with the addition of increased discussion regarding employment in high ADI versus low ADI hotspots (see Figure 2).

Conclusion: This work demonstrates a novel framework for assessing differential sentiments correlating to income, education, and housing disparities. This, with integration of COVID-19 hotspots, offers increased insight into differential topics and concerns inferred from the text in hotspots vs non-hotspots and in areas with low vs high ADI.

Symptom Clustering of Patients with Suspected Acute Coronary Syndrome at Emergency Department Triage
Stephanie O. Frisch, PhD, RN\(^1\), Zeineb Bouzid, MS\(^1\), Jessica Zègre-Hemsey, PhD, RN\(^2\), Holli A. DeVon, PhD, RN, FAAN\(^3\), Harry Hochheiser, PhD\(^1\), and Ervin Sejdić, PhD\(^1\)
\(^1\)University of Pittsburgh, Pittsburgh, PA, USA; \(^2\)University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; \(^3\)University of California Los Angeles, Los Angeles, CA, USA

**Introduction**: Accurate Emergency Department (ED) assessment of symptoms associated with acute coronary syndrome (ACS) or a heart attack is a driving force for timely critical treatments. Patients with a confirmed diagnosis of ACS report an average of 5 symptoms at ED triage. Agglomerative clustering is ideal for categorical data and has successfully been used on potential ACS symptoms. Understanding symptom clusters for these time sensitive events is key to developing evidence-based clinical decision-making tools to improve identification of patients with suspected ACS.

**Methods**: This was a retrospective observational cohort study of adult patients who present to the ED, at a regional health care system, with at least one symptom that was highly suspicious for ACS according to the American College of Cardiology guidelines. Independent reviewers extracted 24 symptoms from the electronic health record from the initial ED encounter. All chest pain and anginal-like symptoms were combined into one variable. We performed agglomerative hierarchical clustering with the following parameters: 1) clusters=2, 2) affinity=Euclidean, and 3) linkage=average. We computed the silhouette coefficient for each point and averaged it across all of the samples to determine the silhouette score to assess the clustering quality.

**Results**: Our sample included 1651 patients (age 64±14, 46% female, 10% black, 1% Hispanic). The top 5 most prevalent symptoms were: chest pain and anginal-like symptoms (64%), shortness of breath (54%), radiating pain (28%), feeling light headed (24%), and sweating/diaphoretic (18%). All other symptoms occurred in less than 18% of the sample. Twenty-four symptoms that were collected at initial ED encounter were analyzed using agglomerative hierarchical clustering with an average silhouette score of 0.346. Figure 1 represents the dendrogram with each color representing a cluster.

**Conclusion**: Agglomerative clustering had a fair ability to cluster symptoms of patients with suspected ACS at ED triage. Symptom clustering of patients with suspected ACS may be a useful technique for clustering symptoms or clustering individuals to improve risk stratification.

A Machine Learning Approach to Predicting Time Needed for Outpatient Surgery and Patient Recovery at a Freestanding Ambulatory Surgery Center

Authors: Rodney A. Gabriel, MD, MAS1,2 and Bhavya Harjai, BS3
1Department of Anesthesiology, University of California, San Diego, La Jolla, CA, USA
2Division of Biomedical Informatics, University of California, San Diego, La Jolla, CA, USA
3Department of Computer Science, Dayananda Sagar College of Engineering, Bangalore

Abstract: In order to more accurately predict whether outpatient surgeries at a freestanding ambulatory surgery center will be efficiently scheduled, we aimed to use machine learning to determine the probability a surgery will end and the patient will be discharged from the recovery room by the expected times.

Background: Freestanding ambulatory surgery centers (ASC) are facilities that perform outpatient surgeries and constitute a significant portion of total surgeries performed in the United States. Operating room efficiency at these centers is an important component of its financial model.1 Due to predetermined staffing of ancillary staff, nursing, and physicians, surgical procedures need to be completed by a set time (to avoid over-time pay for operating room staff) and patients need to be discharged from the recovery room at a set time (to avoid over-time pay for recovery room staff). For example, a typical time for surgical end time is by 5:00pm and for facility discharge time by 7:00pm. Thus, the sequence at which surgical procedures are scheduled in the operating room needs to be optimized so that all surgeries do not go pass 5:00pm and all patients are discharged before 7:00pm. Thus, in order to more accurately predict whether cases will be efficiently scheduled, we aimed to use machine learning to determine the probability a surgery will end and the patient will be discharged from the recovery room by the expected times.

Material and Methods: Our institutional review board (Human Research Protections Program) waived the need to consent for this study as it was not considered human subjects research. Data was collected for surgeries performed at our freestanding outpatient surgery center, including surgical procedure, surgeon estimation of case duration, surgeon, total operating room time estimation, surgeon experience, and patient data (American Society of Anesthesiologists classification score, age, body mass index, and sex). Furthermore, we collected data on actual operating room time required and post-anesthesia care unit (PACU) length of stay. We sought to determine whether a surgery was appropriate to book by a certain time (i.e. 3:00pm in this example). Given that all surgeries need to end by 5:00pm and patient needs to be discharged from PACU by 7:00pm, our binary output was Boolean value that was true if the actual operating room time was less than 120 mins AND the total perioperative time (operating room time plus PACU length of stay was less than 240 mins). We used the following machine learning algorithms (including all independent features into the models): 1) logistic regression, 2) random forest, 3) balanced-bagging, and 4) balanced-random forest. We utilized Synthetic Minority Oversampling (SMOTE) for oversampling the minority class. The metric used to validate the models was the F1-score, which is the harmonic mean of precision and recall. Stratified K-fold cross validation with 10 splits was set for 3 repetitions to get the F1 scores.

Results: There were 12,920 surgical procedures included in the analysis, comprising a mixture of orthopedic (35.6%), obstetrics/gynecology (14.3%), otolaryngology (13.2%), colorectal (8.9%), urology (6.9%), breast (6.5%), minimally invasive (5.6%), and other (8.9%) outpatient surgery. The mean actual total perioperative time (operating room duration plus PACU length of stay) was 182.9 minutes with standard deviation of 85.1 minutes. When predicting whether a surgical procedure may be appropriately booked by 3pm, the mean F1 scores for each machine learning algorithm was: 1) logistic regression = 0.698 and 0.772 (with SMOTE); 2) random forest = 0.811 and 0.943 (with SMOTE); 3) balanced random forest = 0.743 and 0.943 (with SMOTE); and 4) balanced bagging = 0.786 and 0.948 (with SMOTE).

Discussion: In our analysis, we found that when using machine learning approaches – including balanced random forest – in combination with SMOTE for oversampling minority classes, the F1 scores were improved. This type of analysis is important in operating room efficiency within a freestanding outpatient surgery center. In an effort to minimize overtime pay of resources/staff, it is vital that surgical procedures are booked at appropriate times. With these models, we can more accurately predict when surgeries can be booked at various times of the day. In our example, we chose 3:00pm as a case point; however, the model can be adjusted to predict booking appropriateness at various times of the day.

Telehealth Uptake and Continuing Usage During the COVID-19 Pandemic

Cheng Gao, PhD\textsuperscript{1}, Bradley A. Malin, PhD\textsuperscript{1,2}, You Chen, PhD\textsuperscript{1,2}

\textsuperscript{1}Vanderbilt University Medical Center, Nashville, TN; \textsuperscript{2}Vanderbilt University, Nashville, TN

Introduction

Telehealth has been adopted by providers to conduct safe and timely care for patients in response to the COVID-19 pandemic. Thus, the number of telehealth visits has exploded since March 2020. However, the change of telehealth usage in the COVID-19 pandemic and how different service departments use telehealth have never been explored. In this poster, the number of telehealth visits over a nearly one-year period is reported. In addition, We compare the differences in telehealth usage across several treatment facilities from the initial outbreak to the current time.

Methods

We identified telehealth, including audio and video, visits in the electronic health records (EHR) of patients at Vanderbilt University Medical Center (VUMC) between March 2020 to mid-February 2021. According to the trend of the number of telehealth visits, we partitioned the study period into two stages: 1) the beginning of the outbreak (03/01/2020 to 06/26/2020) and 2) continuing stage after the initial outbreak (06/27/2020 to 02/12/2020). We reported the average number of telehealth visits per day for these two stages in six treatment facilities, which had the highest average number of telehealth visits during the pandemic at our medical center. These facilities include Primary Care, Diabetes, Behavioral health, Rheumatology, Neurology, and Psychiatry. Also, the changes in terms of telehealth visits were calculated using \( \frac{\text{# of visits in stage 2} - \text{# of visits in stage 1}}{\text{# of visits in stage 1}} \).

Figure 1. The daily number of telehealth visits from 03/01/2020 to 02/12/2020

Results

Figure 1 reports on the total number number of telehealth visits per day. It can be seen that the volume increased exponentially during the first few weeks of the pandemic. The volume decreased from mid-April 2020 and became relatively steady in early July 2020. However, we observed a gradual increase of telehealth visits in December 2020, which coincides with the surge of COVID-19 cases in Tennessee during the same period.

The average number of telehealth visits for the outbreak and continuing stages for each of the facilities is shown in Table 1. Each of the facilities experienced a decrease in telehealth usage between the outbreak and continuing stage. However, there was a notable variation in such reductions. Four of the facilities, (Primary Care, Diabetes, Rheumatology, and Neurology) exhibit a dramatic drop of over 40%. By contrast, Behavioral health and Psychiatry facilities experienced only a minor reduction on the order of 10%.

</table>

Discussion

The mild reductions in telehealth usage between the outbreak to continuing stage indicate that telehealth may be more suitable for Behavioral health and Psychiatry. The reasons why a dramatic drop in telehealth usage transpired for certain treatment facilities (e.g., Primary Care) and not others are unclear. Possible causes include doctors’ concerns about care quality, reimbursement policy change, and access barriers for patients (e.g., lack of high-speed internet and hardware). Further investigation is suggested on these reasons.
Leveraging Assets-Oriented, Data-Driven Approaches in Global Health Informatics Curricula

Grace Gao, PhD, DNP, RN-BC1, Christie Martin, MN, MPH, RN, LHI-HP2, Michelle Wang, BS, BA3, Matthew Byrne, PhD, RN, CNE1, and Joyce Brettner, DNP, RN-BC1
1St Catherine University, St. Paul, Minnesota; 2School of Nursing, University of Minnesota, Minneapolis, Minnesota; 3University of Georgia, Athens, Georgia

Introduction
The COVID-19 pandemic has challenged and intensified social determinants of health (SDH) and social justice issues in global health communities. SDH indicators offer descriptors of different societies and are valuable as predictors of health outcomes relevant to population health worldwide, and as such, are practical and applicable in designing global health informatics curricula. To that end, these related topics can prepare health professionals to transfer seamlessly from education to workforce and from academic informatics education to applied health informatics practice. This poster provides an initial excursion into an innovative, assets-oriented, data-driven graduate global health informatics curriculum with a focus on SDH and social justice indicators in relation to countries’ income and geographical region using open-source databases and platforms including geographic information systems (GIS) maps and data.

Curricular Design Modeling
The curricula that model both global health and health informatics bridge disciplines in social science, health science, information science, cognitive science, and computer science. The proposed global health informatics curricular modeling is intended to bridge these different disciplines by leveraging health informatics as a means of serving the purpose of advancing the study, research, and practice of SDH and social justice in global health. The target audience for this global health informatics curricula is graduate interprofessional health students needing to meet global health informatics competency and skill development focused on SDH and social justice. By employing data-driven approaches that impact what is portrayed as global health, its past, present, and future, students can gain a better understanding of SDH factors and how these factors relate to one another and function in health systems within the context of various social and healthcare settings to discover health assets and detect health challenges facing global communities.

Assets-Oriented and Data-Driven Exemplar
A better understanding of SDH and health inequalities within and across populations can facilitate collaborations aimed at helping communities strategically identify and prioritize health issues, assets, and resources. The group learning activity in this exemplar presents an opportunity for interprofessional health students to collaborate in teams and use open-data sources to identify SDH and social justice factors that may shape health outcomes within the global setting. The learning activity is designed to employ an assets-oriented, and data-driven approach to select and analyze data to work through problems comparable to what interprofessional health students would encounter in real-life settings. Students can also use historical data and apply predictive data analytics to build predictive models. At the completion of this learning activity, students will understand factors that explain unequal distributions of health and disease in various populations worldwide and the role of interprofessional health teams play in addressing these issues.

Limitation and Challenges
Limitations can relate to issues with data integrity such as missing data, time constraints, and data currency, which are also common to real-time analyses of global health informatics data. It is critical to consider time constraints and design learning activities accordingly. In addition, selection bias in choosing data may also exist.

Conclusion
Open-source health data represents a valuable tool for teaching academic informatics since it is readily available and connects students to real-world data sources and settings. Leveraging open-source SDH and social justice data and GIS maps to discover potential health assets within countries by region can enhance students’ data analytic skills and competencies to address global health SDH concerns and promote health equity and social justice.
Application of a Pharmacy Alert Management Program to Reduce Nuisance Medication Clinical Decision Support Alerts

Sean S. Garcia, PharmD1, Vera L. Taylor, PharmBS1, Michael W. Mickan, MDiv, BSN1, Sandy Kyriakos, MBA, BSN1, Nnaemeka G. Okafor, MD, MS1
1Memorial Hermann Health System, Houston, Texas, United States

Introduction
Medication clinical decision support (mCDS) alerts assist clinicians with order entry and improve patient safety1. It has been reported, however, the majority of alerts are overridden by ordering providers, with override percentages of 96%1. If there is no institutional alert management program, alert fatigue occurs as a result of excessive, clinically insignificant alerts and diminishes the effectiveness of mCDS1. Several strategies of optimizing alerts to decrease alert burden on clinicians have been reported in the literature1. We report on our approach of using an informatics-led pharmacy alert management program to collaborate with pharmacist stakeholders and combat alert fatigue.

Methods
Dashboards available on Cerner’s Lights On Network (Kansas City, Missouri, United States) were utilized to identify mCDS alert types that were firing excessively at Memorial Hermann Health System, which operates 14 hospitals. The highest-volume alert types identified were targeted for optimization and alert suppression. Data was extracted from the Lights On Network to analyze the alert types further and determine the specific alerts that were firing to pharmacists. From August to October 2020, meetings led by an informatics pharmacist occurred monthly as needed to review mCDS alert data with pharmacy stakeholders from across the enterprise. Medication safety officers, pharmacists, pharmacy managers, and pharmacy directors were engaged for collaboration to gain consensus on which alerts were deemed nuisance alerts, which were defined as clinically insignificant alerts. Alerts identified as a nuisance were suppressed thereafter.

Results
The mCDS duplicate therapy (DT) alert and drug-drug interaction (DDI) alert types were observed firing the highest volume of alerts in our system, with peak DT alerts (42.4 alerts/100 orders; override rate (OR) 91.5%) in September 2020 and peak DDI alerts (29.9 alerts/100 orders; OR 96.8%) in October 2020. As pharmacist positions were receiving the most alerts in our system, the target population for alert suppression was pharmacists. DT nuisance alerts were suppressed in October 2020. From November 2020 to February 2021, 75,093 DT alerts per month on average were suppressed. The average monthly DT alert rate was 32.8 alerts/100 orders (22.6 % reduction) compared to the baseline DT alerts observed in September 2020. The average OR for the same time period is 89.65% and represents a 1.85% increase in the acceptance rate of DT alerts. Six of the highest-volume DDI alerts were suppressed in November 2020. From December 2020 to February 2021, 52,173 DDI alerts per month on average were suppressed. The average monthly DDI alert rate was 24.1 alerts/100 orders (19.4 % reduction) compared to the baseline DDI alerts observed in October 2020. The average OR for the same time period is 94.47% and represents a 0.33% increase in the acceptance rate of DDI alerts. Extrapolating a median alert dwell time of 7 seconds for pharmacists from prior studies, pharmacists across the enterprise are saved an estimated 146 hours (DT alerts) and 101 hours (DDI alerts) per month from suppressing nuisance alerts.2

Conclusion
A pharmacy alert management program, consisting of an informatics pharmacist routinely collaborating with pharmacist stakeholders, can allow institutions to target and refine mCDS duplicate therapy alerts, reduce nuisance alerts, modestly increase clinician acceptance rate, and recover hundreds of hours of pharmacist time per month.

Patient-Centered Care Practices in Secure Messaging: Qualitative Analysis of Interviews with VHA Primary Care Teams

Lynn A. Garvin, PhD,1,2 Emily Leonard, MPH,3 Linda Am, MPH,3 Timothy P. Hogan, PhD, 3,4 Stephanie L. Shimada, PhD2,3,5

1Center for Healthcare Organization and Implementation Research (CHOIR), VA Boston Healthcare System, Boston, MA; 2Boston University School of Public Health, Boston, MA; 3CHOIR, VA Bedford Healthcare System, Bedford, MA; 4Department of Population and Data Sciences, UT Southwestern Medical Center, Dallas, TX; 5University of Massachusetts Chan Medical School, Worcester, MA.

Objective: Understand secure messaging (SM) practices of primary care teams across the Veterans Health Administration (VHA). Identify challenges and practices that support patient-centered care (PCC). Methods: Thematic analysis applied to data from qualitative interviews with 20 VHA primary care team members. Results: Teams identified barriers and facilitators to SM use at VHA/facility-, team- and patient levels to build patient-provider relationships. Conclusions: Teams can incorporate SM into clinical practice to support PCC.

Introduction. Over the past decade, the Veterans Health Administration (VHA) has reorganized its primary care services into Patient Aligned Care Teams (PACTs) to deliver patient-centered care (PCC) and communication.1 Secure messaging (SM) through VHA’s patient portal My HealtheVet is one PCC tool. Studies have explored how SM supports PCC,3 yet little is known about how primary care SM practices enable or hinder PCC. This study’s purpose was to understand current VHA SM practices, and identify strong practices and improvement opportunities.

Methods. We conducted 20 semi-structured interviews with VHA PACT members (September 2020-March 2021), recruiting from VHA facilities nationwide among: primary care providers (PCPs), registered nurses (RNs), licensed practical nurses (LPNs) and other staff. Interviews were audio-recorded, transcribed, and double coded following principles of thematic analysis. Researchers identified factors impacting PACT SM use and strategies.

Results. (1) SM roles among PCPs and nurses. Team nurses triaged the messages received, delegating them to others for role-related action. PCPs principally responded to delegated SMs (e.g., authorizing prescription refills).
(2) SM work characteristics. Participants described prioritizing speed in responding to messages because patients report increased confidence in their care teams and peace of mind based on prompt replies. PCPs reported dedicating roughly 30 minutes per day to SM; RNs and LPNs spent approximately 30-60 minutes per day on SM.
(3) SM philosophy or mental checklist. Participants tried to strengthen quality of care through timely message responses, and through messages that engage patients in their care and not get “lost” to follow-up.
(4) SM protocols. Most participants start messages with a greeting that includes the patient’s name to build rapport. Participants said they matched the purpose and tone of the message in their response: brief and transactional or longer and personal. Most conclude their SM using the automatic signature block (with name and credential).
(5) SM in the patient-team relationship. Use of SM ensured a timely, reliable response that built patient trust in PACT clinicians and VHA. SM reduced unnecessary walk-ins and provided a record of the SM exchange.
(6) PCC in SM. Participants respected patient communication preferences (i.e., SM, phone call, or visit) while recognizing their responsibility to respond using the method appropriate to the patient’s health situation.
(7) Types of SMs that get special handling. If patient messages presented medical, mental health or emotional complexity or urgency, participants elevated their response (via SM, phone call, appointment scheduled).
(8) Improvements to SM at organizational, team and individual levels. Improvement recommendations ranged from IT communication on SM system downtime, to interoperability and user interface, to patient training.

Discussion. VHA’s focus on PCC practices in SM is reflected in primary care teams’ efforts to improve patient access to their health information and patient experience with their care. SM is an integral component of PCC.

While the wide spread adoption of EHR allows access to clinical data for AI modeling, constructed cohorts at institutional levels tend to be small due to inevitable data sparsity issues, which poses a challenge to build interoperable models performing well across health systems. This work addresses such interoperability challenges, focusing on the development of time-to-event models to estimate Type 2 Diabetes Mellitus (T2D) complication times. To investigate the interoperability of such models across health systems, we applied state-of-the-art survival models on cohorts from two different health systems: US and Japan. The US cohort is extracted from a large claims dataset spanning 5 million enrollees. The Japanese cohort is extracted from Fujita Health University Hospital (FHUH). In both cohorts, we use the first T2D diagnosis as the index event and model the onset of Neuropathy. The US (FHUH) cohort covers 6981 (123) enrollees, of whom 232 (41) developed Neuropathy, respectively.

![Figure 1: Interoperability across health systems](image)

Deep survival (DeepSurv) and variational autoencoder Cox (VAECox) are two of the state-of-the-art methods and we used these two to study model interoperability. The concordance index (CI) results of applying these methods on our cohort are shown in Figure 1. The models trained on FHUH show less generalization when evaluated on the US cohort. For example, the CI of the DeepSurv model when trained and evaluated on FHUH is 0.907. However, when evaluating the pre-trained FHUH model on the US cohort the CI dropped to 0.543. This might indicate that the model trained on FHUH can not be generalized to other cohorts. On the other hand, the CI of DeepSurv when trained and evaluated on the US cohort is 0.605. Also, when evaluating the pre-trained US DeepSurv model on FHUH the CI does not drop down. Similar finding using the VAECox were obtained. Figure 1 shows the important features contributing to the estimation of the pre-trained US DeepSurv model using SHAP. Each dot represents one patient; higher values for the features are colored in red and lower values are colored in blue. The results show that having other nervous system disorder increases the risk of Neuropathy. The model shows that male (blue dots for SEX) are more prone to Neuropathy than female. As part of the ongoing analysis, we plan to investigate why patients with Disorder of lipid metabolism have lower risk of Neuropathy. We are also studying various transfer learning techniques to address such model interoperability challenges.

Utilizing Advanced Visualization Technology to Study Home Care Challenges

Denise Goldsmith MPH, MS, RN, FAAN, Sara Flash BS, Jim Holdnack PhD
Patricia Flatley Brennan RN, PhD, FAAN
National Institute of Nursing Research, Washington, DC

Introduction
Digital technologies have dramatically impacted patient care with the advent of electronic medical records, wearable medical devices, and big data analytics. The Advanced Visualization Branch (AVB) of the National Institute of Nursing Research (NINR) evaluates the potential for advanced digital visualization technologies to understand the personal and environmental challenges of homecare and self-management. These technologies offer the potential to study common self-care and home-care activities in a controlled environment. As robust data collection and evaluation is a critical element of digital research platforms, we are beginning to develop informatics guidance to characterize advanced visualization for research and intervention. We use immersive virtual reality (IVR) to study how people carry out instrumental activities of self-care management, the impact of cognitive challenges and distractors on performance, and the way observations may complement or supplant self-report data.

Method
The AVB develops interactive IVR simulations that present information to patients with a variety of complex health conditions. These simulations enable observation and measurement of problem-solving behaviors that may impact health outcomes within home-based care environments. This research evaluates digital technologies as a tool to aid in the assessment and management of factors that impact the transition from acute care settings to outpatient environments. Virtual reality environments enable us to build standardized natural settings with experimental controls that would be nearly impossible to perform in real life. We can unobtrusively observe real-time decision making so that the measurement does not perturb the natural behavior of the participant and are able to modify behavior by giving immediate behavioral feedback during intervention trials. We utilize informatics principles of naming conventions, structured information labels and written descriptions of objects, including metadata that supports mapping of virtual object’s physical parameters. Large volumes of data are captured and exported as flat files for later statistical analysis.

Results
Our first simulation investigates how individuals behave in a virtual grocery store. We are inspired by the challenge of assessing patients’ ability to follow sodium restricted diets. In the simulation, the user navigates through a typical grocery store, reads nutrition labels with sodium information, selects food as if for purchase, and places food into a basket. We measure behaviors associated with and indicative of cognitive process, such as frequency of label referencing, product comparison, search strategy and completion of selected tasks common to a shopping trip. At checkout, the selected parameters, such as dietary sodium content, are calculated and users receive visual feedback.

Discussion
We utilize a consistent approach to presenting sodium content, use formal terms to represent nutritional values and common units of measure. Some of these are used to systematically plan store layout while others are presented to the participant. We apply principles of formalization, standards, and nomenclature to characterize this novel environment. This exploratory work leads us to interesting questions: can we capture and realistically represent environmental conditions that disrupt successful self-care behavior, and can we unobtrusively measure individual differences that contribute to successful outcomes?

Self-Reported Symptoms for COVID-19 Public Health Surveillance: A Window to Social Determinants of Health

Hope G. Gray, MTS, RBC, Mohanraj Thirumalai, PhD, Wayne H. Liang, MD, MS, James J. Cimino, MD, FACMI, FACP, FAMIA, Sue S. Feldman, RN, MEd, PhD
University of Alabama at Birmingham

Introduction
In response to the COVID-19 pandemic, we launched HelpBeatCOVID19.org, a novel self-reporting symptom surveillance system based at the University of Alabama at Birmingham and focused on Alabama and the Southeast region of the United States\(^1\). Helpbeatcovid19.org captures social determinants of health (SDOH) data and is focused on a region of the USA that is particularly vulnerable to the potential sequelae of COVID-19. This study concentrates on Jefferson County, Alabama, which is 43.5% Black, has a 2018 CDC Social Vulnerability Score of 0.6621 and a high score of 0.899 for the Race/Ethnicity/Language Theme\(^2,3\). This presentation will report on research in progress to understand the utility of self-reported data with communicable disease outbreaks.

Methods
Individuals voluntarily completed an online questionnaire at HelpBeatCOVID19.org which captured SDOH data and other disease surveillance variables. The data are stored on HIPAA-compliant servers. De-identified self-reported data were culled from the HelpBeatCOVID19 database, cleaned, sorted, and analyzed by zip code. Using STATA/SE 16.1, we used regression analysis to understand associations based on zip codes, especially where there are health disparities in historically African American neighborhoods in Jefferson County. Comparisons were also made with Alabama Department of Public Health COVID-19 case reports by zip code.

Results
To date there are 102,308 people who have reported their symptoms in HelpBeatCOVID19. Of those, 77,903 are from Alabama. Midfield, AL, a predominantly African-American neighborhood (81.1\(^4\)), has 74.1% of people reporting underlying conditions where the median household income is $38,750\(^4\). By comparison, Vestavia Hills, AL, a more affluent neighborhood with 88.8% White population and median household income being $109,485, had more people participating in HelpBeatCOVID19 (3,920), yet a smaller percentage (15.2%) with underlying health conditions.

Discussion
Our intermediate analysis of the data reveals that in Jefferson County, AL, a greater number of people in more affluent communities participated in the study. Whereas state-wide, a greater percent of individuals indicated that they had zero symptoms. Limitations of this study include the unclear reliability of self-reported data, and incorrectly entered data (such as phone numbers entered in a zip code field). Although many people have smart phones, we are uncertain how the lack of accessibility to technology and reliable internet connectivity could impact the use of web based surveillance systems.

Conclusion
We believe that future studies can include additional questions to help capture SDOH and their impact on health disparities. This study begs the question: It is possible that people under reported their underlying conditions while using HelpBeatCOVID19.org and would benefit from further investigation.

Design, Development, and Usability of a Hypertension Medication Self-Management Conversational Agent (Medicagent)

Ashley C. Griffin, PhD, MPSH\textsuperscript{1,2}, Stacy Bailey, PhD, MPH\textsuperscript{3},
Saif Khairat, PhD, MPH, FAMIA\textsuperscript{1,2}, Yue Wang, PhD\textsuperscript{1,2},
Jaime Arguello, PhD, MS\textsuperscript{1}, Arlene E. Chung, MD, MHA, MMCi, FAMIA\textsuperscript{1,2}
\textsuperscript{1}University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; \textsuperscript{2}Carolina Health Informatics Program, Chapel Hill, NC, USA; \textsuperscript{3}Northwestern University, Chicago, IL, USA

Introduction

Hypertension is the most common chronic disease in the U.S. and leading risk factor for heart disease\textsuperscript{1}. While approximately 75\% of adults with hypertension are taking medications, only half have adequately controlled blood pressures\textsuperscript{1}. Conversational agents, which are systems that converse with people, have demonstrated early potential to deliver interactive self-management interventions. Very little research has focused on conversational agents for hypertension. We leveraged a user-centered design process to design and develop, and evaluate the usability of a conversational agent focused on hypertension medication self-management called “Medicagent.”

Methods

Features of Medicagent were informed by semi-structured interviews from our prior study of patients’ needs and preferences on topics such as medications, refills, communication with the care team, and resources. Based on these needs, a functional, text-based prototype of Medicagent was iteratively designed and developed using Google Cloud’s Dialogflow natural language understanding engine. Dialogflow utilizes machine learning to match natural language utterances to intents (i.e., goal of the user’s query). The prototype underwent extensive pilot testing from health professionals and informatics researchers. We iteratively added utterances identified from chat logs to the training phrases (e.g., “view medication list” or “add my blood pressure”). For usability testing, purposive sampling was used to select ten adults with hypertension taking at least one prescribed medication based on age, race, gender, education, and number of medications. Usability testing sessions were conducted on a web-based version of Medicagent on participants’ personal computers during virtual video-recorded sessions. The session included: 1) background questionnaire, 2) ten hypothetical tasks within Medicagent using concurrent think aloud methods, 3) System Usability Scale (SUS) questionnaire, and 4) a brief semi-structured interview. Effectiveness, efficiency, and satisfaction metrics in the International Organization for Standardization 9241-11 standards were used to assess usability of the prototype.

Results

Ten participants completed the usability testing session. The average age was 60 years, 50\% were female, 50\% were Black, and 50\% had at least a college education. Participants were taking on average four medications. Participants spent a mean of 18 minutes (SD=10) interacting with Medicagent during the testing session, and nearly all tasks (98\%, 98/100) were completed. Two participants made errors inputting the correct medication and confirming that a new medication was added to the medication list. 8.6\% (11/128) of utterances were not successfully mapped to an intent. These errors resulted from unrecognized spelling or formatting of dates, times, and blood pressure values. Medicagent achieved a mean SUS score of 78.8/100, which demonstrates acceptable usability. Several participants had difficulties navigating the conversational interface without menu and back buttons, felt additional information would be useful for redirection when utterances were not recognized, and reported the need to provide a health professional persona.

Conclusion

In the emergent field of conversational agents for self-management, this study is one of the first to describe the design, development, and usability of a conversational agent focused on hypertension medication self-management. We identified areas for refinement, which could be used to inform the subsequent phase in the user-centered design process towards evaluating potential efficacy. Additional usability research for conversational agents should investigate the appropriateness of responses and unintended consequences of errors within the context of self-management.

Digital Methodology for Mobile Clinical Decision Support Development

Amy Grimsley, MSN, RN, CCRN-K1, Katrina Boles, MS1, Chelsea Howland, MSN1, Chuka Emezue, PhD, MPH, MPA1, Malaika R. Gallimore, RN, MPH1, LeeAnne B. Sherwin, PhD, MS, FNP-BC1, Jo-Ana D. Chase, PhD1, Blaine Reeder, PhD1, Allison B. Anbari PhD, RN1

1University of Missouri, Columbia, MO, USA

Introduction
Research at academic institutions faced a number of barriers during the global pandemic when in-person interactions were limited to prevent the spread of the COVID-19 virus. Research activities to develop a mobile clinical decision support app in the Precision Smart Technologies and Application for Rapid Translation (Precision START) laboratory at the University of Missouri quickly pivoted from a traditional face-to-face methodology to a fully digital methodology and maintained the project momentum. Our Mobile Application Information System for Integrated Evidence (MAISIE) project to bring evidence-based apps to nursing homes (NH) launched right before stay-at-home orders in March 2020. MAISIE extends prior work that developed a mobile clinical decision support app for evidence-based urinary tract infection (UTI) symptom concordance and anti-microbial stewardship in NH1.

Methods
The MAISIE team is homed in the Precision START laboratory. Lab membership totals nine members (five graduate students and four faculty) in five states. Our digital methodology implements methods translated from previous experience gained in applied technology research in NH and other contexts. Specifically, we pivoted from in-person meetings to video meetings for all lab activities including weekly team, stakeholder, and software developer meetings. App feature sets were accessed via the web when posted by the developer. Usability and function testing were conducted remotely. Test results were aggregated and discussed online.

Results
The MAISIE team has met exclusively online since March 2020 with limited interruptions to project progress. The creation of new case scenarios and interface design recommendations extended previous work. The MAISIE app was developed with interfaces that follow a head-to-toe assessment workflow typical of nursing practice (Figure 1). In addition to implementing a UTI symptom checklist based on prior work1, we added a COVID-19 symptom checklist feature based on guidance from the Centers for Disease Control and the World Health Organization. The app is ready for testing with external stakeholders and nurses in NH settings who will download and install the app from a development website and conduct usability tests via synchronous remote testing.

Conclusion
A completely digital methodology enables successful design, development, and testing of mobile clinical decision support apps. Advantages of this approach are minimization of project delays, inclusion of remote research team members, and elimination of infection risk for team members, software developers, external advisors, NH staff and residents. This digital approach can be applied to any health-related mobile app regardless of setting or target user. Next steps are to implement features for the five most common conditions that lead to preventable hospitalization for NH residents. Full description of methodology and current evaluation results will be presented at the conference poster session. Evaluation metrics will include participant usability and technical testing.

Impact of Comorbidity Profiles on Pain Trajectories in Breast Cancer Patients by Using Electronic Health Record Data

Jia-Wen Guo, PhD1, Katherine A. Sward, PhD1, Ann Lyons, PhD1, Susan L. Beck, PhD1,
Gary W. Donaldson, PhD1, Wendy W. Chapman, PhD2, Lewis J. Frey, PhD3
1University of Utah, Salt Lake City, Utah, USA; 2University of Melbourne, Australia;
3Medical University of South Carolina, Charleston, South Carolina, USA

Introduction

Approximately 20% to 30% of the breast cancer patients reported different levels of pain,1 despite a variety of treatments. According to the Integrated Model of Multimorbidity and Symptom Science,2 comorbidities, or the coexisting conditions in addition to a primary disease of interest, are part of the contributing or risk factors to patient outcomes. The impact of comorbidities on pain in breast cancer patients has been little studied. Therefore, the purpose of this study was to examine the association between pain trajectories of breast cancer and the comorbidity profiles.

Methods

This is a secondary data analysis from a retrospective, observational cohort study using electronic health record (EHR) data from a single medical center. In the primary study, four types of comorbidity profiles, based on the 17-items Charlson comorbidity index, were identified from 4412 adult inpatients (age>18 years) of any kind of cancer diagnosed from 12/2010 to 05/2019. In this study, only breast cancer (N= 1740) was included from the primary study dataset. The comorbidity profiles of the sample were: few comorbidities with nonmetastatic cancer (68.8%), few comorbidities with metastatic cancer (24.3%), multiple comorbidities with nonmetastatic cancer (4.4%), and multiple comorbidities with metastatic cancer (2.5%). To identify distinct longitudinal patterns of pain trajectory, the patients’ first two-year pain score data (0=“no pain”, 10=“worst pain possible”) since the first admission was used by group-based trajectory modeling (GBTM). Then, Multinomial logistic regression modeled the comorbidity profiles as predictors of pain trajectory patterns, including age and cancer stage as covariates.

Results

The mean age of the sample was 57.8 years (SD=12.7, range=20.9-96.7). The majority of the sample were female (99.2%), non-Hispanic/Latino (94.2%), White (90.3%), and a cancer stage of <=2 (79.7%). Four pain trajectory patterns were identified by GBTM: stable/consistent very mild pain (79.0%), increasing from mild to moderate pain (8.4%), decreasing from mild to very mild pain (7.8%), and consistent moderate pain (4.7%). When comparing patients’ demographic and clinical characteristics among different pain trajectory patterns, patients in consistent moderate pain were more likely to be at the late cancer stage (p<.001). The multinomial logistic regression analysis compared other trajectories to the stable/consistent very mild pain pattern; the comorbidity profiles were the significant predictors in all the pain trajectory patterns. Moreover, the cancer stage was another predictor in the trajectory decreasing from mild to very mild pain (OR:1.28, 95% CI: 1.06–1.56, p=.012) and the consistent moderate pain trajectory (OR:1.44, 95% CI: 1.13–1.84, p=.003). Age was not a significant predictor for any of the trajectory patterns.

Conclusions

Identifying risk factor profiles shared by specific subgroups of patients provides the first step to assist clinicians in caring for patients with complex cancer pain; however, this study was constrained by the limits of the EHR data included in the primary study. Clinically, patients in increasing from mild to moderate pain and consistent moderate pain trajectory could benefit from provider awareness of the trajectory for better pain management. Further studies by including other variables and taking consideration of different comorbidity profiles will assist in developing tailored interventions for patients with a specific pain trajectory.

YouTube Video Analytics for COVID-19 Literacy
Yawan Guo, MS¹, Xiao Liu, PhD², Anjana Susarla, PhD³, Rema Padman, PhD¹
¹Carnegie Mellon University, Pittsburgh, PA; ²Arizona State University, Tempe, AZ; ³Michigan State University, Lansing, MI

Introduction
The rapid evolution of COVID-19 into a pandemic has called for improved health literacy to inform and educate the public.¹ YouTube, the largest video-sharing social media platform, hosts several million health-related videos about the pathogenesis, diagnosis, treatment, and prevention of various medical conditions and provides publicly available, user-generated health information in a rich visual format, which may be easier to understand and comply with for patients at all levels of health literacy. However, YouTube video contents may also misinform and contradict reference guidelines and there is lack of a clear and consistent mechanism to retrieve high-quality videos for health education.² This preliminary study develops an automated solution to filter and evaluate YouTube videos on COVID-19 topics from health literacy perspectives that consumers can access on a rapidly evolving and dangerous pandemic.

Methods
Our data collection process generates keywords about COVID-19 and retrieves videos matching these keywords, along with their metadata, using YouTube Data API. Keywords are collected from WHO’s and CDC’s FAQ pages, and online forums where consumers pose relevant search terms for information they seek. We extract features from the collected videos to assess their medical information content and understandability. Videos are annotated for understandability using AHRQ’s Patient Education Materials Assessment Tool (PEMAT)³ for audio-visual materials by graduate students with medical and non-medical backgrounds to represent clinical and consumer perspectives. Google Cloud Video Intelligence API functions such as object detection, video transcription, scene detection and optical character recognition are applied to extract important video features to automate PEMAT constructs. The Unified Medical Language System acts as a reference for medical information annotation and used to train a Bidirectional Long Short-Term Memory Recurrent Neural Network to extract medical terms from video descriptions and assess medical content. Finally, medical content and understandability features are used to train and evaluate several machine learning classifiers to recommend videos for patient education on COVID-19 related topics.

Results
We fetch the top 25 videos, contributed by both individual users and reputable healthcare organizations, for 40 search terms and store their ranking and metadata for further analysis. Limiting to videos of short duration (1-6 minutes) for easy viewing resulted in 304 unique videos for annotation. 33 features are extracted from the videos for building different classifiers for video recommendation classification. The models are trained on 228 randomly selected videos and evaluated on 76 hold out videos using four widely used machine learning methods. Results in Table 1 show the Random Forest classifier exhibiting the best performance. In addition to the number of unique medical terms extracted from the video narratives by the Bi-LSTM deep learning model, indicating the importance of medical content, video engagement measures such as duration, favorites and comments are also significant predictors for the recommended videos. 24 videos are in the final recommended set.

Discussion
In this study, we synthesize information retrieval, machine learning and statistical methods to identify YouTube videos on COVID-19 related topics that encode understandable medical content. Our findings have implications for consumers, healthcare and public health professionals, patient educators, researchers and policymakers. Next steps include extracting additional features to help delineate specific infectious disease related topics, improving classification performance, adding criteria such as content accuracy and evaluation by clinical experts and consumers.

Movement disorders is a subspecialty of neurology, and includes several disabling, common and rare neurological disorders, including Parkinson's disease (PD), essential tremor, dystonia, Huntington's disease etc. PD is the most well-known of all movement disorders(1), and related to PD, there is a group of rare but rapidly progressive and even more disabling disorders, collectively termed as atypical parkinsonian disorders (APD). Although there are distinct clinical and pathological diagnostic criterion for PD and APD, patients present in the clinic with overlapping clinical features, which evolve with a great deal of variability and complexity over time. This leads to high level of uncertainty in the prediction of diagnosis and progression for an individual patient on clinical grounds. These challenges faced by patients, their families and clinician are further exacerbated by the lack of sensitive or specific diagnostics tests and biomarkers. Therefore, there is a clear need for a clinical decision support tool that can integrate and organize relevant data for informed decision making. A key critical gap in this respect is the lack of a comprehensive domain ontology for movement disorders, which can enable formal knowledge model for data input, semantic data integration, and support analytical queries for predictive modeling in parkinsonian disorders.

Although an ontology for Parkinson’s Disease (PDON)(2) has been developed, the focus of PDON is on basic science research that significantly limits it use in clinical as well as clinical research data query and retrieval from PD databases and biorepositories. In this abstract, we introduce the Parkinson and Movement Disorders Ontology (PMDO) that has been designed to: (i) Improve access to both research and clinical trial data being made available by open-access PD databases, such as Accelerating Medicine Partnership in Parkinson Disease (AMP PD) and Parkinson Progression Marker Initiative (PPMI), and clinical trials databases maintained by the Parkinsonian Study Group (PSG); (ii) Enable interoperability and mappings between a variety of instrument/scales that are used in the evaluation of patients in movement disorders clinical centers; and (iii) Facilitate multi-institution research studies through the development of interoperable data management tools with adequate statistical power.

The development of PMDO was based on three criteria: (i) literature survey on the phenotypic and genotypic characteristics of parkinsonian disorder; (ii) diagnostic criteria used for patient evaluation; (iii) metadata as well as data attributes of research cohorts, including longitudinal study methods and cohort inclusion exclusion criteria. The PMDO was developed using an iterative collaborative process with the use of clinical workflow used by movement disorders specialists as reference protocol for prediction of diagnosis, progression, and prognosis, as we all as ontology engineering best practices that included use of structural metrics to evaluate the information content of the ontology and identify modeling errors and improve the structure of class hierarchy. The PMDO class hierarchy uses the Basic Formal Ontology (BFO) as a reference upper-level ontology. The current version of PMDO consists of terms representing the phenotypic traits of PD and APD, the components of diagnostic criteria used during patient evaluation, and data elements used in the PPMI and AMP PD cohort studies, which are modeled as subclasses of the three BFO classes of DependentContinuant, IndependentContinuant, and Occurrent.

We are currently expanding PMDO to include all relevant clinical and research terms of all movement disorders, with a particular focus on modelling the complexity of the underlying pathophysiological characteristics that lead to disparate phenotypes in patients, with an emphasis on modeling genotypic data with explicit correlation with symptoms exhibited by patients. In addition, there is a clear need to model the neuropathology findings in terms of fluid and imaging biomarkers. As for application of PMDO, we are integrating PMDO with the Insight system(3) and the PPMI database for creating Insight-PD, an Ontology-driven data integration and patient cohort query platform for retrospective datamining of such databases. Furthermore, PMDO will form the foundation of Ontology-based, Real-time, Machine learning Informatics System for Parkinson’s Disease (ORMIS-PD) clinical informatics system for predicting PD subtype and prognosis at point-of-care in clinic. The PMDO is currently available at BioPortal at following link: https://bioportal.bioontology.org/ontologies/PMDO.

A Mixed-Methods Evaluation of Telehealth Adoption in Frontier Critical Access Hospitals

Saira N. Haque, PhD, MHSA, FAMIA, Alison Banger, MPH, Sydney DeStefano, BS, Regina Rutledge, PhD, Melissa Romaire, PhD
RTI International, Research Triangle Park, NC

Introduction

Frontier areas have low population density at great geographic distance from population centers and services. As a result, the Critical Access Hospitals (CAHs) that serve these areas might not be able to provide the services that are needed in the community. One way to ameliorate these challenges is through telehealth. Policy and reimbursement considerations are among the most significant barriers to greater telehealth uptake. Thus, the Center for Medicare and Medicaid Services (CMS) embarked on the Frontier Community Health Integration Project Demonstration (FCHIP) from August 2016 through July 2019 to learn how changing payment for telehealth to cost-based reimbursement impacted telehealth uptake and use. In particular, we were interested in impacts on hospital administration, hospital finances, patient/consumer access and spillover effects in the community.

Methods

We conducted a mixed-methods evaluation of the 8 hospitals in Montana, Nevada, and North Dakota that participated in the telehealth component of the FCHIP demonstration. The study was reviewed by the RTI International Institutional Review Board. Quantitative methods involved comparing frequencies and types of telehealth claims of Medicare beneficiaries who were part of the FCHIP demonstration versus a comparison group of beneficiaries in non-FCHIP CAHs in Montana, Nevada, and North Dakota. Primary analyses were hospital-based frequencies and secondary were beneficiary-based differences. Qualitative methods were key informant interviews and document review. We developed semi-structured interview guides that were tailored to common roles across FCHIP CAHs (e.g., provider, telehealth coordinator, administrator). We conducted annual in-person or telephonic interviews through the duration of the demonstration, which were recorded and transcribed. In addition, we reviewed program documentation that the FCHIP CAHs provided. Transcripts and documents were coded using NVIVO to support thematic analysis for all four domains of interest (hospital administration, hospital finances, access and spillover effects).

Results

We found varied results across the four domains of interest. For hospital administration, the FCHIP CAHs used technical support and assistance provided to demonstration participants to inform telehealth implementation, marketing and outreach. Implementation support included changes to clinical and administrative workflows and training and identifying clinical and administrative champions to facilitate workflow changes and coordination between the sites. Claims volumes were low, which resulted in nominal impacts on hospital finances. By the end of the demonstration, 6 out of the 8 participating sites billed Medicare for telehealth services, although all reported providing telehealth services. Some CAH administrators noted positive impacts on hospital finances due to ancillary services being conducted at the CAH at the direction of distant sites. The 6 FCHIP CAHs that billed Medicare had 289 telehealth encounters for 150 unique beneficiaries. The specialists that were accessed the most were cardiology, nephrology and behavioral health. CAHs reported that their patient population appreciated not having to travel great distances to receive care. Spillover effects such as impacts on the surrounding regional health delivery system, providers of community-based services and payers, varied across CAHs. The variation was based on factors such as relationships with neighboring hospitals.

Conclusion

The frontier setting is characterized by low population, and thus the volumes of telehealth services provided in the CAHs and comparison sites are low. Overall, CAHs reported that patient satisfaction was high and expressed the desire for more virtual services. Telehealth service selection was informed by community needs, but formal community needs assessments were not completed. Future work could include standardized, formal community needs assessments and assistance finding distant providers to meet those needs. Implementation support services helped CAHs integrate telehealth into clinical and operational workflows. However, billed telehealth services were fewer than reported services. This indicates a need for assistance around billing.

Enhancing Clinical Relevance of Health Behavior Insights via Semantics

Jonathan Harris¹, Deborah L. McGuinness, Ph.D.¹, Marco Monti, Ph.D.², Oshani Seneviratne, Ph.D.¹, Mohammed J. Zaki, Ph.D.¹, Ching-Hua Chen, Ph.D.³
¹Rensselaer Polytechnic Institute, Troy, NY; ²IBM, Italy; ³Center for Computational Health, IBM Research, Yorktown Heights, NY

Introduction
Personal health applications are designed to help users adopt healthier lifestyles. In general, however, it has been challenging to bring consumer health applications into clinical settings. The insights provided to users for tracking and monitoring their progress are not always immediately related to clinically meaningful concepts. To enable richer and more meaningful summaries, we extended an existing Time-Series Summarization (TSS) framework to dynamically generate semantic representations of frequent and/or anomalous behavioral patterns discovered from personal health data that is tracked over time. These behavioral patterns are used to populate a personal health knowledge graph (PHKG). To improve clinical relevance, we implemented a semantic reasoner that reasons over the PHKG as well as semantic rules based on health guidelines from the American Diabetes Association (ADA).

Method
Based on interviews with 21 adults with type 2 diabetes, we defined a Personal Health Ontology (PHO) to capture behavioral concepts (e.g., dietary patterns and preferences) and relationships to be instantiated in the PHKG. The TSS generates Resource Description Framework (RDF) triples to populate the PHKG with summaries of the user’s dietary behaviors. The PHKG has been instantiated as a queryable Blazegraph™ database. Additionally, several ADA guidelines related to diet and activity were modeled in a computable form using the Web Ontology Language (OWL). A semantic reasoner performed logical inference over the PHKG, the guideline rules, and an existing Food KG (which contains knowledge of hundreds of thousands of popular recipes) to answer a user’s query. An example of a supportable query is shown in Figure 1.

Figure 1: Example of an anomaly and trend in carbohydrate intake discovered by TSS and translated into RDF triples for the PHKG. A semantic reasoner reasons over the ADA guidelines, the Food KG and PHKG to answer the query.

Conclusions
Using the available set of ADA guideline OWL formalizations and the PHKG, a semantic reasoner can be used to infer whether the individual has been adhering to behaviors that are consistent with the guidelines. In any cases of violations, the semantic representations allow us to provide evidence-based recommendations based on their lifestyle and diabetes condition. Ongoing and future work is focused on (1) expanding the PHO to accommodate concepts important for comparing behaviors to ADA guidelines, (2) incorporating other knowledge resources such as the Healthy LifeStyle (HeLiS) ontology, which integrates knowledge related to food and activity.

Promoting Use of Common Data Elements in Research Studies

Paul A. Harris, Ph.D., Rob Taylor, MA, Vaishali Jagtap, Douglas Conway, Stephany N Duda, Ph.D., Alex C. Cheng, Ph.D., MEM
Vanderbilt University Medical Center, Nashville, TN, USA

Introduction
The COVID-19 pandemic heightened interest in standardizing research data collection for observational studies and clinical trials. The U.S. National Library of Medicine (NLM) manages federally sanctioned common data element (CDE) sets in the NIH CDE Repository. While the NIH CDE Repository makes data elements available in a central location, the process of finding and transferring CDE details when creating study data collection instruments is cumbersome. REDCap (Research Electronic Data Capture) is a secure, web-based software platform designed to support data capture for research studies. REDCap is developed at Vanderbilt University Medical Center and widely used by research teams at more than 4900 partner institutions in 141 countries. We implemented a self-service workflow tool within REDCap to promote awareness and adoption of CDEs from the NIH CDE repository.

Methods
The REDCap CDE workflow tool uses an application programming interface (API) available from the NIH CDE Repository to search and retrieve metadata associated with NLM-curated CDEs. This API-driven approach enables real-time CDE content refresh and eliminates the need to download and store large amounts of CDE metadata within the REDCap application. After exploring CDE metadata content, our development team reviewed existing REDCap project creation workflow options and anchored the CDE discovery tool within the context of a larger workflow where research teams create case report forms or survey instruments for individual studies. In this process, researchers typically add a field to a data collection instrument by providing details about the desired data element (e.g. question label, type of input field, categorical options and codings, and validation requirements). The new CDE workflow tool simplifies this process by inviting end-users to “import from field bank” when adding a new data element. Once invoked as a workflow choice, research end-users are prompted to enter a keyword for real-time retrieval of associated CDEs within the NLM CDE Repository. Researchers can choose an option to retrieve information about CDEs curated by a specific institute or program such as NHLBI, NINDS, or RADx-UP. A keyword search triggers retrieval of one or more relevant CDEs. Then researchers are presented with a form-rendered version of the CDEs with relevant attribution details and options (e.g. contextual text labels) and are invited to assess fitness of use in their study. Upon selection of a specific CDE for inclusion, metadata details (e.g. question text, response option codes, response option text, and CDE ID number) are automatically transferred to the study data collection instrument and immediately available for research data collection and management.

Results
The REDCap CDE workflow tool was tested at Vanderbilt and disseminated to the REDCap Consortium in mid-January 2021 with REDCap version 10.7.0. Our decentralized model for REDCap dissemination does not allow for detailed evaluation of use from Consortium partner sites. However, we can access coarse usage details from institutions that choose to report statistics. In the two months post-release, we are aware of 357 partner institutions where the new CDE workflow tool is available to research teams. Researchers at 24 institutions have imported at least one CDE from the NIH CDE Repository into REDCap. Among these institutions, 189 CDEs have been imported. Researchers at Vanderbilt University Medical Center have imported 22 CDEs.

Discussion
We have created a user-friendly workflow designed to promote the use of CDEs by research teams using REDCap. This tool will not solve all problems associated with national and international adoption of CDEs, but we hypothesize that we can increase awareness and use of CDEs within the REDCap Consortium. In discussions with early adopters within the REDCap Consortium, we have received requests to consider content from additional CDE sources, including international CDE repositories. Future plans include evaluation and evolution of the CDE workflow tool with early adopters and potential expansion to include additional CDE repositories.

COVID-19 Dashboard: Visual Exploration of the Regional Pandemic Trend

Huan He, PhD 1, Liwei Wang, PhD 1, Andrew Wen, MS 1, Ming Huang PhD 1, Yanshan Wang, PhD 2, and Hongfang Liu, PhD 1

1Department of AI and Informatics Research, Mayo Clinic, Rochester, MN, USA
2Department of Health Information Management, University of Pittsburgh, Pittsburgh, PA, USA

Introduction: The fast spread of the coronavirus disease 2019 (COVID-19) has led to a worldwide pandemic and health crisis since December 2019. To address the urgent needs of tracking the regional trends of the COVID-19 outbreak, many organizations collected datasets from multiple sources and developed interactive dashboards to show the situation. However, due to the complexity of pandemic, it is challenging to explore and compare how the COVID-19 outbreak evolves in different regions. To address this challenge, we therefore present the COVID-19 dashboard to explore both the geographical and temporal patterns of the COVID-19 pandemic and update it daily.

System and Visual Design: To compare the regional pandemic difference intuitively, we proposed a new indicator, namely CrRW status, which is defined by combining the 7-day smoothed average case rate per 100k capita (Cr7d100k) and Cr7d100k ratio (i.e., the ratio of today Cr7d100k to 7 days ago) with the following empirical thresholds in the past seven days: the GREEN status, if Cr7d100k<15 and RW_Cr7d100k<1; the RED status, if Cr7d100k > 30, or if Cr7d100k > 15 and RW_Cr7d100k > 1.1; and the ORANGE status for everything else. To ensure that the dashboard could be updated continuously and automatically, we developed a data pipeline to collect data from public data sources (e.g., USAFacts, John Hopkins Coronavirus Resource Center, etc.) and calculate the indicators such as positive test rate, vaccinated percentage, as well as our proposed CrRW status for each region. We collaborated with domain experts from our clinic and developed the COVID-19 dashboard. As shown in Fig.1 (A), we designed a calendar-based heatmap to show the overall CrRW status changes. Users could click on the date cell to check the pandemic status of a specific date and the maps on different levels will be updated accordingly (Fig.1 (B)). We designed a novel trend chart to show how the pandemic changes overtime (Fig.1 (C)).

Discussion: As the COVID-19 pandemic situation changes, we could observe the trends by using this dashboard. We found that selecting appropriate indicators is important to capture the pandemic status accurately, especially when the pandemic varies from region to region. Although the outbreak has been significantly controlled by the non-pharmacological interventions and the massive vaccination, it is still not completely over. We will keep tracking the pandemic and adding new data such as new variants reports when dataset is available.

Overview and Descriptive Analysis of a New Ontology for Normalizing Section Types in Unstructured Clinical Notes

Paul M. Heider, PhD¹, Stéphane M. Meystre, MD, PhD¹
¹Medical University of South Carolina, Charleston, SC

Introduction: Context is critical to understanding the relevance of terms mentioned in unstructured clinical notes. Just as note types provide a gross sense of context, note sections refine that context by restricting the domain. Splitting notes into sections consists of two subtasks: finding boundaries and adding standardized labels. We present a new section type ontology to facilitate and standardize the work done in this second normalization subtask. Systems that address both subtasks can be mapped to our standard for easy cross-system comparison. Systems that only address the first subtask can benefit from more consistent corpus annotation. We provide descriptive statistics for two section-annotated corpora, including section labels for the first of these corpora which has not previously been normalized.

Methods: The core ontology was constructed by analyzing consistencies between other existing section type classification systems with the goal of comparing work across these different systems. These listings included: SecTag¹², Textractor¹, SOAP, LOINC, and an early prototype for processing clinical notes related to COVID-19 patient visits. We targeted a shallow hierarchy with depth introduced for section types that are as frequently addressed together as addressed individually (e.g., “Assessment/Plan”, “Assessment”, and “Plan”).

Our first corpus augmentation was on the i2b2 2014 Shared Task⁴, which consists of 1,304 de-identified clinical notes. Dai et al.⁵ released section split annotations (i.e., subtask 1) pre-annotated with machine-generated spans and corrected by the authors. We semi-automatically mapped these section header strings to our own section ontology types. Headers that directly matched an ontology label were mapped to that label. All other headers were manually reviewed for mapping by the first author with consultation with the second author. Our second corpus augmentation was to update the normalized section types in a corpus originally part of Textractor¹ development at the University of Utah. As the Textractor type system had already been mapped to the current ontology, this work consisted of updating the normalized string in the reference standard and porting it from Knowtator XML to brut and UIMA CAS XMI formats.

Results: The ontology consists of 29 top-level section types. Six of those concepts have one level of subtype. All top-level types and subtypes total to 50 unique section types. The Dai et al. corpus contains 13,133 total section header strings with 1,316 unique strings. Mapped to our new ontology, an average note has 10.1 headers with 8.5 unique section types. The Textractor corpus contains 2,920 total section header strings with 944 unique strings. Mapped to our new ontology, an average note has 34.0 headers with 13.2 unique section types.

The ontology structure, types, and mappings to prior section type systems is available via github: https://github.com/MUSC-TBIC. We cannot directly release our corpus augmentations due to restrictive rights. However, we have released (via github) a mapping script that can be applied on top of the Dai et al. annotations for the 2014 i2b2 corpus for individuals who have already gained access to this corpus through standard channels.

Conclusion: One outstanding issue with section normalization, that is also true of clinical note type normalization, is the common occurrence of clearly composed section types that are not indicative of the need for a supertype (e.g., in contrast to “past medical history” and “past surgical history” sitting under “past history”). The LOINC document ontology has taken a faceted approach by allowing multiple, orthogonal labels to be applied to a note (e.g., author’s role vs. type of service). More research is required to understand how pervasive and problematic these headers are.

Evaluating the Downstream Performance Impact of Various Common Off-the-Shelf Clinical NLP Components

Paul M. Heider, PhD1, Stéphane M. Meystre, MD, PhD1
1Medical University of South Carolina, Charleston, SC

Introduction: As the field of clinical natural language processing (NLP) matures, the available full system pipelines and individual customizable modules grow in pace. Researchers dutifully compare their systems to a subset of reasonable baselines. Often, however, performance metrics do not include variation introduced by upstream (pre-processing) modules or by their own contributions on downstream modules. We argue that part of our scientific due diligence is to facilitate and publish off-the-shelf protocols and scripts to cover these gaps in the literature. Prior studies1, 2 have documented system deployment and evaluation of the same task. We compare the downstream impact of system-critical NLP pre-processing modules. That is, how does the choice of tokenization and sentence boundary detection alter the (downstream) performance of a dictionary look-up module and a machine learning module?

Methods: To maintain consistency, we used a single (but configurable) Apache uimaFIT3 pipeline for testing. Output was evaluated using the ETUDE engine4, a freely available open-source evaluation tool for unstructured data and extractions. The pipeline, available via https://github.com/MUSC-TBIC, is described below. We focused on two upstream pre-processing tasks essential to most NLP work: sentence splitting and tokenization. For our dictionary look-up task, we used UMLS Metathesaurus-based dictionaries containing terms for symptoms commonly associated with COVID-19 and matched them using UIMA’s ConceptMapper. For our machine-learning task, we used the base version of a BiLSTM-CNN-CRF de-identification system trained on a MIMIC-III-based word embedding model.

Results: The top half of Table 1 presents scores for each tokenizer on symptom extraction, as the dictionary look-up was configured to ignore sentence boundaries. The bottom half of Table 1 presents scores for tokenizer and sentence splitter pairs. We found tokenization had a more significant impact on these particular downstream tasks than sentence boundary detection. Holding the tokenizer constant, different sentence boundary detection algorithms only impacted the F1-score by at most 5%. In contrast, holding the sentence splitter constant effected the F1-score by up to 56%.

Integrating Medical and Dental Histories for Translational Science

Darren W. Henderson¹, Malini S. Kirakodu², James R. Aaron, MHA¹, Tamela J. Harper, MHA¹, Daniel R. Harris, PhD¹, Jeffery Talbert, PhD¹, Luciana M. Shaddox DDS, MS, PhD²

¹Center for Clinical and Translational Sciences, University of Kentucky, Lexington, KY 40506; ²College of Dentistry, University of Kentucky, Lexington, Kentucky 40506.

Abstract We present our efforts to integrate University of Kentucky College of Dentistry clinical data into our i2b2 warehouse. This linkage allows researchers to easily combine dental health history with other facets of the electronic medical record when predicting patient cohort sizes. By integrating these disparate clinical systems, we successfully link a meaningful subset of the dental patients (25%) and encounters (42%) into our existing clinical i2b2 data warehouse comprising both inpatient and ambulatory encounters in the UK Healthcare system.

Methods There is broadening evidence supporting the need to link oral health with overall health¹ and the integration of electronic dental data with other clinical data²,³. The University of Kentucky College of Dentistry averaged 44,072 patients per year from 2010-2020 (1.1 million visits in total). We extended i2b2 by adding an ontology matching the Current Dental Terminology (CDT) developed by the American Dental Association; local codes were added as children within CDT. This metadata development enabled the low-effort intersecting of dental observations with other clinical observations in i2b2. The dental data uses the multi-fact table approach supported by i2b2 and could be easily adopted by other institutions.

Discussion Using a deterministic method allowing fuzzy matching, we matched 25% of the available patients in the dentistry data to their general UK Healthcare record. Only 8% of patients strictly matched on social security number, name, and date of birth; allowing the social security number to be optional greatly increased the matches. Internal efforts are underway to improve the quality and completeness of patient records at the dental clinics which will further increase the linking success rate. With 25% of the population matched, we were able to link these dentistry patients to 17.2% of the UK Healthcare encounters, representing 13.6% of the overall clinical facts available in i2b2.

Development of a Health Equity Integration Dashboard (HEID) using Race Ethnicity and Language (REaL) Data in a Pediatric Hospital Setting: Lessons Learned in Visual Strategies and Key Data Elements

Raquel G. Hernandez MD MPH1,2,3, Paola Dees MD3, JoAnn DeRosa4, Fiorella Gonzalez4, Christine Hammerschmidt MA4, John Morrison MD PhD1,2,3, Benton Ng MD5, Ashish Shah MD MBA5, Luis Ahumada MSCS PhD1

1. Johns Hopkins All Children’s Hospital, Institute for Clinical and Translational Research, St. Petersburg, FL.
2. Johns Hopkins University School of Medicine, Department of Pediatrics, Baltimore, MD.
3. Johns Hopkins All Children’s Hospital, Department of Pediatric Medicine, St. Petersburg, FL.
4. Johns Hopkins All Children’s Hospital, Division of Quality and Safety, St. Petersburg, FL.
5. Johns Hopkins All Children’s Hospital, Heart Institute, St. Petersburg, FL.

Introduction: Efforts to promote health equity hinge on effective and visually intuitive methods of quantifying and monitoring clinical outcomes stratified by social determinants of health (SDOH). The development of health equity dashboards using health informatics strategies is a novel approach with favorable results in addressing disparities observed in early models. We describe our institution’s experience in developing and vetting a pediatric health equity integration dashboard (HEID) focused on addressing racial-ethnic disparities in hospital readmissions, length of stay and cardiac surgical mortality.

Methods: Johns Hopkins All Children’s Hospital (JHACH) is a 259 bed quaternary free-standing children’s hospital that is a safety-net for uninsured and underinsured children and serves a racial-ethnically and linguistically diverse population. Past QI efforts within the organization have leveraged EMR-based clinical outcomes focused on 30-day inpatient readmission and length of stay and cardiac surgical mortality. These outcomes have not previously been stratified by race, ethnicity or language (REaL). Composite REaL categories were created (e.g. Black-Non-Hispanic, Black Hispanic) allowing each clinical outcome to reflect a control group (lowest risk) and group of interest (highest risk). Visualization strategies for these data include: 1) use of empiric quarterly metrics vs. relative rates, 2) use of area under the curve (AUC) to compare rates, 3) limiting the use of traditional “traffic light” visuals and colors and promoting more objective color schemes to limit bias and inferences on observed disparities.

Results: Our Health Equity Integration Dashboard model (Figure 1) reflect three main strategies: 1) Display of Quarterly/Year metric rates by group of interest (dark blue) against comparison group (light blue). 2) Display of moving average rate into an AUC graphing approach to help display group disparities in parallel. 3) Linear depiction of the moving average difference between the group of interest and comparison group to help depict patterns of change and values close to zero indicating improvement in disparities. (Software: Tableau, version 2020.4.1; Data depicted on this chart are simulated and do not represent observed rates).

Figure 1: Health Equity Integration Dashboard

Discussion: Development of a health equity dashboard by leveraging existing datasets is an efficient and pragmatic approach to begin monitoring for health disparities. Creating robust racial-ethnic strategies and including key visualization and data elements such as those described may facilitate building of dashboards tailored to the needs of other hospitals and organizations. Inclusion of multi-disciplinary team perspectives is critical to promoting value and effectiveness in dashboard use. Such monitoring strategies will be critical to monitoring ongoing hospital QI interventions in real-time and promote timely and effective approaches towards health equity.
Expanding Exposure Notification Verification Code Issuance in WA State

Amanda Higgins, MSHI\textsuperscript{1,2,3}, Shannon O'Keefe, MSHI\textsuperscript{1}, Bryant T. Karras, MD\textsuperscript{1,2}
\textsuperscript{1}Washington State Department of Health, Olympia, WA, \textsuperscript{2}University of Washington, Seattle, WA, \textsuperscript{3}University of New England, Biddeford, ME

Abstract

Exposure notifications enhance contract tracing and case investigation efforts by decreasing the time in which known and unknown contacts are notified of possible exposure to COVID-19. This has the potential to reduce infections and save lives. In Washington State, additional methods of verification code issuance expand the functionality of the app by notifying more people as quickly as possible.

Introduction

In an unprecedented collaboration among competitors, Google and Apple partnered to develop Bluetooth based exposure notification technology originally proposed by researchers\textsuperscript{1} to assist the public health response to the COVID-19 pandemic. The Google | Apple protocol GAEN (Google-Apple Exposure Notifications) is a privacy-preserving tool that is available at no cost for public health authorities to enhance contact tracing and case investigation efforts by decreasing the time contacts are notified of possible exposure to SARS-CoV-2\textsuperscript{2}. GAEN-based technology works based on the exchange of random keys via low energy Bluetooth between phones that have exposure notifications enabled. When a user tests positive for COVID-19, they can anonymously consent to alert others they were near by entering a verification code, which triggers the upload of the random keys stored on their device to a national key server maintained by the Association of Public Health Laboratories (APHL). All phones with exposure notifications enabled periodically check the key server for a match for positive keys. If there is a match, the user will receive an alert that they may have been exposed and guidance from the public health authority on what to do next.

Methods

At the launch of WA Notify, verification codes were issued only during case interviews by case investigators and contact tracers to positive cases who attested that they were using WA Notify. This included an integration into the Case Management system (CREST) via an API to the verification code generator for Centralized State case investigators. Local health departments not using CREST manually issue codes to cases by logging in to the verification code generation portal. To reduce the time to issue codes, in January 2021, a mass SMS text issuance process was implemented to send verification codes to all phone numbers associated with a positive test reported to the Washington State Disease Reporting System (WDRS) the previous day.

Results

The addition of direct texting via mass SMS of the codes increased the use of Bluetooth Exposure Notification significantly. Central investigations issued 1477 codes successfully, Local Public Health interviews resulted in 1577 codes, and mass SMS resulted in 3070 claimed codes during January – March 2021.

Conclusion

The exposure notification app, WA Notify, is an integral tool along with masking, hand-hygiene, physical distancing, the recent widespread availability of vaccines to slow the spread of the virus. The increase in mass gatherings and travel as states re-open, breakthrough cases, and vaccine opt-out rates support the continued need for this valuable tool in the public health toolkit to reduce the spread of the virus and save lives.

Identifying Narrative Documentation of Clinician Concern about Patient Deterioration in Home Healthcare: A Text Mining Study

Mollie Hobensack, BSN, RN1,2, Jiyoun Song, PhD, RN1, Maryam Zolnoori, PhD1, Marietta Ojo, MPH1, Kathryn H. Bowles, PhD, RN2,4, Sena Chae, PhD, RN3, Erin Kennedy, BSN, RN4, Margaret V. McDonald, MSW2, Maxim Topaz, PhD, RN1,2

1Columbia University School of Nursing, New York, NY, USA; 2Center for Home Care Policy & Research, Visiting Nurse Service of New York, New York, NY, USA; 3University of Iowa School of Nursing, Iowa City, IA, USA; 4University of Pennsylvania School of Nursing, Philadelphia, PA, USA

Introduction

In the United States, home healthcare (HHC) agencies provide care to more than 3.4 million adults per year1. One of the key objectives of HHC is to identify early signs of patient clinical deterioration to activate prompt interventions reducing the risk of hospitalization and other adverse events2. There is evidence that HHC narrative documentation can inform identification of patients at risk for deterioration. This study explores an inclusive approach to identify patients at risk using status and situations described in clinical narrative notes.

Methods

A retrospective observational study with secondary data analysis was performed using HHC narrative notes (visit notes and care coordination notes) from one of the largest HHC agencies in the US from the years 2015 to 2017. To create the gold standard, expert annotators with a clinical background were asked to review a subset of random narrative notes and label each narrative note as either “concerning” or “not concerning.” Traditional Algorithms (Naive Bayes, Random Forest, and Support Vector Machines), Neural Network, and Transformer Algorithms (BERT and GPT-2) were applied to train and compare model performances, and identify important features.

Results

Of the 4,000 narrative notes, clinicians identified 20% (n=800) as “concerning.” Best performance across all models was achieved using the BERT algorithm as indicated in Table 1. Figure 2 visualizes the most informative features. Words that were associated with the highest entropy scores were “pain,” “lives,” “bed,” and “meds.”

Table 1. Machine learning predictive performance

Conclusion

This study is the first to build an NLP algorithm to predict HHC narrative notes as “concerning” or “not concerning” regarding adverse events using expert clinician judgment. The results of this study show the feasibility of creating algorithms that can help identify patients who are developing “concerning” clinical trends. Next steps are to embed the algorithm within an EHR system. If identified as “concerning,” these patients can then be prioritized for risk reduction interventions to support clinical decision making.

The Impact of Quality Feedback and Reporting on Hospital EHR Medication Safety Improvement

A Jay Holmgren, PhD MHI, David W Bates, MD Msc

1University of California, San Francisco, San Francisco, CA; 2Brigham & Women’s Hospital, Boston, MA; 3Harvard Medical School, Boston, MA

Introduction

One mechanism by which EHRs were expected to improve safety was the implementation of computerized provider order entry (CPOE), paired with clinical decision support (CDS). However, national CDS medication safety performance has been variable, with many hospitals not alerting on potentially harmful orders. One policy mechanism to improve quality is public quality reporting. We therefore sought to evaluate whether public quality reporting and feedback is a useful mechanism to incentivize hospital EHR quality improvement. We used national US hospital data from the Leapfrog CPOE Evaluation Tool to identify the effect of providing hospitals with feedback on their EHR medication safety performance. Leveraging a change in the scoring and feedback aspects of the evaluation in 2017, we used a regression discontinuity to assess whether hospitals that receive negative feedback regarding their safety performance improve more?

Methods

The CPOE Evaluation Tool is included as part of the Leapfrog Hospital Survey and is one of several process quality measures used by the Leapfrog Group in their evaluation and rating of US hospitals. The CPOE Evaluation uses simulated patients and orders to test whether a hospital’s production EHR system generates a clinical decision support order of any type when inputting an order that would cause an adverse drug event. Public scores displayed on the Leapfrog website are reported qualitatively, with hospitals scoring over 50% receiving “Full Demonstration of Safety Standards”, and hospitals from 30%–49.99% receiving “Substantial Demonstration”, and hospitals below 30% receiving “Completed Evaluation” The sample included hospitals who took the Leapfrog Hospital Survey, including the CPOE Evaluation Tool Evaluation, in both 2017 and 2018. This data was combined with American Hospital Association survey data to capture hospital characteristics. We employed a sharp regression discontinuity design between the top publicly reported score, “Full Demonstration” and the “Substantial Demonstration” score in 2017. Our dependent variable was hospital improvement from 2017 to 2018. We used the traditional OLS model, as well as a nonparametric method developed by Calonico et al.(2).

Results

The final sample consisted of 1,183 hospitals in a balanced panel. We identified a clear discontinuity in performance improvement at the 50% cutoff in 2017. In our regression models, hospitals on the cut-off receiving the “Substantial Demonstration” feedback was associated with improved performance in the subsequent year in both OLS (B=4.71, p<0.001) estimates and in our robust, non-parametric estimates (B=8.44, p=0.03) The effect was consistent both with hospital covariates, and robust to a wide array of robustness checks.

Discussion

Hospitals that received publicly reported negative feedback improved significantly more than those who receive positive feedback in the subsequent year. Despite this progress, there is considerable room for improvement especially in advanced decision support, with few hospitals receiving a perfect score. These results show that publicly reported feedback on specific dimensions of EHR-focused process quality such as medication safety can lead to improvement, even in the absence of direct financial incentives.

Validating the Value and the Usability of Real-Time Prescription Benefit Data

Megan A. Holsopple, PharmD, BCPS1, Kyle Campbell, PhD1, Anna Baer MS1, Mihir Parikh, MS1
1RxRevu Inc., Denver, CO

Introduction
Real-time prescription benefit (RTPB) is a relatively new technology being leveraged by prescribers and health systems. This technology equips prescribers with helpful insurance information medication (e.g., formulary coverage, alternative therapies, out-of-pocket costs) as they are electronically prescribing medications. Awareness of patient prescription affordability has been shown to help increase adherence, improve chronic disease state management, and reduce future healthcare costs through transparency of patient-specific pharmacy benefit coverage.1,2

Beginning January 2021, Medicare and Medicaid Services (CMS) and Medicare Advantage Part D plan employers, unions, or insurance carriers must implement an electronic RTPB tool capable of integrating with at least one electronic prescribing system or health record.3 While RTPB technology is transforming traditional prescribing workflows, the response and impact is still being established. The expectation is that through transparency of patient-specific pharmacy benefit coverage at the point-of-care, RTPB can provide prescribers with helpful insurance information to improve cost-of-care conversations, increase patient access to drug therapy, and optimize medication therapy selection when possible. This case report evaluates the impact of RTPB on prescriber behavior.

Methodology
A total of 138,488 ambulatory prescription orders were linked to RTPB transactions from 2 academic medical centers and associated community hospitals and ambulatory clinics. The primary objective was to assess prescriber response to payer alternatives (e.g., pharmacy and medication) and payer coverage alerts. Secondary objectives evaluated patient cost-savings as well as health system personnel time and costs associated with processing coverage alerts.

Key Results
Payer returned pharmacy or medication alternatives were displayed over 30% of the time with the most common alternatives including same drug class alternatives (e.g., HMG-CoA reductase inhibitors). Selection of a medication or pharmacy alternative ranged from 2% to 3%. Coverage alerts were presented to end-users up to 15% of the time with ‘prior authorization required’ and ‘refill too soon’ alerts being the most common. The coverage alert, “Refill too soon; Refillable after “x” date” appeared to be the most impactful alert resulting in provider response of “suspend order” 52% of the time.

Payer coverage information at the point-of-care also resulted in financial savings for patients with pharmacy or medication switches driving an annualized cost savings of $96,000. Brand to generic switches saved patients an average of $390/prescription annually and pharmacy switches from a retail to a mail order setting saving patients an average of $105/prescription annually.

Prior authorization avoidance where the prescriber selected a therapy alternative without a prior authorization resulted in up to 11 weeks of personnel time saved and upwards of $27,000 and $7,000 of pharmacist and pharmacy technician resource costs saved respectively.

Conclusion
Patient-specific prescription coverage information through RTPB enables data-driven prescribing decisions, behavior change, patient savings opportunities, and streamlines operational costs associated with processing medications that have coverage alerts.

Evaluation an Opioid Reversal Alert at an Academic Medical Center

Bernard M. Hsia, PharmD; Diana J. Schreier, PharmD, BCPS, MBA; Benjamin J. Anderson, PharmD, MPH; Jenna K. Lovely, PharmD, BCPS

Mayo Clinic - Rochester, MN

Purpose
The advent of computerized prescriber order entry systems (CPOE) has reduced medication errors by providing real-time alerts to prescribers. However, an excessive number of alerts can lead to alert fatigue resulting in alerts being bypassed 49-96% of the time. This project evaluated an opioid reversal alert in the institution’s electronic medical record (EHR) by determining how frequently it was being accepted or bypassed. The alert was created during our institution’s EHR implementation in 2018, and fires when an opioid order (scheduled doses or patient controlled analgesia) is placed with no active reversal agent on the patient’s profile. A naloxone order is recommended by the alert. This was the first analysis conducted since implementation to evaluate the effectiveness of this alert.

Methods
Data for a six-month period (08/27/2020 to 1/26/2021) were collected and analyzed using a self-reporting tool provided by our institution’s EHR vendor. Data regarding the number of actions taken, bypasses, departments with the most bypasses, and reasons for alert bypasses were reviewed. Based on the findings, a restriction was added to exclude alert firing on patients on end-of-life care. The alert was reassessed for an additional six-month period (4/1/2021 to 9/30/2021).

Results
The alert was bypassed 26.2% (n=5054) of the time. The hospice and palliative medicine department had the most bypassed alerts with 1183 (23.4% of all bypassed alerts). The patient with the most bypassed alerts (n=20) was on end of life care, which resulted in a modification to the alert. Preliminary 3-month data evaluating the modified alert are shown in Table 1.

Conclusion
In our analysis, the alert was firing and being bypassed an excessive amount on patients receiving end of life care. As a result, the alert was modified to prevent firing in patients with end-of-life care, thus reducing alert fatigue.

COVID-19-Catalyzed and Informatics-Driven Evolution to a Learning Health System

Allen Hsiao, MD FAAP\textsuperscript{1,2}, Lisa Stump\textsuperscript{1}, & Nitu Kashyap, MD FAMIA\textsuperscript{1,2}

\textsuperscript{1}Yale New Haven Health, New Haven, CT; \textsuperscript{2}Yale School of Medicine, New Haven, CT

Abstract

We share the experience of how a health system and affiliated medical school rapidly evolved in response to the COVID-19 pandemic to become a true learning health system, driven by informatics and built upon an enterprise EHR and information technology foundation. Two separate organizations aligned to systematically integrate, evaluate, and disseminate new data and knowledge to the bedside to meet the rapidly evolving challenges facing clinicians and operational leaders.

Introduction

Yale New Haven Health is a five hospital (seven hospital campus) health system with over 2,500 beds predominantly along the coastline of Connecticut and one hospital in southern Rhode Island. It’s largest hospital, Yale New Haven Hospital, serves as the academic medical center for the separate but affiliated Yale School of Medicine. COVID-19, catalyzed tremendous changes that evolved the at times uneasy affiliate relationship into a true learning health system. We outline some of the key components of a learning health system and our COVID-related highlights\textsuperscript{1,2}:

**Culture & Leadership:** A centralized Hospital Incident Command Structure (HICS) was initiated bringing together senior leaders together in daily meetings to review COVID numbers, manage resources and expedite transfers. Daily huddles of the CMOs, egular employee Town Halls, and email communications were initiated. The culture shifted to embrace evidenced based medicine across all of the hospitals, adopting a single approach to clinical care informed by the infectious disease experts.

**Systematic Evidence:** Internal and external (CDC, WHO) data was regularly sought out and analyzed, informing clinical pathway CDS with regular updates. A single set of masking and PPE policies were adopted and modified by evidence, a massive call center stood up nearly overnight to support thousands of calls from the patients and community searching for information and advice. A single resuscitation and triage protocol was created and adopted for the entire system based upon the work of a multi-disciplinary group of clinicians, ethicists, and faculty.

**Informatics and Information Technology:** The CIO, CMIO, ACMIO, and other senior information technology leaders were quickly embedded into clinical and operational leadership; the enterprise EHR grew in its importance as a foundational system, serving as a contact tracing tool, data collection device, and CDS delivery system for COVID-19. Clinical pathways for COVID and MIS-C with complex decision support were created and integrated into the EHR. Telemedicine was adopted and embraced in record time, supporting >4,000 visits a day, up from 15 pre-COVID. Innovation and “failing fast” was embraced, leading to over 700 telemedicine carts were assembled by the IT team with off-the-shelf CPU, camera, and speaker parts.

**Data & Analytics:** The use of data and analytics was embraced as never before, with a system-wide real-time dashboard created built upon the EHR and enterprise datawarehouse, allowing operational and clinical leaders to monitor bed and ventilator availability across all of the hospitals in a single view. Two COVID predictive models were independently created by two different teams utilizing EHR, testing, and waste-water data to predict volumes. This information was used to drive bed planning, staffing, supply chain, and overall strategy. Other dashboards were quickly created to monitor telemedicine efforts, call center volume, and supply chain needs such as PPE and COVID-medication availability. Race/ethnicity data evaluated to identify vulnerable populations & for community messaging.

Conclusion

The COVID-19 pandemic has been a devastating challenge; however, it has also served as a catalyst to push the evolution of our separate health system and school of medicine into an informatics-driven learning health system. The change in culture, operational changes, embracing of evidence and data creates a LHS foundation that will serve our patients well and enable us to improve patient care not just for COVID but challenges to come.

The Combination of Graph Neuron Network and Multi-Task Learning Model for Cancer Drug Combination Prediction

Kanglin Hsieh, Ph.D., Yu-Chun, Hsu Ph.D., Xiaoqian Jiang Ph.D., Yejin Kim Ph.D.
Center for Secure Artificial Intelligence for Healthcare, School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX, USA

Introduction: Combination therapies have become a standard treatment strategy for complex diseases, including cancer, asthma, diabetes, and bacterial infections[1], by increasing therapeutic efficacy and reducing toxic side effects compared to standard monotherapies. High-throughput screening (HTS) instruments can profile and evaluate several markers for drug combination effects such as IC50, EC50 under cell level. However, the combinational searching space is proportional to the number of testing drugs and making HTS is not cost-effective for systematic screening. This challenge motivated us to apply A.I. for drug combinations. Currently, Knowledge graph (KG) is widely applied to drug repurposing by consideration of multiple modality information including drug targets, gene-gene interaction, side effects, and an indication of drugs. The growing trend of utilizing graphic neural networks (GNN) to learn and abstract the knowledge graph has demonstrated great potential. In this research, we highlight the potential of using GNN to build the embedding of KG and utilize the embedding for drug combination prediction.

Materials: We used several biological databases for building the biological network for drug combination, including Comparative Toxicogenomic Database (compound - compound target, compound - compound-related pathway, compound - disease, and disease - disease related pathway), Cancer Cell line Encyclopedia (Cancer Cell line - overexpression/suppression genes), and STRING (gene - gene). The Drugcomb portal is used to train and validate the drug combination results.

Methods: For determining high-confidence relationships between cell lines and gene expression, we adapted gene-wide z score which selected cell line - gene pair which z score is above 3 or below -3. We selected the protein-protein pairs which p-value is below 0.05. Other pairs have adapted the information provided by CTDbase. For training the graph embedding, we used GrapheSAGE, an inductive framework, which leverages node feature information to efficiently generate node embedding for previously unseen data. The model (Fig.1a) leverage five GrapheSAGE layers to learn five types of information including 1) drug - drug targets : 421,078 pairs, 2) gene - gene : 123,722 pairs, 3) cell line - gene : 179,715 pairs , 4) disease related information : 195,285 pairs, and 5) pathway-related information : 625,524 pairs. 90 % of pairs are used for training, and 10 % of pairs are used for testing. The node features come from Drug Repurposing Knowledge graph, the largest currently available knowledge graph embedding[2].

To test our hypothesis, we randomly selected 90 % of drug pairs within the same cell line for training, and 10 % for testing. Loewe score was applied to determine 1) antagonistic effect (Loewe <= -10), 2) additive effect (-10 < Loewe < 10), and 3) synergistic effect (Loewe >= 10). The prediction model adapted a multi-tasks deep neural network. The model is multiple task models(Fig.1b). Task one is the prediction of combination effects, and task two is the prediction of the Loewe score.

Results: We evaluate the model performance on the following tasks: 1) prediction of novel drug combinations, 2) prediction of novel drug combinations on new cell lines, and 3) prediction of novel drug combinations on novel drugs. For each task, we further examine the synergistic effect (classification task) and Loewe score (regression task). In this preliminary task, we set up the Loewe score over 10 as the threshold to calculate sensitivity, specificity, precision, recall, and AUC over each task. In general, the AUC of task one was 0.815, task two was 0.850, and task three was 0.675

Discussion: In this preliminary study, we only used the cell line and drug embedding information for prediction. This may limit the model performance. We will continually utilize more embedding information such as disease, pathway, and genes to improve the performance. We will also try to add other information such as gene regulation, gene expression data for further testing.

Conclusion: The GNN derived embedding has the potential to predict drug combination effects.
Disparity analysis of patient portal messaging use for COVID-19 in urban versus rural locality

Ming Huang1, Andrew Wen1, Huan He1, Liwei Wang1, Sijia Liu1, Yanshan Wang1, Nansu Zong1, Yue Yu1, Julie E Prigge2, Brian A Costello2, Nilay D Shah1, Henry H Ting1,3, Chyke Doubeni4, Jung-wei Fan1, Hongfang Liu1 and Christi A Patten5,6*

1Department of AI and Informatics, Mayo Clinic, Rochester, MN, USA; 2Center for Connected Care, Mayo Clinic, Rochester, MN, USA; 3Department of Cardiovascular Medicine, Mayo Clinic, Rochester, MN, USA; 4Department of Family Medicine, Mayo Clinic, Rochester, MN, USA; 5Center for Clinical and Translational Science, Community Engagement Program, Mayo Clinic, Rochester, MN, USA; 6Department of Psychiatry and Psychology, Mayo Clinic, Rochester, MN, USA

Introduction: The fast spread of the infectious coronavirus disease-2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has led to a worldwide pandemic with high morbidity and mortality rates since December 2019[1]. Rural populations are disproportionately affected by COVID-19 and vulnerable to its impacts due to limited resources (e.g., shortages of key pandemic specialists and underfunded hospitals) to respond to the pandemic. At the same time, COVID-19 has rapidly accelerated a change in health care delivery from in-person visits to virtual care [2]. The COVID-19 pandemic and the associated mitigation activities have caused patients to postpone or cancel non-acute medical encounters. Millions of clinic visits have transitioned to online platforms for continued care access [3]. Patient online services (patient portals) could serve as an attractive virtual platform and resource for patients from rural populations to seek support from their providers for COVID-19 and non-COVID related issues [4]. In this work, we propose to analyze the urban versus rural differences in portal messaging utilization for COVID-19 during the first wave of the pandemic.

Methods: We collected more than 1.4 million portal messages generated by patients in the midwestern US between February 1 and August 31, 2020. We then filtered the patient-generated messages (PGMs) associated with COVID-19 using relevant keywords (e.g., COVID-19, Pandemic, Coronavirus, SARS-CoV-2, and 2019-nCoV) and their synonyms and morphological variations. We performed descriptive statistics on the acquired PGM data set and examined the following four aspects of patient utilization of portal messaging for COVID-19 in the Midwest: (1) Patient counts. We calculated the patient counts in terms of five different roles of the patients: (A) the patient involved in EHR, (B) the patients involved in portal, (C) the portal users, (D) portal message senders, and (E) COVID-19 message senders. (2) Numbers of PGMs on COVID-19 and unique patient senders. We calculated the daily numbers of PGMs on COVID-19 and unique patient senders in the Midwest and its urban and rural areas. (3) Message use for COVID-19 related care. We analyzed the PGMs used for assessing COVID-19 symptoms and discussing COVID-19 diagnostic tests and results and care plan in the Midwest including urban and rural areas. Message use for other healthcare issues caused by the COVID-19 pandemic. We examined other healthcare issues related to COVID-19 reported in the messages to understand COVID-19 impacts on health services and patients.

Results: The urban to rural ratio of portal users, message senders, and COVID-19 message senders was 1.18, 1.31, and 1.79. The urban to rural ratio (1.69) of PGMs on COVID-19 was higher than that (1.43) of general PGMs. The urban-rural ratios of messaging were 1.72-1.85 for COVID-19 related care and 1.43-1.66 for other healthcare issues on COVID-19. The frequent senders of COVID-19 related messages were 40+ years old, female, married, white, and English language speakers. Compared to urban patients, the disproportion of message use was aggravated for sending messages on COVID-19 among rural patients.

Discussion: In the Midwestern health care setting, rural patients have significantly lower utilization of portal messaging than urban patients. The urban-rural disparity of portal messaging exacerbated in order of portal users, message senders, and COVID-19 message senders. Compared with urban patients, rural patients sent fewer messages for COVID-19 diagnosis and treatment but more messages on other COVID-19 related healthcare issues (e.g., isolation, anxiety). Results suggest opportunities for increasing equity in rural patient engagement in patient portals (in particular minority populations) for COVID-19.

Conclusions: The findings can provide us useful information about patient utilization difference of portal messaging to address COVID-19 crisis for improving patient-centered care.
Addition of auditable testing rational provides real-time information on hospital practice patterns

Michael S. Icardi MD, Larry A. Mole PharmD, Mark Holodniy
US Dept. of Veterans Affairs Public Health Laboratory, Palo Alto

Introduction
Early shortages of SARS-COV-2 virus testing reagents lead to rationing of testing resources. This necessitated redirection of supplies to address critical testing vs discretionary testing needs. Existing metadata, based on physician request for rapid testing and test utilization, was not enough to allow for supply re-allocation to cover regional outbreaks. We investigated if addition of metadata indicating if testing was ordered for Diagnostic, Screening or Monitoring would provide data enough to show ordering demand and triage test utilization.

Method
Test ordering and reporting data was standardized to require selection of testing category at the time of ordering into Diagnostic (Symptomatic patients/COVID-19 is suspected), Screening (Testing performed to enable scheduling of procedures or admissions) and Monitoring (testing performed as part of a series to allow early outbreak detection in long term care facilities). Ongoing data was collected starting from mid-November and broken down by region, site and type for comparison and outliers investigated. Comparison of December regional and facility data showed differences in overall testing demand were affected by local testing policy variation and outbreak status making total test utilization unsuitable for use to direct testing supplies toward critical vs discretionary test needs.

Figure 1. Standard test data contains only test results with no indication of rational for testing. Total test utilization vs positivity rates do not allow enough discrimination to determine critical test demand from discretionary testing.

Figure 2. Comparison of regions and member hospitals with A.) Non-outbreak, B.) Overwelked-outbreak C.) Well supplied-outbreak, with added metadata. Region B.) shows increased unclassified (referral) testing and decreased screening testing along with increased positivity in diagnostic testing compared to A. Region C. shows a similar diagnostic testing expansion and positivity increase as B. but is well compensated lacking expansion of referrals.. Of note Region A. appears to have similar testing demand as Region B but this is due primarily to discretionary testing and not critical need.

Conclusion:
Addition of auditable testing categories can provide real-time information on test utilization patterns not available in standard test metadata. This can be used to direct limited supply allocation to critical areas in emergent health responses.
Challenges and Opportunities of Information Technology Adoption by the Caregivers of Home Care Patients

Onimi Jademi, PhD, Abir Rahman, Bsc., and Güneş Koru, PhD
University of Maryland, Baltimore County, Baltimore, MD

Introduction: Home health care (also referred to as home care) is a Medicare reimbursed service where supportive care is provided by clinicians dispatched by Home Health Agencies (HHAs), i.e., skilled nurses, physical and occupational therapists, speech therapists etc. to support patients’ recovery and rehabilitation in their own homes. During home care episodes, the caregivers of home care patients are usually family members providing unpaid and non-skilled care and have to frequently interact with both home care clinicians and patients. Information technology (IT) presents tremendous potentials in terms of supporting caregivers in overcoming or managing some of their challenges, e.g., by reducing the complexity of caregiving tasks and by enabling communication mechanisms which can be used to alleviate emotional burden and reduce social isolation. No study has investigated what IT tools family caregivers adopt and what are the challenges and opportunities in doing so which can serve all stakeholders investing their resources to facilitate such adoption purposes. Therefore, this research 1. explored the IT tools adopted by the primary caregivers of home care patients, and 2. identified the challenges and opportunities related to caregivers’ IT adoption.

Methods: An interview-based qualitative approach was followed due to a lack of prior research and evidence related to the study objectives which provided rich contextual data. The participants for interviews were selected from the primary family caregivers of patients admitted by a home-health agency in the mid-Atlantic region of the United States. A total of fifteen caregivers were interviewed for this study as data saturation was achieved by this point. The Framework method was used to analyze the qualitative data resulting in a hierarchy of emerging themes and typologies. Member checks were employed to improve data accuracy by providing the transcripts of the interviews to the participants and asking whether they have any additions or corrections. Cohen’s Kappa analysis score of 76.92% was obtained showing substantial agreement range.

Results: (1) Eleven caregivers expressed requiring information regarding patient care, billing and insurance, lab results, diagnostic reports, and medication. Caregivers conveyed that often lack of care-giving information hindered their ability to provide effective care. Participants also expressed often finding information regarding billing and insurance was complex and were unsure what the insurance covered expenses were. Three participants expressed that access to a portal where they could get the test results and medication information would help reduce their need to visit physically or make phone calls. Ten participants who used IT regularly utilized publicly-available online search engines to obtain information about caregiving. Five participants reported using online social networks: four of them used Facebook as a forum to ask questions to verify information they found through online searches. Four participants were aware of the portal made available by the health system but they still prefer to use public search engines to search for medical information. Four participants used YouTube as a mean of learning about caregiving.

(2) The identified challenges are lack of awareness of IT solutions, unfavorable perception of IT, perceived complexity, information overload, lack of support, security concerns, and preferring face to face communication over IT. Ten caregivers reported being unaware of the patient portal already available to them. Another challenge was related to perceived complexity and lack of usefulness, where six participants felt that it was difficult for them to learn new tools due to complexity. One participant expressed a need for help and guidance in using patient portals. The participants also expressed insufficient guidance and training as the reason for lack of IT adoption. Six participants mentioned that the information overload experienced using search engines and social networks, and the effort needed to find relevant information among scattered pieces were overburdening. Three participants wished their HHAs were proactive and pointed them to better organized resources. The participants also brought up privacy, security, and trust issues as reasons for not adopting IT; three participants mentioned not using IT because of the fear of their data being stolen or leaked. Nine caregivers mentioned they prefer face-to-face communication over using IT to retrieve caregiving information. The opportunities include, availability of IT tools, availability of information resources, and improving digital literacy. Eleven caregivers used a device connected to the Internet regularly or frequently. Five caregivers were able to find necessary caregiving information using Google, YouTube, or Facebook. Despite the caregivers’ lack of awareness, a patient portal was available to all. Eleven of the caregiver responded having some form of digital literacy and are interested to learn new technology that can help them improve their caregiving. Two more caregivers responded they were willing to learn and use IT.

Conclusion: This study presents evidence about the variety of information needed by the caregivers and the room for improvement in using IT for better management and utilization of such information. Moving forward, HHAs and their partner healthcare organizations should more actively promote the IT solutions they make available to their patients and caregivers through their websites, social media channels, and various community events and activities. The solutions should have an intuitive user interface that is similar to other commonly applications that patients already use and free of jargon or require specific technical knowledge to operate. IT vendors should build related information privacy and security protections for caregivers into the design of their systems to alleviate caregivers security concerns.

Utility of the Observational Medical Outcomes Partnership Common Data Model for Representation of Non-Query Data Mappings in the Arden Syntax

Robert A. Jenders, MD, MS, FACP, FACMI, FHL7, FAMIA
Charles Drew University & University of California, Los Angeles, CA

Introduction

Arden Syntax is a formalism supervised by Health Level Seven International (HL7) for representation of procedural medical knowledge with the goal of facilitating sharing units of knowledge known as medical logic modules (MLMs). Some site-specific changes must occur for a knowledge base to be transferred from one site to another. Key to minimizing site-specific changes is the standardization of database linkages, which in turn requires identification of a standard data model, vocabularies and query syntax. While these linkages primarily are queries to retrieve data for processing in an MLM, they also include non-query data mappings such as event statements that are used to define MLM triggers and destination statements that route MLM output. This is sometimes known as the “curly braces problem” of Arden because of the syntactic construct used to enclose these site-specific references. While possible data models have been examined in HL7 for this purpose, none has yet been selected. The Fast Healthcare Interoperability Resources (FHIR) standard has been considered, but it continues to evolve rapidly. By contrast, the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) has evolved to v6.0 and is commonly used to aggregate data from disparate sources in registries and other health data repositories. Previous work demonstrated that the CDM is adequate to represent data query elements in MLMs. The present work extends this to assess the CDM’s utility as a standard data model for non-query data mappings in the Arden Syntax, which is important because of Arden’s use internationally in the systems of multiple vendors in organizations that would benefit from knowledge sharing.

Methods

A previously assembled, robust convenience sample of MLMs was examined. The MLMs were concatenated; regular expressions in a text editor were used to extract the non-query data mappings; and the data elements therein were identified. Each then was assessed to ascertain whether it could be represented using OMOP CDM v6.0.

Results

A total of 331 MLMs were pooled from 6 source CDS systems, including 19 from 3 vendor knowledge bases and 312 from 3 academic medical centers, encoded in Arden Syntax v2.1 but compatible with the latest v2.10. MLMs concerned mainly with lab tests were the most common (138/331 = 42%), followed by clinical assessment or classification (75/331 = 23%) and medication (45/331 = 14%). The remainder addressed administrative and miscellaneous topics. Each MLM contained at least one non-query data mapping. A total of 1457 explicit non-query data mappings were identified – 430 event statements (30% of all mappings) and 1027 destination statements (70%). These mappings were compared to the OMOP CDM to assess whether they could be represented. The most common event mappings were hospital admission (representable as a VISIT_OCCURRENCE), laboratory test result (as MEASUREMENT) and ordering of a medication (as DRUG_EXPOSURE). Although many MLMs had an unmapped, implicit output destination (usually the patient’s electronic chart), the plurality (429/1027 = 42%) of the explicit destination statements were email, while most of the rest were special project logs and intermediate interpretations intended as blackboard entries to be consumed by other MLMs. OMOP lacks an explicit concept for a message and its destination, but these could be represented as an OBSERVATION or NOTE, although, given the limitations on accepted concepts for some attributes in the CDM, there is no exact alignment between CDM and a destination. A limitation of the analysis is the absence of variables expressed with object notation in the MLM corpus which could have improved alignment between Arden Syntax data mappings and a standard data model.

Conclusions

OMOP CDM is adequate to represent the non-query data mappings found in a large, diverse corpus of Arden Syntax MLMs, although CDS output messages and their destinations lacked explicit supporting constructs in the CDM. However, because CDM can nicely represent query data elements and many non-query data mappings, consideration should be given for its use as a standard data model for the Arden Syntax. Future work includes creating a syntax for data references in Arden Syntax that incorporates CDM as part of developing Arden v3.0.
Discovering Adverse Events Induced by Drug Interactions in COVID-19 Patients

Eugene Jeong, MS1, Anna K. Person, MD1, Joanna L. Stollings, PharmD1, Lang Li, PhD2, You Chen, PhD1

1Vanderbilt University Medical Center, Nashville, TN; 2The Ohio State University, Columbus, OH

Abstract

Polypharmacy is highly associated with adverse clinical outcomes in COVID-19 patients. But few studies have investigated DDIs in COVID-19 patients. The aim of this study is to detect novel DDIs by a comprehensive analysis of FDA Adverse Event Reporting System data. We discovered 643 drug-drug combinations by using five DDI detection algorithms. 226 of them were novel. Thus, this study showed the potentiality of using five models for identifying potential drug-drug interactions in COVID-19 patients.

Introduction

COVID–19 patients with multiple comorbid illnesses are more likely to be using polypharmacy to treat their COVID–19 illness and comorbid conditions1. The more medications a patient is taking, the higher the risks of adverse events (AEs) induced by drug-drug interactions (DDIs). This study aims to identify AEs caused by potential DDIs in COVID-19 patients using five typical DDI-AE detection models.

Methods

Our study extracts 22,669 adverse event reports whose indications for use were COVID–19 in the FAERS database from January 2020 to December 2020. We call groups of those reports as the COVID-19 cohort. We also extracted the FAERS reports before the pandemic (from January 2004 to December 2019) to create the non-COVID-19 cohort. We pulled two groups of drugs for each of the cohorts: i) drugs used to treat COVID–19 (Drug 1), and ii) drugs used to treat illnesses other than COVID-19 (Drug 2). We detected the potential DDI-AEs using five typical DDI-AE models that rely solely on the information as described in a four-by-two contingency table2 (Table 1). The five algorithms are Ω shrinkage measure model, additive model, multiplicative model, combination risk score, and chi-square measure. The significances of DDI-AEs were assessed for COVID-19 and non-COVID-19 cohorts, respectively. We considered DDI-AEs confirmed by all five models as significant ones. Significant DDI-AEs appearing in both cohorts were not considered as DDI-AEs in COVID-19 patients, and thus they were excluded. We used DDI–AE and single drug-AE confirmed by existing works as gold standard datasets to validate whether we identified novel DDI-AEs in patients with COVID–19.

Table 1. Four-by-two contingency table.

<table>

</tr>
<tr>
<td>Only Drug 2</td>
<td>e</td>
<td>f</td>
</tr>
<tr>
<td>Both Drug 1 and Drug 2</td>
<td>g</td>
<td>h</td>
</tr>
</tbody>
</table>

Results

The number of DDI-AEs were 2,083,200. Among all DDI-AEs investigated, the significances of the 643 were confirmed. The number of DDI-AEs identified in the golden standard datasets was 417, and the remaining 226 were novel ones.

Conclusion

This study augments the existing knowledge base for DDIs in patients with COVID-19 in that it discovered the potential DDIs from the spontaneous adverse event reports. Further genetic and chemical validation studies are needed to experimentally confirm the findings.

Introduction
The open-resource literature hubs [1] have been created for tracking up-to-date, scientific information regarding the 2019 novel coronavirus (COVID-19), which forms knowledge bases to explore the explicit or implicit associations amongst diverse biomedical entities, further enabling researchers to answer clinical questions related to COVID-19. However, most knowledge graphs are constructed based on the co-occurred biomedical entities, which result in false-positive predictions in the applications (e.g., link prediction), as the co-occurrence in literature does not always represent the true biomedical associations. Here, we propose a method to leverage the variants of a Generative Adversarial Network (GAN) to automatically generate knowledge graphs from raw COVID-19 literature. The full version of the study is currently under the journal submission process.

Method and Results
Given a network G(V, E) where V stands for a set of vertices (i.e., biomedical concepts in the literature) and E represents the edges among two vertices (i.e., the co-occurrence of two concepts), edge E consists of a small number of known true associations L, and a large number of unknown true associations U. Our goal is to find true associations among U. We adapted the GAN variant (e.g., NetGAN[2] and CELL[3]). By sampling random walks from the raw graph which consists of unlabeled edges, the discriminator of GAN learns to distinguish the random walks sample. After training, the random walks sample from the generator will be used for filtering the unreal edge in the raw graph.

We generated two datasets for this study, 1) a synthetic dataset based on CORA-ML [4], and 2) a real dataset extracted from CORD-19-on-FHIR datasets [5]. For the synthetic dataset, it was formed with the positive associations labeled as 1 and sampled negative associations labeled as 0. For real data, we extracted a network from two annotated networks (LitCovid [6], PubTator [7]) via SPARQL query. Three types of nodes are used (Gene, Chemical, Mutation/Disease) with a total of 23,578 nodes and the corresponding 288,270 edges (i.e., 228,148 for chem-disease, 32,611 for gene-disease, and 27,511 for gene-chemical) were used to form a network in the experiment.

We designed three tasks to evaluate our work, in which we briefly show two here due to the page limit. We show four methods, “Base NetGAN”, “Base CELL”, “NetGAN”, and “CELL” for the test over the synthetic data. There is no big difference between the two methods when considering the base case (i.e., without using unlabeled associations) for “Base NetGAN” and “Base CELL”. However, when unlabeled information is taken into consideration, both methods achieved better performance compared with random classification. CELL overall outperforms NetGAN (0.828 for CELL vs 0.724 for NetGAN with synthetic data and 0.706 vs 0.549 with real data).

Discussion
In this study, we have proposed a method to automatically generate a knowledge graph by removing the co-occurred edges from biomedical literature. Despite the capability and stability of our investigated methods shown in this study, there are a few limitations. Firstly, we only used the limited labeled associations in our real dataset due to a limited number of resources. During the annotation, the annotators found some bias could be introduced when there is a vagueness for the concepts used in different biomedical literature. Secondly, despite achieving improvement with AUC in our real dataset compared with random classification, there is still a gap between the experimental results in a controlled environment and the adaptation of the proposed method for data curation in real scenarios. Performance improvement is still needed.

Introduction
Health IT has experienced large and rapid growth in the last several decades. In the United States, electronic health record (EHR) adoption rates among office-based physicians increased from 20.8% in 2004 to 85.9% in 2017, more than a four-fold increase in 14 years. By 2015, CDSS use in office-based primary care settings increased to a range between 68.5% and 100%, depending on the type of CDSS[1]. Nevertheless, the interoperable patient record is still not a reality in routine healthcare services after over a decade, as seen in the case of e-patient Dave. Our current effort is to build a CDSS ontology to facilitate interoperable CDSS rules by using CDC-recommended vaccination schedules as examples.

Methods
Our first step is to construct the ontology. The manual curation process includes at least four lines of effort: (1) the investigation team brainstorm, engages in iterative discussion, and provides recommendations based on their experience. (2) The investigation team conducts a manual review of the automatic method results. (3) The investigation team conducts thought experiments in regard to scenarios for two vaccines (MMR and HPV) in terms of the following key components: development, management, maintenance, and operation of CDSS rules. AHRQ CDS implementation guides and the existing CDSS taxonomy[2] are used to guide the thought processes, and the team records the detailed processes and extracts concepts that should be included in the ontology. (4) The investigation team conducts a manual review of and selects/adopts key concepts from the relevant ontologies, NIH common data elements, book chapters from CDSS (particularly Chapters 3, 15-20, 28 and 29)[3], AHRQ CDS knowledge artifacts, HL7 CDS standards and implementation guidelines, ONC US Core Data for Interoperability (USCDI), and CDC CDS for Immunization & Immunization Information Systems as well as other resources. The automatic approach focuses on using natural language processing approaches to identify relevant entities from the selected literature, from which the investigation team will decide whether or not to include and how to classify the entities.

Results
The basic metrics of the current version of the ontology are as follows: 160 classes, 97 properties, and 547 axioms. The broader categories and main structures of the ontology include activities (events), components and behaviors of CDSS, all of which provide building blocks for CDSS rules in the next stage.

Discussion
Our effort is ongoing, and the ontology will be published via Bioportal. Ideally, if we can use some production-level documents/resources as sources for the CDSS ontology, that would be helpful. However, such documents are not publicly available. The artifacts from AHRO and implementation guides and the standards from HL7 that we used as sources can substitute for these documents. The CDSS ontology has the potential to enable CDSS rules’ reuse, sharing, and maintenance, which will directly affect whether CDSS is using the most updated rules. The routinely updated CDSS rules, especially in under-resourced settings, can improve adherence to clinical guidelines and enable CDSS to play a critical role in clinical quality assurance.

Patient-Specific Modeling with Lazy Random Forest (LazyRF)

Adriana Johnson MS1, Gregory F Cooper MD PhD1, Shyam Visweswaran MD PhD1
1Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh PA

Introduction. The goal of precision medicine is to provide high-quality, individualized care for each patient, and predictive models can be useful tools in achieving that goal. However, standard machine learning methods may fail to capture informative patterns that are only present in small subgroups of the population. Personalized machine learning methods optimize a predictive model for each individual patient and may provide more informative predictions for each member of the population. Personalized decision paths (PDPs) are a type of personalized method based on decision trees introduced by Friedman in the form of the LazyDT1. Several types of PDPs have been assessed in the biomedical domain, often demonstrating superior performance to population methods2. However, little has been published on ensembles of PDPs. We introduce a novel ensemble method of PDPs based on random forests called Lazy Random Forest (LazyRF) and assess its performance on six clinical and genomic datasets for patient-specific prediction.

Methodology. LazyRF consists of bagged randomized PDPs. Using bootstrapped datasets, PDPs are trained on random subsets of the features present in the patient of interest, and features that optimize an information gain scoring criterion are included in the model. The resulting patient-specific ensemble of PDPs can be used for prediction by averaging the predictions from each path in the forest. We compared the predictive performance of single, non-randomized PDPs, bagged non-randomized PDPs, and our novel LazyRF method on six clinical and genomic datasets in terms of area under the receiver operating characteristic curve (AUROC). We also compared the performance of our LazyRF to a standard random forest of decision trees in terms of AUROC and model complexity as measured by mean predictive path length. We compared AUROC pairwise using DeLong’s test on each dataset, and compared AUROC and mean path lengths across all six datasets using the Wilcoxon Signed Rank Test.

Results. Table 1 contains the results of our experiments. Our LazyRF had statistically significantly higher AUROCs than the single PDPs for 5/6 datasets (indicated in bold), statistically significantly higher AUROCs than the bagged PDPs for 4/6 datasets (indicated in italics), and statistically significantly higher AUROCs than standard random forest for 1/6 datasets (indicated in red) as measured by DeLong’s test at the 0.05 level. LazyRF had statistically significantly higher average AUROCs overall than the single PDPs as measured by the Wilcoxon Signed Rank Test at the 0.05 level. The standard random forest had a statistically significantly higher AUROC than LazyRF for one dataset when compared via DeLong’s test (indicated in red) at the 0.05 level. When average performance was compared via Wilcoxon Signed Rank Test, the random forest and LazyRF did not have statistically significantly different AUROCs, but LazyRF had statistically significantly shorter mean path lengths than the random forest at the 0.05 level.

</table>

Conclusions. Our results show that a novel personalized random forest method, LazyRF, achieves higher predictive performance than simpler personalized methods. Compared to the traditional random forest method, LazyRF has comparable predictive performance, but produces simpler models, which may be easier to explain. LazyRF may therefore be useful for providing accurate, personalized predictions in support of precision medicine.

Clinical Research Coordinators’ Perceptions of Electronic Data Capture Systems Adopted in Clinical Research

Michelle E. Johnson¹, Fei Yu¹, PhD
¹University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Introduction
Despite their critical role in the success of clinical research studies, the needs of clinical research coordinators (CRCs) and study nurses are rarely addressed in clinical research informatics research. Additionally, few studies have evaluated CRC perceptions towards electronic data capture (EDC) systems or whether such perceptions reveal critical systems design challenges.¹ To address this gap, this study aims to investigate user experiences (UX) and perceptions towards common EDC systems, identify unmet information needs of CRCs, and address potential barriers to EDC technology acceptance by those who utilize these systems the most.

Methods
After the Institutional Review Board approved this study (IRB# 20-2620), semi-structured interviews were held with 15 CRCs working across ten study sites throughout the U.S. Interviews were audio-recorded, manually transcribed, and coded in NVivo 12² using an inductive, data-driven approach.³ Following a reflexive thematic analysis approach, recurring patterns were identified from transcribed data and collated into major themes. Then, themes were contextualized according to constructs within the Technology Acceptance Model (TAM) and UX models.

Results and Discussion
We identified 5 major themes related to EDC acceptance and CRC perceptions (Table 1). Within these themes, we confirmed ease of use and perceived usefulness as important facilitators of EDC technology acceptance. Identified themes will be used to construct a set of guidelines and recommendations for improving the design and overall user experience of EDC systems for CRCs.

Exploring Effectiveness of Domain and Task-Adaptive Pretraining for Clinical Information Extraction

Venkata Joopudi, MS, Ananya Poddar, MS, Bharath Dandala, PhD, Ching-Huei Tsou, PhD
IBM TJ Watson Research Center, Yorktown Heights, NY

Introduction
Pretrained transformer-based language models have demonstrated state-of-the-art performance on a wide variety of clinical natural language processing (NLP) tasks. Recent advances in adaptive pretraining methodologies have been mostly limited to the general domain. In this study, we apply this novel methodology to the clinical domain to establish best practices, and to assess if further adaptation to the task’s unlabeled data (task-adaptive pretraining (TAPT)), can help boost the performance of clinical NLP tasks, such as note-section recognition and clinical summary categorization.

Materials and Methods
We use expert-labeled sections on 1,303 summary sentences over 63,016 sentences from the i2b2 corpora for the note-section recognition task, and 84,424 summary spans and 63,594 summary sentences for the span-based* and sentence-based* clinical summary categorization tasks respectively. We use a BERTBASE* cased model to establish the baseline and utilize Clinical BioBERT (pretrained on biomedical, and further on clinical corpora) as our domain-adaptive pretraining (DAPT) model. For each task, we further pretrain the DAPT model using task-specific training data (DAPT + TAPT), with an unsupervised masked language modeling objective. In this process, we artificially augment the task-specific dataset by randomly masking different words (with a 0.15 masking probability) across 100 epochs.

During fine-tuning, for the note-section and sentence-based summary categorization tasks, we pass the final layer’s [CLS] token representation to a task-specific feedforward layer for classification. For the span-based summary categorization task, we pass the final layer’s token representations \{T_1, ..., T_N\} to a CRF layer for token classification.

Results and Conclusion

Table 1. Fine-tuning results for three clinical NLP tasks across different pretraining methodologies.

As shown in Table 1, our results confirm the well-known observation that DAPT improves performance on multiple clinical NLP tasks. Additionally, further pretraining of a DAPT model on a task-specific dataset (DAPT + TAPT) consistently improves performance on multiple tasks in the clinical domain. Through this study, we establish a better practice to leverage the limited task-specific dataset more efficiently to obtain considerable performance improvements, particularly in a clinical setting where manual curation of ground truth is expensive. Future work includes exploring data augmentation techniques that leverage semantic information (such as synonyms and hypernyms) available in knowledge bases to further expand the task-specific pretraining dataset.

References

* We normalize the span-based clinical summary dataset into a sentence-based dataset to account for the inter-annotator differences for the marked spans. We perform this normalization by first segmenting each note into sentences, and then expanding the human-annotated summary span label to the entire sentence.
Perceptions on Granular Data Sharing in Behavioral Health Populations

Tina Kaing, BS1, George Karway, MS1, Julia Ivanova, MA1, Anita Murcko, MD1, Michael Franczak, PhD2, Mary-Jo Whitfield, MSW3, Adela Grando, PhD1

1College of Health Solutions, Arizona State University, Scottsdale, AZ; 2COPA Health, Phoenix, AZ; 3Jewish Family and Children’s Services, Phoenix, AZ

Introduction: While studies indicate patients desire more control over their health data, little is known about data sharing preferences among behavioral health patients with behavioral health conditions1. The Substance Abuse and Mental Health Services Administration (SAMHSA) has developed a tool, Consent2Share, to give patients granular control over how their medical records are shared2; however, Consent2Share has not been evaluated with patients.

Objectives: Conduct a prospective, phone-based study within adult Spanish and English-speaking populations with general mental illness (GMI) and serious mental illness (SMI) to evaluate whether (1) patients desire granular sharing options offered by Consent2Share, (2) data recipient, data type, and purpose of use influence granular data sharing choices, and (3) supported granular data choices (domestic violence, genetic information, substance use, sexual and reproductive health, and mental health) satisfy patients’ data privacy needs.

Methods: Participants were recruited by phone among two integrated care clinics. Participants completed a demographics survey, answered questions related to three data sharing scenarios (sharing with primary care provider (PCP) within a shared facility, sharing with PCP at an outside facility, and sharing with a behavioral health provider (BHP) at an outside facility) supported by Consent2Share and completed a survey about the study and the supported granular data choices. Descriptive statistics and correlations were assessed.

Results: 200 participants were recruited (80 with SMI and 120 with GMI; 5 Spanish speakers and 195 English speakers). A majority (87%) of respondents indicated that knowing who or what facility would be using their data (either for care or research) improved overall levels of comfort with sharing. Participants were generally more willing to share within a shared facility as opposed to an outside facility (Figure 1), with participants diagnosed with GMI sharing more on average than those with SMI. Among the granular data categories provided, most (83%) participants indicated that supported granular data choices were sufficient to fully capture sharing preferences.

![Figure 1. Willingness to share between GMI and SMI patients, based on data recipient scenarios.](image)

Conclusions: Findings suggest a strong desire for mechanisms to support granular information sharing in current consent processes. Provided data sharing choices accommodated patient data privacy needs. Outcomes of this study will guide the development of future technologies and initiatives towards granular data sharing.

References

Introduction: Increasingly data are leveraged to promote health outcomes, and practitioners are turning to data from different economic sectors to address social determinants of health. Unfortunately, the US does not have a comprehensive data protection law; instead there is a patchwork of laws. The variation in data protection laws is particularly vexing for efforts to promote data sharing to promote population health. In this review we have aggregated and screened through the publicly available resources that may help public health officials and practitioners navigate the data sharing landscape.

Materials and Methods: We used a general-purpose search engine (www.google.com) to identify the resources published between 2010 and 2020. We developed a complex search pattern yielding 75 individual searches, where each search included a common string pattern: [common search stem] + [sector] + [data protection term]. The common search stem was: ("data sharing" OR "data use" OR "information sharing" OR "information use") + ("law" OR "regulation" OR "legislation" OR "statute"). We identified search terms to target a total of 24 different sectors and an additional set of searches were executed without a specified sector (24 sectors and 1 overall). The common search stem and the sector search terms were executed a total of three times, each with a different data protection term: “privacy”, “confidentiality” or “consent” (in that order). This search pattern yielded a total of 75 individual searches and first 50 hits for each search were saved. We scored each resource on a scale of 1 to 4 (lowest: 1, highest: 4) in terms of their depth of legal issues discussion, depth of data sharing discussion and value for addressing legal barriers.

Results: Our sector specific searches provided a total of 3710 hits, out of which 989 were duplicates. After removing the duplicates, remaining 2721 unique URLs were subjected to scoping screening. Full-text of 321 in-scope resources were reviewed by two reviewers, out of which 164 were selected for final coding. Among the resources selected for coding, an upward trend in number between the years 2010 to 2018 was observed. A total of 22 sectors (including 1 ‘other’ category) were covered in the included resources. Among them, clinical healthcare was the most prominent sector with a mention in 76 websites/files. The reviewed resources covered a total of 66 laws in different degrees but plurality of them focused on only a handful of laws (only 18 laws were discussed in more than 4 resources). HIPAA, FERPA and 42 CFR Part 2 were the top three federal laws discussed in the resources with higher depth of legal discussion (i.e. scored 3 or 4 out of 4). Among the 164 full-text resources coded, around 14% (n=23) discussed legal concepts and issues (e.g., consent, legal agreements) but did not expressly discuss a specific law, around 70% (n=114) discussed >1 laws and around 85% (n=139) discussed >1 sectors. In terms of depth of legal issues discussion, depth of data sharing discussion and value for addressing legal barriers, the number of resources with a score of 4 was 48, 39 and 48, respectively.

Discussion: This is the first systematic study of publicly available resources on legal data sharing issues. Our findings suggest that good resources are difficult to find. Practitioners trying to find pertinent resources will have to sift through voluminous search results that are not useful to identify, understand, and address legal barriers to data sharing. A relatively small proportion (1.76%, n=48) of our 2721 unique search results were scored as having the greatest depth of legal discussion. Consequently, the difficulty of finding quality resources likely amplifies the perception of legal data sharing barriers among practitioners.

Conclusion: Our findings describe the existing landscape of publicly available resources addressing legal data sharing issue and can help identify future needs.

Expanding Access and Continuity of care during COVID Crisis, in Safety Net Hospital
Sentaye Kassa, Brett Moran, Parkland Health and Hospital System

Introduction: When COVID-19 started to spread and affect patient care in March 2020, continuity of care and access to services were challenges for all our patients, particularly those living in undeserved communities. Telemedicine has experienced marked growth both in the US and globally over the past few years with exponential adoption noted with the COVID-19 pandemic [1]. While there has been promotion and advocacy of telemedicine by the government, reimbursement by CMS has been limited to only telemedicine which includes video, with special waiver for audio-only visits allowable only during the pandemic [2]. Uptake of audio-video telemedicine has been limited in some health systems due to budgetary issues as well as problems surrounding the “digital divide”, particularly impacting safety net systems. In Dallas, over 40% of households are without fixed internet [3], leading the top 10 cities in the US with largest digital divide [4]

Methods: During the beginning of the COVID-19 crisis in March 2020, we had to think outside the box to continue caring for our patients. We started training physicians and other hospital staff through WebEx, Pathway Modules, and a hands-on recorded didactic tutorial, then expanded virtual care to all specialty departments. This initiative was widely implemented across the hospital system within two to three weeks. This led to uninterrupted continuity of care for our vulnerable patients, protecting them and the staff from COVID. Most visits were conducted via telephone, and no personal information was compromised.

Results: Pre-COVID, we had a hospital-wide campaign to improve MyChart sign up rates, which increased MyChart utilization from 21% to 30%+. This facilitated the implementation of virtual care. The average Virtual Visit from April 2019 to Feb 2020 was about 5000 per month, but after the wide implementation of Virtual Visit the numbers from March 2020 to December 2020 increased to about 40,000 per month, an 800% increase. When it comes to show rate, the data shows that from Jan 2019 to Dec 2020, Virtual Visit show rate averaged 83.5 % while the face-to-face show rate average was 77.39 %. A survey was distributed from Sept 29, 2020, to October 23, 2020, via email to 774 physicians and APPs from 65 departments. 440 of them responded. Press Ganey patient portal data was reviewed regarding patient Audio-only virtual care experiences.

Conclusions: During COVID-19, through rapid expansion of Audio-only Virtual Care, we were able to reach out to our undeserved patients, overcoming the health disparity in primary and specialty care. When our homeless patients were moved to a hotel and isolated, the only way to get to them was through Virtual Care. We implemented Audio-only Virtual Visits. We improved access, sustained continuity of care, and engaged our patients, and as a result we observed better show rate, staff, and patient satisfaction. We gathered data by survey, Press Ganey patient portal, Slicer Dicer, and Dashboard. We can attest that Audio-only Virtual Visits can be successful in diverse undeserved populations.

Systematic identification of ACE2 expression modulators reveals cardiomyopathy as a risk factor for mortality in COVID-19 patients

Navchetan Kaur1, Boris Oskotsky1, Atul J. Butte1, and Zicheng Hu1,*

Introduction: Angiotensin-converting enzyme 2 (ACE2) is the cell-entry receptor for SARS-CoV-2[1]. The binding between ACE2 and spike (S) protein of SARS-COV-2 initiates the viral entry into target cells. ACE2 plays key roles in both the transmission and pathogenesis of SARS-CoV-2. To comprehensively profile the expression patterns of ACE2, we not only need to characterize its expression in healthy tissues but also identify diseases, drugs, and genetic perturbations that modulate ACE2 expression.

Methods: We developed a computational framework named GENEVA (Gene Expression Variance Analysis) to identify the most relevant datasets for visualization and detailed manual analysis. GENEVA prioritizes the datasets that have a large variance of ACE2 expression. At the same time, GENEVA controls for the overall heterogeneity of the samples to prioritize datasets in which ACE2 is specifically modulated by experimental conditions rather than due to tissue type differences. In addition, GENEVA embeds the meta-data into numerical space and prioritizes datasets with high correlations between ACE2 expression and the metadata.

Results: We applied the GENEVA tool to 9,124 publicly available RNA-seq datasets. We identified multiple drugs and diseases that modulate the ACE2 expression, revealing potential risk factors for severe illness from COVID-19. Here, we highlight three ACE2 modulating conditions. Data from GSE89714 show up-regulated expression of ACE2 in cardiomyopathy. Data from GSE104177 showed that RAD140, a selective androgen receptor modulator, induces ACE2 expression in human breast cancer xenografts. Data from GSE114013 show that Itraconazole, an antifungal drug, up-regulates ACE2 expression in two colorectal cancer cell lines, HT55 and SW948. These findings suggest that these drugs should be studied with respect to ACE2 expression in lung and cardiac cells and tissues and that patients on these drugs should be studied closely during the pandemic. Our GENEVA analysis is consistent with an increased death rate in COVID-19 patients with heart conditions[2–4] and suggests that higher ACE2 expression can contribute to the increased risk. We identified 3936 COVID19 patients from the electronic health records (EHR) of the University of California San Francisco (UCSF) hospital. We first compared the COVID-19 patients with cardiomyopathy (N = 43) to patients without cardiovascular diseases (N = 3269) and confirmed that cardiomyopathy is significantly associated with the risk of death (p = 0.004). We next compared the cardiomyopathy patients to patients with other cardiovascular diseases (N = 624). Multivariable Cox proportional-hazards regression confirms that cardiomyopathy is significantly associated with the risk of death (p = 0.038, 438 % increase in observed death rate).

Image-based Phenotyping for Risk Stratification in the National Lung Screening Trial

Mirza S. Khan, MD1,2,3, Kaiwen Xu, MS2, Stephen A. Deppen, PhD3, Kim L. Sandler, MD3, Bennett A. Landman, PhD2,3

Introduction
Annual lung cancer screening (LCS) with low-dose computed tomography (LDCT) is recommended for those at high risk for lung cancer based on age and smoking history. Yet, there remains an increased incidence in lung cancer among groups that fail to meet existing LCS criteria. We use image-based clustering analysis of complete thoracic images from high risk patients to identify sub-phenotypes at highest risk for lung cancer.

Methods
We randomly selected 1,200 male subjects with biopsy-proven diagnoses as reported in the National Lung Screening Trial (NLST); 200 of whom had biopsy-confirmed lung cancer. The first LDCT scan for each subject was pre-processed and then rigid registered to a common reference space as in Xu et al. We evaluated each rigid registered image and excluded 14 images due to missing lung fields or malorientation. We applied intensity-based hierarchical agglomerative clustering with complete linkage and mean absolute difference as our pairwise distance measure as described by Jin et al. We identified the optimal number of clusters with the elbow location of residual dissimilarity. We analyzed patient characteristic differences across clusters using the Kruskall-Wallis test for continuous variables and Chi-squared test for categorical variables. We studied the time to cancer diagnosis for each cluster using the Kaplan-Meier (KM) method and applied the log-rank test to assess for inter-cluster survival difference. To study the effect of each cluster on incident lung cancer diagnosis events, we used the Cox proportional hazards (CPH) model.

Results
Median body mass index (BMI) was lowest among those in Cluster 4 and Cluster 2 at 22.4 and 25.8, respectively. Lung cancer diagnosis rates differed among the clusters (p = 0.04) and was highest among Clusters 2 and 4; 20% in both. KM curves shown in Fig. 1A; log-rank test: $\chi^2 = 10.23$ (p = 0.04). As shown in Fig. 1B, Cluster 2 has a hazard ratio (HR) of 1.61 (95% CI 1.08, 2.38, p = 0.02) and Cluster 4 HR = 1.67 (0.98, 2.86; p =0.06).

Figure 1: (A) Kaplan-Meier curves for each cluster. (B) Hazard ratios from Cox Proportional Hazards model.

Conclusion
In this preliminary work, we identified 5 clusters, 2 of which demonstrate reduced time to lung cancer diagnosis. We find that these high-risk phenotypes may manifest clinically relevant features known to be associated with increased lung cancer mortality, e.g. low BMI. This work may be useful to guide consideration of other risk factors for LCS.

Description of the Problem
Child abuse is an important cause of morbidity and mortality; evidence-based recommendations for screening children with suspected abuse is important for early recognition. The objective of the study was to disseminate an electronic health record (EHR)-embedded child abuse-clinical decision support system (CA-CDSS) developed in the Cerner EHR into the Allscripts EHR.

Methods
The CA-CDSS was disseminated into Northwell Health’s EHR at 4 emergency departments (ED) including a tertiary care pediatric hospital, 2 tertiary care adult hospitals, and a community-based hospital. After meetings with key stakeholders at each ED, a prototype was developed and refined based on usability testing with end users in less than 6 months. The CA-CDSS consisted of: 1) trigger system (including high-risk chief complaint triggers and a 5 question child abuse screen (CAS) (questions below) for children less than the age of 13 years), 2) ED status board alert, 3) provider alerts within clinical documentation, and 4) injury-specific order sets based on American Academy of Pediatrics guidelines. Use of the screen and positive screens was collected from June 2019-April 2020 (live period).

CAS Questions
1) For children presenting for evaluation of a possible injury, was there a possible or definite delay in seeking medical attention given the severity of the injury/injuries?
2) Are you concerned that the history may not be consistent with injury or illness?
3) Is the child developmentally “cruising” or walking? (different question(s) appear(s) based on response selection of yes or no)
4) Are there findings that might reflect poor supervision, care, nourishment or hygiene?
5) Are there any additional comments or concerns related to child abuse or neglect and/or additional explanations for any “yes” responses above?

Results
During the live period, the CAS was completed during 71% (33,876/47,943) of all patient visits of children < 13 years old; a Completion of the CAS was 64% in June 2019 and 84% in April 2020. The percentage of CAS that was positive was 1.6% (552/33,876).

Conclusions
The increase of the CAS completion rate at the end of the live period was sustained due to continuous monitoring, refresher trainings, and utilizing the CA-CDSS as a communication tool between nurses and providers. The CAS was completed at a high rate by ED nurses to aid in identification of children who should be further evaluated by ED providers for possible abuse and neglect. Each ED had a different clinical setting and it was important to evaluate site specific post-implementation strategies. Prior work in this area has focused on integration of guidelines into the workflow as well as order sets in the EHR. Our work includes utilization of a “trigger” system in the EHR to identify children for further assessment by selection of high-risk chief complaints and/or a positive CAS. Additional data for the CAS affecting rates of referral to child protective services during the baseline and live period is forthcoming.

COVID-19 screening system utilizing daily symptom attestation helps identify hospital employees who should be tested to protect patients and co-workers

Ellen Kim, MD, MPH1, Charles Morris, MD, MPH1, Michael Klompas, MD, MPH1, Haipeng Zhang, DO, MMSc1, Adam Landman, MD, MS, MIS, MHS1, Sunil Eappen, MD, MBA1, Hojjat Salmasian, MD, MPH, PhD1

1Brigham and Women’s Hospital, Boston, MA

Introduction
During the first few months of the SARS-CoV-2 (COVID-19) pandemic in 2020, there was uncertainty about the rate of COVID-19 transmission, transmission precautions needed for suspected and confirmed COVID-19 infections, and supply and accuracy of diagnostic tests. Consequently, symptom screening was used as a key infection control mechanism. The effectiveness of a symptom-based screening of healthcare workers for COVID-19 was unknown but required by a Massachusetts Department of Public Health mandate.

As previously described by Zhang et al1, our institution rapidly deployed a novel employee screening system that included a digital daily symptom attestation application called COVID Pass, whose source code was also shared online so other institutions could use it. All employees were screened with COVID Pass before entering the hospital or clinic for the day. Employees who attested to having symptoms were evaluated by our Occupational Health and Safety (OHS) team before being cleared for work or undergoing additional testing. Employees who were concerned about a potential infection were also encouraged to skip the attestation process and contact OHS directly.

Methods
We performed a retrospective cohort study of all employee attestations and COVID-19 tests at our institution. Descriptive statistics (chi-squared, Wilcoxon, and Kruskal-Wallis tests) compared characteristics of employees who submitted symptomatic attestations and tested positive for COVID-19.

Results
After data linkage and cleaning, we were able to study 2,117,298 attestations submitted by 65,422 employees between March and June 2020. Most attestations were asymptomatic (99.9%). Among the 2,026 symptomatic employees, the most common symptom was sore throat (25%); the most common symptoms associated with a positive COVID-19 test were anosmia (23% vs 4%) and fever (46% vs 19%).

We identified 905 employees who were tested within 14 days of a symptomatic attestation, and 13% of these tested positive. This is significantly higher than the <0.5% positive rate in the community and multiple healthcare setting scenarios2 and slightly higher than the reported 10% positive tests among symptomatic health care personnel (HCP) reported by one of the small departments at our institution during a much shorter period of time3.

Conclusion
Our daily symptom attestation system seems to help identify employees who should be tested for COVID-19 while preserving scarce tests and reducing exposure to patients and co-workers. It may also help unwell HCP to stay home from work, and could even help to start changing the prevalent culture of presenteeism in healthcare. Our results also support the continued use of daily symptom screening of patients and visitors before entering a hospital/clinic, to better protect themselves, patients, and HCP.

Information Needs Analysis of Diabetes Self-Management Education and Support for Older People with Diabetes

Min Soon Kim, PhD1,2, Ploypun Narindrarangkura, MS, MD1, Suzanne A. Boren, MHA, PhD1,2, Uzma Khan, MD3, Eduardo J. Simoes, MD, MSc, MPH1,2,
1Department of Health Management and Informatics; 2Institute for Data Science and Informatics; 3Department of Medicine, University of Missouri, Columbia, MO, USA

Introduction

Over one-fourth of Americans aged 65 years or older have diabetes. Diabetes self-management education and support (DSMES) has become a significant component of diabetes care for older people with diabetes. The AADE7® Self-Care Behaviors® (AADE7®) is a patient centered DSMES guideline for people with diabetes. AADE7® has seven principles: Healthy Eating, Being Active, Monitoring, Taking Medication, Problem Solving, Reducing Risks, and Healthy Coping. Successful DSMES can improve glycemic control and health outcomes. However, it is unknown whether diabetes providers are aware of DSMES and specifically AADE7® principles for providing care. In this study, we conducted a survey among providers with experience of providing care to adults with diabetes aged 65 and over to determine the acknowledgment and gap of AADE7® and DSMES. The long term goal of this study is to develop a patient centered DSMES intervention integrated into the clinic note to improve care of people with diabetes.

Methods

We invited family and community medicine providers and diabetes care specialists at the University of Missouri Health Care. An electronic survey was sent through the Research Electronic Data Capture (REDCap). The survey consisted of two parts: demographic and evaluation of randomly selected deidentified representative clinic note of older patient with diabetes. We collected information on age, gender, race, work experience, acknowledgment of AADE7® and DSMES. The clinic note evaluation part consisted of four questions: Q1) Does this note address the AADE7® principles? Q2) On a Likert Scales of 1 to 5, please mark if the note provides helpful information for patients about each AADE7® principle. Q3) Do you think the information in this note would be easily understandable by a patient with diabetes? Why? Q4) Do you have any additional comments on the information that may make this note address AADE7® principles to improve diabetes care?

Results

We analyzed responses of 42 providers (response rate 43%). Mean age was 52 (SD 14). 22 providers (52%) were female, and the average diabetes care experience was 23 years (SD 12). 25 providers (60%) were familiar with general DSMES guidelines; however, 27 providers (64%) were not familiar with AADE7®, 31 of 42 providers completed the clinic note evaluation. Per Q1, most providers (28, 90%) agreed the clinic note addressed the AADE7 principle of Taking Medication, but not the Healthy Coping principle (3, 10%). Per Q2, the parts of the note providing helpful information were Healthy Eating (2.2±1.0), Being Active (2.3±1.0), Monitoring (1.8±0.9), Taking Medication (2.9±1.1), Problem Solving (1.5±0.9), Reducing Risks (2.0±1.2), and Healthy Coping (1.5±0.9). Per Q3, 77% of providers agreed that the information in the clinic note would not be easy to understand for people with diabetes. 17 of 30 providers commented the excessive use of “abbreviations” would be the main reason prohibiting patients from understanding the clinic notes. Per Q4, 5 of 17 providers proposed a note template that outlines the seven principles in the note and would remind them to discuss each principle with patient at each visit.

Conclusion

This study investigated the acknowledgment and gap of AADE7® during clinic visits of older people with diabetes. Our preliminary results by providers showed that the current clinic note did not address important DSMES or AADE7® principles. Providers had difficulty delivering DSMES and AADE7® to older people with diabetes via a clinic note. We suggest that providers should consider readability for seniors and provide patient centered DSMES intervention at a fourth- to sixth-grade reading level, the following NIH guidelines. We are currently conducting a survey of older people with diabetes to determine patients’ information needs on DSMES to be integrated into the clinic notes. The comprehensive information needs from both groups will inform development of patient-centered clinic notes for the older people with diabetes.

Abstract

Patient vital signs are underutilized in health risk assessment using electronic health records. Using an added value framework, we evaluated patient body mass index (BMI) and blood pressures (BP) and found improvement in predictions of patient cost and utilization over a commonly used tool, the Charlson comorbidity index. Healthcare systems and physicians could benefit from incorporating patient vital signs into their stratification of patient risk, especially in situations where little other diagnostic or historical information is recorded.

Introduction

Electronic health records have been integral in advancing health risk assessment and modeling, but health systems have not always made use of the very granular information stored in them.¹² This may especially be true in the case of patient vitals and laboratory findings. We believe these data are increasingly valuable in informing clinical decision support. We sought to replicate prior findings with respect to the added predictive value of body mass index (BMI) and blood pressure (BP) markers in health risk and utilization modeling. We also explored alternative definitions reflecting change in vital signs over time using this added value framework.

Methods

This study relied on a retrospective cohort design using electronic health records (EHR) records from Johns Hopkins Community Physicians (JHCP). Data reflect multiple emergency and outpatient care facilities throughout the Baltimore-Washington MSA. Structured patient level annual summaries for 2016 and 2017 were developed using the Johns Hopkins ACG System (v11.0). Patient Charlson comorbidity index and scores were attached to the patient summary file using the Washington MSA. Structured patient level annual summaries for 2016 and 2017 were developed using the Johns Hopkins Community Physicians (JHCP). Data reflect multiple emergency and outpatient care facilities throughout the Baltimore-Washington MSA. Structured patient level annual summaries for 2016 and 2017 were developed using the Johns Hopkins ACG System (v11.0). Patient Charlson comorbidity index and scores were attached to the patient summary file using the comorbidity package of the R programming language. 12,820 total patients met inclusion criteria and had at least one recorded value for BMI and BP in 2016. Values for patient height, weight, BMI, systolic and diastolic blood pressures were extracted from EHR flowsheet tables. Raw values were then transformed to a common scale for each measure and aggregated across patients by year of observation. Annual means for BMI and BPs were used to classify patient obesity and hypertension risk. Change (i.e. annual variability) was defined as the difference between annual maximum and minimum values for BMI and mean arterial pressure (MAP). Added value was assessed through model performance estimates using repeated 10-fold cross validation compared to base model point estimates for: (1) patient age & sex, (2) age, sex and the Charlson weighted index, (3) age, sex and the ACG system’s Dx-PM risk score. Added value of categories and change were evaluated as percent improvement in R² and AUC over base in predicting key outcome metrics, including total, medical or pharmacy costs and whether patients had concurrent or prospective ED visits, inpatient hospitalizations, and fell within the top 5% of sample for total costs.

Results

The largest subgroup of either classification is characterized as overweight (26.7%) and having elevated BP (46.8%). Both categorical BMI and BP were progressively indicative of disease comorbidity, but not uniformly related to healthcare utilization or cost. Categorical BMI and BP only significantly improved R² or AUC performance metrics compared to base models including just age & sex. Annual change BMI and MAP independently and additively improved concurrent year predictions over the Charlson weighted index for annual medical cost, emergency room visits, hospitalization and whether a patient was among the top 5% of patients by total annual cost.

Conclusion

Healthcare systems can leverage patient vital signs to improve risk assessment models but may experience diminishing returns when other factors are considered. These measures have little added value for models including commonly used indices of comorbidity and risk, though observed change or volatility in vitals over time may still yield positive results over diagnosis-derived risk scores alone. When a healthcare delivery system does not have other risk assessment information for a patient, recorded vitals may allow some simple estimation of disease risk, cost and certain outcomes.

Introduction

The coronavirus disease 2019 (COVID-19) pandemic has highlighted both the promise and current challenges in electronic health record (EHR) research. The Consortium for Clinical Characterization of COVID-19 by EHR (4CE) is a recently-convened international consortium of over 350 hospitals across nine countries on four continents.

Here, our goal is to calibrate our analyses by developing a multi-site proxy measure to detect whether COVID-positive patients are hospitalized for a COVID-related pathology. As hospital systems begin to open up, more patients are being admitted for routine surgeries. Because a COVID test is routinely performed at hospital admission, some patients will be COVID-positive asymptomatically during an otherwise routine hospitalization.

We apply a combination of chart review by clinicians at 4CE sites with an approach called “hospital dynamics.” In this approach, the analysis focuses on the metadata about a hospitalization rather than the treatments themselves. In previous work, we have found that meta-measures such as total number of lab tests on the day of admission, or time of day of lab tests can be highly predictive of disease course.

Methods

We defined a protocol in which clinical experts manually review the charts of COVID+ patients at their institutions and record a flag as to whether they were admitted for COVID or non-COVID reasons. We then utilize this manually annotated gold-standard to develop phenotyping algorithms for automatically predicting which hospitalizations are COVID-related.

We defined eligible patients for this study as those in the 4CE “COVID-19 cohort”: all hospitalized patients (both pediatric and adult) with their first positive test for SARS-CoV-2 +14/-7 days around the hospitalization.

Protocol details were based on clinical expertise and manually reviewed COVID+ patient charts at two hospitals. Our review found some complex cases in which it is hard to tell cases if a hospitalization is COVID-related, because COVID diffusely affects so many organ systems. Therefore, we chose a small set of criteria, instructing reviewers to label a hospitalization as COVID-related only if it included treatment or close monitoring for respiratory insufficiency, hemodynamic changes, or blood clots requiring significant anticoagulation.

We performed a preliminary hospital system dynamics study at one site, reviewing 59 charts from the COVID cohort during the first wave of the pandemic (March 13 to Jul 7, 2020) and recorded whether the hospitalizations were directly COVID-related, according to a review of the admit note and discharge summary. We examined a “Worry level” – the number of labs ordered for the routine vs. COVID hospitalizations.

We are presently in the process of performing a multi-site extension of this work across the full time-period of COVID. Sites will choose a random sample of 20 patients per calendar quarter and record a flag as to whether they were admitted for COVID or admitted for routine reasons. Then we will use hospital dynamics to finalize a proxy measure of routine care, including methods like frequency, association testing, and regression analysis.

Results

Our preliminary hospital dynamics study of 59 patients found that 18% of hospitalizations among COVID-positive patients were unrelated to COVID. We found that the total number of labs ordered on the first day of hospitalization was higher in the COVID hospitalizations. Additionally, when filtered to labs that we have found most correlated with severe COVID, there was an even larger difference. 94% of patients with a COVID-related hospitalization had been ordered LDH, procalcitonin, PaO2, PaCO2 within +/-2 days around hospitalization, whereas only 36% for the non-COVID related hospitalizations. We are in the process of reviewing charts at several more sites and will present further results in November at the Symposium.

Discussion

As hospitals return to normal care patterns, a COVID-positive test does not necessarily mean that COVID affected the patient’s hospital course. Here we employ chart review and hospital system dynamics techniques on an international federated COVID-research network.
U.S. COVID-19 Surveillance in PCORnet®

Introduction

The COVID-19 pandemic prompted the need for wide-reaching national surveillance that could rapidly adapt to accommodate new knowledge, policies, therapeutics, and vaccines. PCORnet®, the National Patient-Centered Clinical Research Network, a distributed data network funded by the Patient-Centered Outcomes Research Institute (PCORI), responded to this need with a focused update of highly current EHR data beginning in April 2020.

Background

PCORnet® is composed of 70 institutions (DataMarts) that streamline their data from diverse EHR sources into the PCORnet Common Data Model, typically refreshed quarterly. PCORnet was uniquely suited to rapidly establish a COVID-19 surveillance system, with infrastructure in place to pull and transform data and flexibility to examine new data elements. Governance for sharing aggregate findings was simplified by PCORnet’s distributed framework, with data maintained behind each institution’s firewall. PCORnet also has existing modular analytic tools that perform across DataMarts’ varied computing environments.

Methods

Forty-two EHR-based DataMarts contributed to the PCORnet® COVID-19 surveillance system, which was funded by the Centers for Disease Control (CDC) beginning in October 2020. DataMarts updated their data biweekly with frequent queries to assess characteristics of patients with COVID-19. To avoid an overload of data, only patients with respiratory illness ICD-10-CM codes (including COVID-19) or lab orders for SARS-CoV-2 tests were included.

We ran seven queries against the PCORnet® COVID-19 dataset between October 2020 and February 2021. Each query separately assessed children (<20 years) and adults, according to COVID-19 diagnoses, laboratory results, and care setting. We stratified these cohorts by age category, sex, race, ethnicity, month, geography (state), weight status, and smoking status. We also assessed comorbidity history and COVID-19-related symptoms and treatments for all cohorts.

Results

As of February 2021, we identified 820,801 adults and 162,471 children with a COVID-19 diagnosis code or positive laboratory result. The PCORnet® case counts over time and by race reflect national trends reported by the CDC. Patients of Black or African American race comprised 15% of all COVID-19 diagnoses, but represented 24% of inpatient diagnoses and 26% of patients treated with mechanical ventilation. During periods of greater COVID-19 prevalence, inpatient and emergency department diagnoses were more common. We observed trends in therapeutic use over time; for example, remdesivir and novel therapeutic use increased, while hydroxychloroquine use decreased.

Conclusion

This work has demonstrated that PCORnet® was well-suited to rapidly initiate COVID-19 surveillance, and that the network’s large patient population can provide timely and customizable insights into national trends over time.

Understanding Enterprise Data Warehouses to Support Clinical and Translational Research: Initial Findings on Enterprise Information Technology Relationships, Data Governance, Workforce, and Cloud Computing

Boyd M. Knosp, MS¹, Catherine K. Craven, PhD, MA, MLS², David A. Dorr, MD, MS³,⁴, Elmer V. Bernstam, MD, MSE, MS⁵, Thomas R. Campion, Jr., PhD⁶

¹Roy J. and Lucille A. Carver College of Medicine and the Institute for Clinical & Translational Science, University of Iowa, Iowa City, IA; ²Department of Population Health Sciences, University of Texas Health Science Center at San Antonio, San Antonio, TX; ³Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR; ⁴Department of Medicine, Oregon Health & Science University, Portland, OR; ⁵Center for Clinical and Translational Sciences, University of Texas Health Science Center, Houston, TX; ⁶Clinical & Translational Science Center, Weill Cornell Medicine, New York, NY

Introduction

In a prior study, we illustrated how Clinical and Translational Science Award (CTSA) hubs have implemented enterprise data warehouses for research (EDW4Rs) with respect to organizational and technical architecture, processes for access, and service management [1]. In this study, we addressed gaps in understanding EDW4R operations regarding enterprise information technology (IT) relationships, data governance, workforce, and cloud computing.

Methods

We conducted semi-structured interviews via Zoom with a convenience sample of EDW4R leaders from 20 CTSA hubs. Data collection occurred between January and October 2020, and the study team conducted a directed content analysis of interview transcripts.

Results and Discussion

For enterprise IT, CTSA hubs collectively referred to infrastructure services provided by health system, university, and, in some cases, medical school IT organizations. 75% (n=15) of respondents stated that the team providing EDW4R service at their institution was in an organizational unit, such as a CTSA-funded research institute, separate from an enterprise IT organization. Some respondents (n=3) described enterprise IT as considering EDW4R needs as “not a priority” or a “stepchild” to health system needs. For data governance, most hubs (n=17) indicated some level of existing data governance to make decisions regarding EDW4R operations. More than half (n=12) indicated there were multiple levels of data governance, such as an oversight group to review external data sharing agreements and an operationally-focused team to review internal requests for data access. To inform how to add data to an EDW4R, eight hubs described user requests as dictating priorities while two indicated that the Observational Medical Outcomes Partnership (OMOP) common data model provided a guide. Regarding workforce, multiple roles comprised EDW4R teams, including managers who provided oversight and budget control; engineers who delivered data pipelines, extract-transform-load (ETL) of data, and technical operations; analysts who engaged with faculty, managed project deliverables, and provided phenotyping services; and faculty who served as clinical or methodological (e.g., machine learning) domain experts. Respondents valued staff versatility with one participant stating “we always need ninjas” and another describing the ideal hire as “more of a Swiss army knife than a dedicated developer.” For cloud computing, implementation for EDW4R has not been widely adopted with only two hubs describing cloud-based EDW4Rs. Some hubs reported strategic plans to move their EDW4R into the cloud, typically with the intent to restructure it into a more cloud-native architecture such as a data lake. Several hubs described using cloud for data enclaves and software as a service for CTSA-specific tools. Using qualitative methods this study characterized trends and opportunities for improvement that may contribute toward best practices for EDW4R operations and inform hubs.

Building with CEDAR and Making Evidence More FAIR

Peter Krautscheid, BS1, Kathy Mikk, JD, MFA1, Mario Teran, MD2, Edwin A. Lomotan, MD2

1The MITRE Corporation, McLean, VA; 2Agency for Healthcare Research and Quality, Rockville, MD

The problem

Considerable delay exists between the emergence of new research evidence, such as patient-centered outcomes research findings, and incorporation of the evidence into routine clinical practice. One reason for this delay is that informaticists and others often rely on time-consuming, manual processes to discover and retrieve the evidence, which must be further transformed into useful, actionable recommendations (e.g., via clinical decision support [CDS] tools).

The project

The Agency for Healthcare Research and Quality (AHRQ) is the trusted home of several evidence repositories that contain systematic reviews, care recommendations, and CDS artifacts maintained by its Center for Evidence and Practice Improvement (CEPI). The CEPI Evidence Discovery And Retrieval (CEDAR) project aims to make evidence more FAIR (Findable, Accessible, Interoperable, and Reusable) by prototyping a reference implementation (RI) using a standards-based application programming interface (API). The API will be publicly-available for other platforms to discover and retrieve AHRQ evidence across multiple repositories simultaneously, making it easier and faster for others to use AHRQ evidence to inform healthcare decision-making.

The analysis

The first task under CEDAR was to understand the current FAIRness of healthcare evidence repositories by evaluating the technical infrastructure and content of the CEPI repositories and relevant standards. The analysis included literature and web reviews; interviews with CEPI repository stewards (1-3 key informants each); review of supporting documentation (e.g., API documentation); and review of FAIR data principles and 12 tools for assessing adherence.

Table 1. CEDAR Analysis and Findings

<table>
<thead>
<tr>
<th>CEDAR Activity</th>
<th>Findings</th>
</tr>
</thead>
<tbody>
<tr>
<td>Identify methods and tools to assess FAIRness</td>
<td>Existing tools are not healthcare-specific; need to develop FAIR assessment criteria better tailored to evaluate AHRQ CEPI repositories and CEDAR</td>
</tr>
<tr>
<td>Document data types in CEPI evidence repositories</td>
<td>Varied data exist at different stages of the research evidence life cycle, e.g., systematic reviews, clinical practice recommendations; clinical decision support (executable code)</td>
</tr>
<tr>
<td>Conduct technical analysis of CEPI repositories</td>
<td>Differences exist in terms of metadata, taxonomies (e.g., MESH), API and search capabilities, and content for download</td>
</tr>
<tr>
<td>Identify applicable health IT standards</td>
<td>Many are applicable, e.g., FHIR; FHIR Clinical Reasoning; Clinical Quality Language; SMART; Info Button; CDS Hooks; FHIR Clinical Guidelines; EBM-on-FHIR; others</td>
</tr>
</tbody>
</table>

Conclusions

Facilitators, challenges, and gaps exist to building a FHIR-based CEDAR RI. The primary technical challenges are building robust search functionality and maintaining reliable data feeds from API and non-API-supported repositories. Ongoing stakeholder input will help clarify needs and opportunities to improve FAIRness of AHRQ’s research evidence. Next steps include designing, testing, and piloting the CEDAR RI for specific use case(s). The CEDAR prototype will likely inform other, external efforts to mobilize computable biomedical knowledge and to build common knowledge platforms across disparate sources of evidence, particularly those already in the public domain.

Randomized user testing of recommender system clinical decision support

Andre Kumar MD MEd, Rachael C. Aikens, Jason Hom MD, Lisa Shieh MD PhD, Jonathan Chiang MPH, David Morales MS, Divya Saini MS, Mark A Musen MD PhD, Michael Baiocchi PhD, Russ Altman MD PhD, Mary K Goldstein MD MS, Steven Asch MD MPH, Jonathan H Chen MD PhD
Stanford University, Stanford, CA

Introduction - Modern clinical practice is compromised by undesirable variability due both to the intractability of manually assimilating vast bodies of information and consistently applying such knowledge at scale. Modern electronic health records (EHRs) create the opportunity for data-driven clinical decision support (CDS) that utilizes the collective expertise of many practitioners in a learning health system. Standard tools such as order set templates already reinforce consistency and compliance with best practices, but maintainability is limited in scale by a top-down, knowledge-based approach requiring the manual effort of human experts. We previously developed clinical order recommender algorithms to dynamically produce decision support content from the bottom-up by data-mining clinical data sources. Yet, open questions remain on how clinicians would react to such suggestions.

In this randomized user testing study, we sought to determine how machine learned clinical order recommender systems for electronic order entry for simulated inpatient cases would affect clinical users.

Materials and Methods - We recruited 43 licensed physicians with experience treating medical inpatients to use a clinical order entry interface for five simulated emergency medical cases, where the system dynamically suggests lists of clinical orders based on presenting diagnosis and orders placed thus far. Each physician-case was randomized whether to have access to our previously developed clinical order recommendation system. A panel of board-certified clinicians scored the primary outcome of whether the user’s orders were clinically appropriate on a consensus scale from -10 to +10 per item. Secondary outcomes included usage metrics and survey responses.

Results - Clinical Appropriateness scores for user clinical order decisions was higher with the recommender system on (incidence rate ratio (IRR) 1.06, 95% CI [1.01-1.12]), corresponding to a higher number of orders (IRR 1.09, 95% CI [1.01-1.17]), without a clear difference in mean score per order. Order suggestions from the recommender system were more likely to match physician needs than standard manual search, with fewer clicks to complete cases (IRR 0.90, 95% CI [0.83-0.99]). Physicians used the order recommender in 98% of cases possible, despite being completely optional. 95% of participants agreed the system would be useful.

Discussion - Healthcare systems can improve patient care through standardized tools like order sets, but these may not align well with individual cases. Guidance for up-to-date medical care must come from multiple sources, with a recommender system approach being able to automatically adapt to individual patient cases and emerging practices.

Our expert panel found physicians were placed more useful orders and no more likely to place harmful orders with the recommender. All physicians used the recommender options at least once, even though it was completely optional. In comparison, the physicians did not use manually authored institutional order sets in the vast majority of cases. The tool was positively received by participants, who identified clear benefits toward workflow.

This study is an important step towards automated systems anticipating clinical needs without users even having to ask. People may then feel like the computers are working for them, instead of the other way around.

Conclusions - A clinical order recommender system interface for common clinical scenarios seen in hospital medicine and emergency medicine is usable and accepted by physicians, without adversely affecting the quality of patient care decisions reflected in adverse or irrelevant orders.

Tracking the COVID-19 outbreak in India via Twitter

Sahithi Lakamana, MS¹, Abeed Sarker, PhD¹

¹Department of Biomedical Informatics, School of Medicine, Emory University, Atlanta, GA 30322, United States

Introduction

From March to late May 2021, a COVID-19 outbreak ravaged India resulting in the largest national lockdown in the world.¹ As of July, 2021, India reported over 31 million cases and over 400,000 deaths.² While traditional sources lagged in compiling aggregated data in India, Twitter provided near real-time insights about diverse aspects of the outbreak. Here we report our efforts to track the Indian outbreak from streaming Twitter data using natural language processing and machine learning methods. We have made the outputs available via a public, interactive dashboard.³

Methods

We collected data in real-time via the Twitter streaming application programming interface (API) using COVID-19-related keywords (e.g., COVID, COVID19, corona virus) and used the associated metadata to geolocate the sources. We performed analyses on several topics relevant to the pandemic. Outbreak timeline and location: We used the volume of COVID-19 related tweets over time geolocated from India to track the outbreak timeline. We compared the timeline with other events in India (e.g., opening of public places) and also tracked volumes at the state level when possible. Syndromic surveillance: We applied a previously-developed COVID-19 Twitter symptom lexicon⁴ to detect specific symptoms that were reported by users from India, using inexact matching to detect tweets that may contain misspelled symptoms. We also tracked references to black fungus, which surged during the outbreak. Emotion analysis: We performed linguistic emotion analysis of the tweets using the lexicon curated by the National Research Council, Canada, which contains terms related to anger, fear, anticipation, trust, surprise, sadness, joy, sentiment (negative and positive), and disgust.⁵ In addition to this, we also quantified the aggregated anxiety levels over time, as expressed by the tweets.

Results

Between February and June 2021, over 500,000 tweets about COVID-19 were geolocated to be from India, and over 3.5 million tweets were posted about the Indian outbreak from outside of India. The chatter about COVID-19 increased almost at the same time as the number of confirmed cases in India, with high correlation. In fact, a small bump in Twitter chatter was observed before confirmed cases started rising, perhaps indicating the data could be used to predict the upcoming outbreak. The top tweeting states were Maharashtra, Karnataka, Tamil Nadu, and Uttar Pradesh—states which also recorded the highest number of COVID-19 cases. There was also significant correlation in the state-level case numbers and the number of tweets emerging from those states. Fatigue, Dyspnea and Cough were the top reported symptoms emerging from India, and emotion analysis showed a surge in negative emotions in 2021 compared to the previous year. Anxiety levels and concerns about black fungus (mucormycosis) also surged—the former near the beginning of the outbreak (April) and the latter near the end (May). These increases coincided with the rise in COVID-19 case numbers and the disproportionate increases in black fungus infections later on in the outbreak, respectively.

Discussion and conclusion

Social media, specifically Twitter, chatter encapsulates an abundance of information regarding COVID-19. The knowledge contained within this resource can potentially be leveraged to obtain real-time insights about the current and future pandemics. While our methods and the results presented here focus solely on India, the same methods can be applied to conduct real-time surveillance in other countries, including the United States. Here, we have only presented a selected set of insights obtained from Twitter and further details can be found in our interactive public dashboard.³

COVID Deniers: Analyzing #Scamdemic and #Plandemic Tweets
Heather D. Lanier, MPH, Sameh N. Saleh, MD, Christoph U. Lehmann, MD, Richard J. Medford, MD
UT Southwestern Medical Center, Dallas, Texas

Background: Almost four billion people used social media in 2021 with the average user holding almost nine accounts on different platforms.1 The use of social media during the COVID-19 pandemic has led to an "infodemic" generating mis- and disinformation with potentially grave consequences. To explore means of countering misinformation, we analyzed tweets containing the hashtags #Scamdemic and #Plandemic.

Methods: On Jan 3, 2021, using a Twitter scraping tool called twint, we collected 419,269 English-language tweets that contained "#Scamdemic" or "#Plandemic" posted between Jan 1 and Dec 31, 2020. On Jan 15, 2021, we used the Twitter application programming interface (API) to extract the same tweets (by tweet ID) and additional relevant user metadata. We explored descriptive statistics of tweets including their content and user profiles and determined tweet availability in both datasets. We used natural language processing tools to automatically label tweet sentiment polarity and manually reviewed a subset of tweets to verify sentiment.

Results: In 2020, 60,316 accounts tweeted 310,327 times using our selected hashtags. Frequency of tweets peaked in May 2020 and decreased steadily thereafter. Accounts had a median of 241 followers (interquartile range [IQR], 62 - 901) and 534 accounts (0.9%) were verified. Overall, 22.4% (n = 69,659) of tweets had retweets and 43.1% (n = 133,749) of tweets had likes. Mean weekly sentiment was briefly positive for #Plandemic when the pandemic was declared in March 2020 but was pervasively negative throughout the rest of the study period (Figure 1). Comparing the tweets from the Twitter API to those originally extracted through twint, only 37.5% (n = 77,285) of the tweets remained accessible on Twitter for #Plandemic and 45.8% (n = 47,735) for #Scamdemic.

Discussion: While social media has democratized speech, it also permits users to disseminate potentially unverified or misleading information that endangers people’s lives and public health interventions. Characterizing tweets and users that use hashtags associated with COVID-19 pandemic denial is important for understanding the dispersion of misinformation. Sentiment analysis that worked well for previous COVID-19-related topics2,3 showed only mildly negative mean weekly sentiment, but manual review revealed a pattern of mislabeled positive tweets that were sarcastic in nature. For example, the clearly (for a human reader) sarcastic tweet “This is the Greatest Show! Grab your popcorn! #Plandemic” was attributed a positive sentiment. The majority (59.7%) of original tweets for both hashtags were later no longer accessible on Twitter either due to tweet or account deletion or account suspension. Future work will elucidate those inaccessible tweets due to account suspension versus tweet deletion and exploration of content of tweets to separate misinformation from tweets pointing out and disputing misinformation. We also plan to conduct demographic analysis of users to understand the use of bots and identify profiles more likely to propagate misinformation.

Limitations: Our study was limited by using convenience sampling of two hashtags to explore COVID-19 misinformation as well as limitations of the Twitter API to provide a relevant subset of all tweets. Despite using a tool for sentiment analysis modeled on social media text, we note partially inaccurate sentiment results because our collection contained many sarcastic tweets.

Conclusion: Tweets with the hashtags #Plandemic and #Scamdemic in 2020 had a predominantly negative sentiment or otherwise, were often sarcastic. In conjunction with the preponderance of inaccessible original tweets, we believe that at the time of the tweet, posters were in denial of the COVID-19 pandemic and seeking to disperse related mis- or disinformation.

Figure 1. Tweet Sentiment by week for tweets with the hashtags #Plandemic and #Scamdemic and for all tweets. Link addresses, references to accounts (signified by @'username'), and the hashtags #Scamdemic and #Plandemic were removed. Only tweets with more than two words were analyzed.

A New Corpus for Clinical Findings in Radiology Reports

Wilson Lau¹, David Wayne¹, Spencer Lewis MD¹, Özlem Uzuner, PhD², Martin Gunn, MB ChB¹, Meliha Yetisgen, PhD¹

¹University of Washington, Seattle, WA, ²George Mason University, Fairfax, VA

Introduction

Radiology reports contain a diverse and rich set of information about clinical abnormalities reported by radiologists. Natural language processing (NLP) offers a way to access this embedded information, which is critical to improve clinical care and enable secondary use applications. In this study, we proposed an event-based schema to capture details of two types of clinical findings (lesions and medical problems) in radiology reports. Our gold standard corpus contains 300 CT radiology reports randomly sampled from the University of Washington (UW) clinical repository. In this abstract, we describe the schema and the annotated gold standard corpus as well as present baseline named entity recognition (NER) and relation extraction (RE) results.

Methods

In our annotation schema, each event is represented in a frame that is characterized with a trigger and a set of attributes (Figure 1). The trigger is the key phrase indicating the event (shown in red in Figure 1). Attributes are fine-grained details that describe the trigger. Two annotators annotated 500 CT reports by using the BRAT rapid annotation tool. The inter-rater agreement on event annotations in 30 notes was 0.83 F1-score. The final gold standard corpus included 2344 lesion and 8065 medical problem event annotations (presented in detail in Table 1). To automatically extract event frames, we defined trigger and attribute extraction as NER tasks and linking the extracted attributes to triggers as a RE task. We split the gold standard with 4:1 ratio into training, test sets. We experimented with two neural NER architectures: (1) Bi-LSTM-CRF (NeuroNER) and BERT². We trained a BERT RE classifier in a multi-task fashion to predict relations between the triggers and the attributes.

We compared the performance of different BERT models (BERT base², BERT clinical³, BERT rad⁴). We report results of the best performing BERT model, BERT rad, which we pre-trained on 3 million UW radiology reports. BERT rad model also captured the in-domain knowledge and outperformed NeuroNER in NER tasks (Table 1). Baseline RE results are promising. As future work, we will expand our gold standard annotations and improve the extraction performance on the baseline results.

Evolving the PCORnet data pipeline for National COVID Cohort Collaborative (N3C)

Adam M. Lee1, G. Marshall Clark1, Sofia Z. Dard1, Kellie M. Walters1
1 University of North Carolina at Chapel Hill, Chapel Hill, NC

Introduction

The North Carolina Translational and Clinical Sciences Institute was called to submit recurring extracts from our PCORnet Common Data Model (PCDM) to the National COVID Cohort Collaborative (N3C). We aimed to deliver data weekly; however, the existing data pipeline took more than two days. The request forced us to evolve the data pipeline (i.e., Epic Clarity to PCDM) from a half-week, hands-on endeavor to an over-the-weekend automated task.

Methods

The environment and data pipeline involves 3 phases 1) create PCDM tables from SQL files [transform] using the source SQL Server, 2) extract those PCDM tables 3) load into an Oracle database. The first phase was to evaluate the data pipeline components used to populate the PCDM and determine where time savings methods could be utilized.

Previous State: A Python script was used to independently build each PCORnet table on a shadow copy server of Epic’s Clarity analytical reporting database (SQL Server). The completion time for this process was about 51 hours. The actual sequential run time totaled 33.83 hours, but the process had to be paused for nightly database maintenance, adding to the overall time. Next, SAS was used to extract data from SQL Server, load it into an Oracle 19c database, and generate SAS datasets for each table. This process took about 4.5 hours. Another SAS program performed data quality checks and migrated the Oracle Schema from staging to production. All these steps occurred in sequence.

Current State: Efforts were made to make processing parallel where possible and find faster data transfer methods. Python was chosen as the platform language to optimize the process. The Python code was revised to allow parallel table builds. Dependencies (e.g., demographic, encounter) were generated first. Then all independent tables (e.g., diagnosis, procedures) were created in tandem. Instead of outputting into a native SQL Server table, output was directly written to disk. We replaced SAS with Oracle SQL*Loader as the tool to load data into Oracle and noted faster speeds. Python was used to execute all commands with SQL*Loader. Finally, we created the SAS data files from the Oracle tables rather than embedding this step in the extraction process.

Results

The process optimizations resulted in a 70.28% decrease in time for the ETL process of the PCDM data pipeline.

<tr>
<td>Previous State</td>
</tr>
<tr>
<td>Current State</td>
</tr>
</tbody>
</table>

Discussion

One significant barrier that drove this solution was the topology of the analytical reporting database. In the previous state, database writes were permitted but slow. A new topology utilizing linked servers further made writes complex, but database reads more optimal. By opting for directly writing CSV files of the PCDM tables, we could bundle the extraction and transformation phases. Running the tables in parallel was the biggest time saver and allowed us to avoid nightly downtimes altogether. Further improvements could be gained if either the source data could host the PCDM data or switch to incremental data processing.

Conclusion

Overall, we were able to redesign and improve the data pipeline timeframe by utilizing parallel processing and tools more native to the technologies driving the databases. Streamlining processes allowed the removal of downtime and effectively delivered N3C data payloads without intermission or delays.
Predictive Modeling of Healthcare Utilization Metrics Identifies Adult Patients at High Risk for Suicide Attempt in the Primary Care Setting

Katherine Lee, B.S.¹, Colin G. Walsh, M.D., M.A.¹,²
¹Vanderbilt University School of Medicine, Nashville TN; ²Vanderbilt University Medical Center, Departments of Biomedical Informatics, Medicine, and Psychiatry, Nashville TN

Introduction: Suicide is one of the leading causes of death. Current guidelines recommend the use of screening tools such as the PHQ-9. However, these tools require time, have variable quality, and display limited sensitivity. A potential solution to the limited clinical utility of isolated predictors lies in machine learning, though challenges of overfitting and low precision modeling remain. One clinically implemented model has validated performance with feasible numbers needed to screen (NNS) and Area Under the Receiver Operating Characteristic Curve (AUROC) of 0.82 for a 30-day prediction window to automate “first-pass” screening for suicidality. To reduce gaps where these models do not perform equally well in all settings, e.g., in primary care, an improved understanding of setting-specific risk factors is necessary. To this end, we present a preliminary study of healthcare utilization in the primary care setting incorporating novel and nuanced feature engineering to identify usage patterns that contribute to suicide risk.

Methods: This is a retrospective cohort study of adults with a historic primary care encounter at Vanderbilt University Medical Center (VUMC) and a computed risk score for future 30-day suicide attempt from June 2019 to January 2021. Data were derived from the Research Derivative, a database containing clinical electronic health record data at VUMC. One hundred and four unique providers as well as admitting source and discharge location of encounters for the prior 6 months and 5 years. Cases were defined as patients with a risk score for future 30-day suicide attempt in the highest validated risk quantiles (above 1% predicted risk, NNS ~368) as validated prior. Controls were defined as those with a prediction of less than 0.01. The data were split into a random hold-out of 75% for training and 25% for testing. Feature importance was measured using SHapley Additive exPlanations (SHAP). Logistic regression hyperparameter tuning was conducted via grid search. All preprocessing and analyses were conducted in Python.

Results: We identified 13,718 risk score calculations for unique encounters, including 4,195 cases and 9,523 controls. A random forest model (RF) with 1000 trees outperformed logistic regression (LR) on the testing set: AUROC 0.89 (0.88-0.91; 95% bootstrap CI) for RF and 0.78 (0.76-0.80) for LR, Area Under the Precision-Recall Curve 0.82 (0.80-0.84) for RF and 0.66 (0.63-0.69) for LR. The SHAP summary plot is shown in Figure 1. “High” risk was most significantly predicted by few care sites and primary care encounters and many discharges to inpatient psychiatry.

Conclusion: A predictive model determined solely by metrics of healthcare utilization predicted suicide risk as “high” or “low” risk. This study builds upon pre-existing models by elucidating specific healthcare usage patterns that impact suicide risk. Further, studying the primary care population facilitates translation of computed risk to actionable interventions for lowering risk, which are frequently and primarily conducted in the primary care setting. Future directions include incorporation of these additional utilization metrics into the primary risk prediction model, inclusion of external data from other hospital systems and state department, and consideration of other algorithmic methodologies including deep learning.

Assessing Clinical Staff Usability & Satisfaction Before and After an Electronic Health Records Implementation Using Health-ITUES

Rachel Lee, PhD, RN\(^1\), Sarah Collins Rossetti, PhD, RN\(^1,2\), Jonathan Elias, MD\(^2,3\), Amanda Muy, MPH\(^2\), Eugene Lucas, MD\(^2,3\), Jessica Schwartz, MPhil, BSN, RN\(^1\), Erika Abramson MD, MSc\(^4\), Jessica Ancker, PhD\(^5\), Susan Bostwick, MD, MBA\(^4\), Kenrick Cato, PhD, RN\(^1,2\)

\(^1\)Columbia University School of Nursing, NY, NY; \(^2\)Columbia University DMBI, NY, NY; \(^3\)New York-Presbyterian Hospital, NY, NY; \(^4\)Weil Cornell Medical Center, NY, NY; \(^5\)Vanderbilt University Medical Center, Nashville, TN

Introduction: The usability of electronic health records (EHRs) is a significant contributor to documentation burden and burnout rates in clinical staff\(^1\). The implementation of a new EHR provides an opportunity to study staffs’ changing perceptions about usability. This study’s primary objective was to survey clinical staff before and after the implementation of a new vendor EHR and compare the changes in EHR usability. The secondary objective was to stratify the survey results by respondents’ roles and settings to describe the effects of individual characteristics on usability of the new system.

Methods: Anonymous electronic surveys were sent out to patient-facing clinical staff at a large academic medical center before and after the implementation of a new vendor EHR system. The survey was customized from the Health-IT Usability Evaluation Scale (Health-ITUES)\(^2,3\). Respondent demographics, including clinical role, specialty, work setting, and other EHR use history were gathered. Questionnaires were considered complete when the amount of missing data was <10%. One-way and two-way analysis of variance tests and pairwise comparisons with Bonferroni correction within groups were conducted on responses based on demographic information. Independent sample t-tests were conducted to assess the differences in means between pre-and post-implementation.

Results: A summary of results are displayed in Table 1 and Table 2. Tables are shortened for submission.

Conclusion: There were significant differences in usability perceptions before and after the EHR implementation across all constructs and by roles and settings. The overall mean of QWL, PU, and UC increased, and the overall mean of PEU and CSSA decreased after the implementation. The significant decrease in PEU were specific to RNs and MNAs while the decrease in CSSA were only observed among OPs and MNAs. The differences in changes reflect the varying experiences with the EHR by roles and settings. This result will inform and guide our future EHR optimization efforts by focusing on certain usability constructs, roles, clinical workflows, and settings.

Introduction: Poor social support is a risk factor for worse outcomes in psychiatric populations1. The electronic health record (EHR) is a valuable repository of longitudinal data of psychiatric outcomes; however few patients have structured data regarding the social determinants of health. Clinical notes-- in particular psychiatric notes-- often contain information about psychosocial factors and have begun to be mined by natural language processing (NLP) techniques. Here we aim to validate a rules-based system for identifying social isolation with note templates on a document level.

Data: The corpus from the Mount Sinai Data Warehouse EHR is drawn from psychiatric inpatient, emergency room, and hospital consult encounters which consists of 286,692 notes for 33,800 patients. An advantage of the dataset is the frequency of clinical note templates containing four relevant questions: (1) ‘lacks social support: yes/no,’ (2) ‘social isolation or lack of social support network: yes/no,’ (3) ‘social isolation or lack of social service: yes/no,’ (4) ‘social isolation: yes/no’.

Method: Regular expression rules were implemented in the entire corpus to identify the social isolation templates (“temp-regex”) and were collected with the response ‘yes’ or ‘no’. A template was found in 41,190 notes, which became the corpus for the methods below. The templates themselves were then removed from the notes. We then developed a regular expression-based NLP system (“lex-regex”) to extract notes containing social isolation terms using a social isolation lexicon consisting of 23 words derived from Zhu et al.2 (e.g., ‘loneliness’, ‘limited social support’, ‘socially isolated’). We searched each lexicon term in our EHR system and observed its context in 100 unique notes. These contexts were reviewed, and based on domain knowledge, regular expressions were added and modified to exclude irrelevant and negated examples. The lex-regex is then tested for its performance measures by being evaluated against the ‘yes’/’no’ answer of the template.

Results and Discussion: The social isolation template was found in 41,190 notes; 1331 psychiatric notes from 552 patients contained both a lexicon seed term and template. See Table 1 for confusion matrix. The precision was 0.64 with a negative predictive value 0.686, specificity of 0.98, and recall of only 0.064. This pattern resulted from the low occurrence of lexicon hits compared to template occurrence, and is currently informing updates to the lexicon. The approach is being implemented at another academic medical center to be validated with patient survey data regarding social support and isolation. This proof-of-concept leverages semi-structured ‘yes/no’ clinical note data to help validate a regular expression-based NLP system which can eventually be used to extract social determinant information from the EHR. Future psychiatry research can utilize social determinant data in the context of other clinical and genetic information associated with the EHR.

MethylDrift: A Software Package for Calculating Age-related Epigenetic Drift in Human Tissues Using DNA Methylation Data

McKenna C. Lewis\textsuperscript{1,2}, Niema Moshiri, PhD\textsuperscript{1}, Kit Curtius, PhD\textsuperscript{2}

\textsuperscript{1}Department of Computer Science & Engineering, \textsuperscript{2}Division of Biomedical Informatics, Department of Medicine, University of California, San Diego, La Jolla, CA, USA

Introduction

Biological aging can be measured from changes in DNA methylation, and machine learning approaches exist to predict the chronological age of a patient based on a small number of CpG sites.\textsuperscript{1} Widespread age-related drift of methylation levels across the genome also influences accelerated biological aging and carcinogenesis,\textsuperscript{2} but it is not typically characterized in studies of differential methylation across tissue types. Our aims were to create a novel informatics tool for computational biologists to identify age-related tissue-specific epigenetic drift in a given dataset, to compute rates of aging across patient samples, and to ultimately apply the pipeline to any tissue of interest given user input.

Methods

We created a Python package called ‘MethylDrift’ that accepts either pre-processed or raw data from Illumina 450K or EPIC methylation arrays, extracts methylation values (\textit{m-values}) at over 450K CpG sites along the genome, and performs linear regressions to quantify age-related drift across a set of patient samples. Assessment can be stratified by sex, race/ethnicity, tissue phenotype/location, or other variables. The package also performs ANCOVA to determine differential drift with age between normal and (pre)cancerous tissues and identifies drifting vs. static CpG islands/sites. The output includes text files with static and drifting CpGs, drift rates of aging for use in downstream analyses, and a Jupyter notebook that renders graphs in a collection of vector PDFs in corresponding subdirectories.

Results

As a case study, we applied MethylDrift to publicly available normal colorectal tissue samples (\textit{n} = 264) and premalignant adenoma samples (\textit{n} = 159). Amongst a list of 12,700 validated drifting CpG sites in normal colon provided as input,\textsuperscript{2} we found 128 normally hypomethylated CpG sites (\textit{m-value} < 0) that undergo positive, accelerated differential drift in precancerous adenomas (Figure 1). Pre-cancer drift rates (mean = 0.017 \textit{m-val}/year, sd = 0.0097) were similar to those found in 322 colorectal cancers in The Cancer Genome Atlas (mean = 0.015 \textit{m-val}/year, sd = 0.0045). This implies accelerated aging begins early in progression and may play a role in malignant transformation, thus warranting consideration in biomarker studies as an included variable beyond patient age. The tool is available at \url{https://github.com/mckennalewis11/MethylDrift}, which also creates a Markdown file for results.

![Figure 1](image1.png)

**Figure 1.** The MethylDrift pipeline takes input sample data, selects CpG sites undergoing age-related drift, plots the results, and computes drift rate distributions that can be used as tissue-specific aging rates in studies of cancer risk.

Conclusion

MethylDrift provides a fast, comprehensive bioinformatics pipeline for the quantification of epigenetic drift in ultra-large datasets, which can then be used to create tissue-specific clocks for inferring ages of precancerous lesions.\textsuperscript{1} The main significance of this work is understanding the impacts of epigenetic drift on normal aging and cancer progression for future use in clinical practice. Integration with other multi-omics and clinical data is part of ongoing work.

Contextual Predictors of Medication Persistence for Patients on Oral Hypoglycemic Drugs

Zhiguo Li, Ph.D.1, Chandramouli Maduri, M.S.1, Ching-Hua Chen, Ph.D.1
1Center for Computational Health, IBM Research, Yorktown Heights, NY, USA

Introduction Oral hypoglycemic drugs (OHDs) are commonly prescribed to people with type 2 diabetes as a first-line of therapy to help control blood glucose levels. It has been shown that 55-65% of patients do not persist with their prescribed OHD within the first year of receiving a new prescription1. Using U.S.-based commercial healthcare claims and encounters data contained in the IBM® MarketScan® Research Databases, we predict the time to first non-adherence event for 46,450 diabetic patients who were newly initiated on an OHD. We examined the relative importance of static (i.e., ‘trait’-like) patient attributes and dynamic (i.e., ‘state’-like or contextual) patient attributes for this prediction task.

Method The index date (ID) for a patient is defined as the date of the first prescription filled for any OHD, with no observed claims for OHDs in the 365 days prior to the ID. Our study window spans 2.5 years of patient history (i.e., 12 months prior to patient’s ID, and 18 months after the ID). We use monthly Proportion of Days Covered (PDC) as a measure of adherence to OHDs in a given month. A PDC value of less than 0.8 is assumed to be indicative of non-adherence. We generated 60 baseline and 66 dynamic features from our data set. The baseline features are summary statistics computed over the 12 months prior to the ID. The dynamic features are time-varying variables that are computed for each month after the ID. The baseline features capture static, or ‘trait’-like patient attributes, while the dynamic features capture ‘state’-like, or contextual, patient attributes. We also include past values of PDC as features for predicting future PDC values. For each of the \( t = 1, 2, \ldots, 18 \) months in our prediction window, we trained a Random Survival Forest model, \( \text{RSF}_t \), to predict the time to first non-adherence. For a given month, \( t \), \( \text{RSF}_t \) is used to predict the time to first non-adherence, using only data from months prior to, and including \( t \). We experimented with training RSF models that utilized only the baseline features, only the dynamic features, only past PDC, and combinations thereof. We use Harrell’s concordance index (C-Index) as a measure of prediction performance.

Results Our results are summarized in Figure 1. The left plot shows that all models perform comparably, with C-index values increasing with \( t \). Additionally, \( \text{RSF}_t \) generates predictions with reasonable C-Index (i.e., above 0.7) when \( t > 3 \). In the right plot, we observe that as \( t \) increases, past PDC values increase in importance, while baseline features decrease in importance. Dynamic features remain consistently important, suggesting that while past behavior helps predict future behavior, contextual factors are also relevant, and may provide insights for intervention (e.g., providing extra support after a recent hospitalization, providing subsidies when there is an increase in medication cost, or simplifying the medication regimen when medication complexity increases significantly).

![Figure 1](image.png)

Figure 1: The plot on the left shows C-Index by prediction month, while the plot on the right shows the contributions of different feature types to model predictions.

An Exploration of Reasons Behind Drug De-escalation and Discontinuation Events in Clinical Notes

Jennifer J. Liang, MD, Diwakar Mahajan, MS
IBM TJ Watson Research Center, Yorktown Heights, NY

Introduction
Understanding the reasons behind the cessation or de-escalation of drug therapy is critical to medication management, allowing providers to better avoid adverse reactions, direct future treatment options, and improve adherence. However, such information is often buried in clinical notes and difficult to find. To automate extraction of this information, prior works have broadly categorized reasons behind drug discontinuation events, and also identified a need for more refined categories of discontinuation reasons. In this work, we explore more fine-grained reasons behind drug de-escalation and discontinuation events using the Contextualized Medication Event Dataset (CMED), and leverage the context dimensions in CMED (Temporality, Certainty, Actor) to provide further insights into these events.

Methods
CMED is a dataset capturing contextual information – Action (Start, Stop, Increase, Decrease, OtherChange, UniqueDose), Temporality (Past, Present, Future), Certainty (Certain, Hypothetical, Conditional), and Actor (Physician, Patient) – for medication changes documented in clinical notes. For this work, we used the subset of CMED where Action is either Stop or Decrease, consisting of a total of 475 medication mentions over 206 notes. We annotated each Stop or Decrease event with its corresponding reason span when available (Figure 1). Each reason span was then assigned 1 of 9 types emergent from the dataset: adverse event (anticipated, perceived, or confirmed), lack of efficacy, no longer need (e.g. due to clinical improvement, diagnosis change), planned regimen, planned procedure, medication change, expired prescription, insurance lapse, and other (e.g. NPO, closed formulary). We then analyzed the reason type along the CMED context dimensions.

Results
Out of 475 Stop or Decrease events, 206 do not have a specific reason for the event documented. The distribution of reason types for the remaining 269 Stop or Decrease events with reason documented are presented in Table 1. Overall, adverse event was the most common type, accounting for 50.2% of documented reasons. On analysis of reason type by context dimensions, we observed a couple interesting insights. First, when analyzing along the Temporality dimension, while Past and Present events have adverse event as the most common reason type, when limiting our analysis to only Future events, the most common reason type is a planned procedure (31.3%), followed by planned regimen (27.1%). Switching to the Actor dimension, when limiting our analysis to only patient-initiated actions (Actor: Patient), the most common reason type is an expired prescription (42.9%), followed by perceived adverse effect (28.6%).

Conclusion
We present an exploration of reasons behind drug de-escalation and discontinuation events documented in clinical notes along CMED context dimensions (Temporality, Certainty, Actor). Our analysis shows the potential of leveraging context dimensions to better understand reasons behind medication changes. In future, we plan to expand annotation to drug intensification events (Action: Start, Increase) in CMED. We are considering releasing these annotations when CMED becomes publicly available to further support development of an automated system for reason extraction.

Cycle-Consistent Adversarial network with criterion for COVID-19 Chest X-ray Generation

Zhaohui Liang, PhD, Jimmy Xiangji Huang, PhD
York University, Toronto, Ontario, Canada

Introduction

Chest X-ray and computed tomography (CT) imaging together with real-time polymerase chain reaction (RT-PCR) test are the commonly used fast screening methods for coronavirus disease 2019 (COVID-19) during the pandemic from early 2020. The COVID-19 positive cases have special bilateral or unilateral mottling and ground-glass opacity patterns on the chest X-ray and CT images. These patterns can be detected by deep neural network (DNN) images classifiers and integrated to the compute-aided health systems. Many successful studies on DNN models either for COVID-19 chest X-ray or CT image detection have been published. However, recently study revealed the seemingly high-performance deep neural networks (DNNs) models for COVID-19 chest X-Ray image detection are vulnerable from network attacks. One constraint is that they are optimized by extremely imbalanced datasets where the COVID-19 images only occupy 5% to 6% of the total. Another drawback is the specific image patterns of medical images, which are different from general-purposed images such as those in the ImageNet dataset. When using transfer learning with DNN models trained by the ImageNet to fine tune a new model for the radiography images, the pretrained feature extractors usually cannot effectively capture the medical significant patterns but developing meaningless pattern combinations. The above weakness contributes to the vulnerability of the current DNN models.

Cycle GAN with Criterion

We develop an enhanced cycle-consistent adversarial network (Cycle GAN) to generate synthetic COVID-19 chest X-ray images from normal images. The conventional Cycle GAN uses two generators and two discriminators to learn the mapping between two distributions by optimizing with a complex objective and reaching a state of adversarial equilibrium. However, the state of the adversarial equilibrium is uncontrollable and usually restricts the generators to reach a better optimal point. To increase the oscillation momentum of the adversarial equilibrium, we added a pretrained classifier with the accuracy of 99.7%, as the criterion to determine whether the synthetic images belong to the correct class, and to inject extra loss once every 5 steps during the Cycle GAN optimization. The new loss function for the generators has four terms: the adversarial loss, the cycle consistency loss, the identity loss, and the classification loss:

$$\mathcal{L}_{total} = \mathcal{L}_{GAN}(G, D_Y, X, Y) + \mathcal{L}_{GAN}(F, D_X, Y, X) + \lambda \mathcal{L}_{cycle}(G, F) + \lambda \mathcal{L}_{iden}(G, F) + \kappa (\varphi \mathcal{L}_{class})$$

where $\lambda$ and $\varphi$ are the parameters to respectively adjust the importance of the different loss terms during the whole Cycle GAN architecture optimization. The classification loss injection is controlled by a function $\kappa$ to determine the frequency of classification loss injection. We set $\kappa$ to be once every five steps in this work because too frequent injection of classification loss will shift the adversarial equilibrium and reduce the fidelity of the synthetic images. The generators follow the U-NET architecture with skip connections to reduce the input feature size from 128-by-128 to 1 by 1 then to restore to 128 by 128. The discriminators follow the PatchGAN architecture with an output of 8-by-8-by-1 feature map to determine with the images are real or fake. The newly added criterion uses the sparse categorical cross entropy as the objective for adversarial optimization, and the leave squared loss is used for the rest terms.

Experiments and Results

We use an COVID-19 image dataset consists of 219 COVID-19 positive images, and 1,064 normal chest X-ray and 1,064 viral pneumonia images to respectively optimize the new Cycle GAN with criterion model and a conventional Cycle GAN model without criterion. The results shows both Cycle GAN models can generate the complete landmark of the chest X-ray images. The conventional Cycle GAN (left in Figure 1) seems to produce more plausible COVID-19 image. However, the pretrained criterion accurately classifies 99.69% of the synthetic images by the new model compared to only 77.30% by the conventional Cycle GAN.

Conclusion

This study demonstrates the new Cycle GAN with criterion can generate more accurate COVID-19 positive chest X-ray images compared to the original Cycle GAN model. The criterion provides a control to the GAN architecture to generate desirable medical X-ray images with complex discriminative pattern associate with medical expertise.

Proactive Documentation Design to Meet Needs Now and Later
Zachary C. Liao, M.D., M.P.H.¹, Michelle Stoffel, M.D., PhD.¹, Michael G. Leu, M.D., M.S., M.H.S.¹,² J.P. Giliberto, M.D.¹, Justin Birge, M.D.³, Laura Higdon, C.P.C, C.P.M.A.¹, Angad P. Singh, M.D.¹

¹University of Washington, Seattle, WA; ²Seattle Children’s Hospital, Seattle, WA; ³University of Nebraska, Omaha, NE

Introduction:
Clinical notes, in addition to documenting care, must satisfy complex financial and regulatory needs. Most providers navigate these demands by creating their own note templates. This results in considerable variability in content and unnecessary data (“note bloat”), making review of these notes inefficient for clinicians, compliance, Health Information Management (HIM), and coders alike. Health system-level interventions have demonstrated promise for reducing documentation burden and associated burnout [1]. We leveraged our health system’s inpatient electronic health record (EHR) vendor transition to prospectively design effective standard notes with the goal of improving provider satisfaction and decreasing documentation time.

Methods:
To establish note standards, we assembled a committee of clinical, technical, and administrative stakeholders. We analyzed existing note templates for five note types (History and Physical (H&P), Progress Note, Consult Note, Discharge Summary, and Brief Operative Note), identifying common components that could be modularized and used across multiple notes. Inclusion of Compliance and HIM in the process ensured that regulatory standards were met during the clinical design phase. We adapted Agile methodology for our build process, employing cycles of rapid prototyping, implementation, and feedback [2]. Physician informaticists completed most of the tool build, which streamlined interactions with our clinical subject matter experts (SMEs). We also identified evaluation metrics to be collected in the months following EHR implementation on March 27, 2021. Measures included total time in the chart and in documentation activities, derived from user login data and direct observations.

Results:
Within five months, we designed and built 133 note templates across the five note types. Notes utilized common modular elements wherever possible, simplifying both maintenance and Compliance/HIM review. For example, our generic H&P template contained 17 modular components, each of which was used across multiple templates. Our “History of Present Illness” modular component was used in 43 templates. All templates were approved by clinical SMEs (representing 31 medical specialties), Compliance, and HIM.

We prioritized functionality and versatility in our standard notes. Collapsible note sections were employed to reduce visual clutter, with only the Assessment and Plan sections expanded by default. We created short and long options for medical history and objective data (e.g., lab, imaging), allowing writers to adjust the level of detail within the standard notes. Wherever possible, we embedded chart navigation links to allow writers to review data in flow without importing superfluous content into the note itself. Specialty-specific refinements were also made; for example, the Newborn H&P was configured to auto-populate labor and delivery information.

Discussion:
Effective documentation tools are critical, as the majority of provider time in the EHR is split between documentation and chart review [3]. Our modular standard note approach leveraged EHR functionality to address both clinical and non-clinical needs, with the added benefit of simplifying future maintenance. However, this strategy requires significant upfront planning and coordination among clinicians and other stakeholders, and the change management needed for implementation may be more challenging in mature EHR settings. Based on analogous research [4], we anticipate that notes created using our standard templates will be more acceptable for downstream clinical, administrative, financial, and technical uses.

Integrating Gaming into Virtual Medication Reconciliation Education
Veena Lingam, MD, Victor Garcia, MD, Chao-Wei Tsai, MD, Jacob Wooldridge, MD, Rachel Wong, MD, MBA, MPH
Stony Brook University Hospital, Stony Brook, NY, USA

Background: The COVID-19 pandemic created the need to re-formulate educational curricula for the virtual setting. With less opportunity for hands-on experience, simulation of essential clinical tasks using games are a potentially scalable way to both teach and evaluate trainees1. Medication reconciliation is the process of clarifying, verifying and reconciling medications on initiation or transfer of care, conducted in both ambulatory and inpatient settings2. The goal was to prepare medical students for their upcoming residency by teaching medication reconciliation during the hospital discharge process through a virtual session with didactic and interactive game material.

Methods: The 1.5-hour session occurred virtually as part of the 4th year medical student 2021 Transition to Residency course. It included didactics on medication reconciliation and cost of medications, with 5 game cases. The game was Electronic Health Record (EHR)-agnostic, web-based and interactive, with clinical cases for users to perform simulated medication reconciliation tasks with feedback on the patients’ outcome based on participant actions. Participants completed a total of 5 game cases over two 15-minute blocks, followed by two 5-minute debriefs. Pre- and post-session surveys were analyzed using chi-square in Python to evaluate change in student knowledge and confidence. Game usability was assessed using a modified version of the System Usability Scale (SUS). Trainee performance was evaluated using the game score for 2 cases pre- and post-didactic.

Results: Survey responses rates of 72/78 (92%) pre-didactic and 50/78 (64%) post-didactic. There was improvement in student quiz answers and self-reported knowledge and confidence. The average SUS score was 71 (good) and 94% of participants agreed that they would recommend the game in the future. Student performance on game cases did not improve pre- and post-didactic.

Discussion: During the pandemic, the need for social distance made it infeasible to have in-person teaching sessions for medication reconciliation. To maintain the hands-on simulation education, the mixed game and didactic session was feasible and scalable. Knowledge and confidence in medication reconciliation increased, and students responded favorably to the use of games in learning the material. Student game scores did not improve in the cases completed before and after the didactic. Each case tested a different clinical pitfall, and the game was not designed to measure improvement for each task. Incorporation of games to perform hands-on tasks has the potential to be practical and effective in delivering virtual clinical education.

Adoption of Telemedicine During the COVID-19 Pandemic: Perspectives of Primary Healthcare Providers

Joe Lintz, Doctor of Health Administration (DHA), Parker University, Dallas, Texas

Introduction
As the pandemic has unfolded across an array of communities worldwide, telemedicine has been promoted and scaled up to attend to and reduce person-to-person transmission of COVID-19 in the U.S. and internationally. This study examined the major barriers to adoption of telemedicine among primary healthcare providers at the primary care clinic of North Texas during the pandemic. In addition, the research gleaned information about respondent characteristics vis-a-vis telemedicine use.

Methods
A self-administered questionnaire was mailed to 67 primary healthcare providers at the primary care clinic of North Texas, with a 70% percent response rate (n=47). The survey collected information on perceived barriers to telemedicine adoption and experience with telemedicine in the last 12 months. In additional to descriptive statistics, multiple logistic regression was carried out to determine characteristics related with telemedicine used in the last 12 months and chi-square test to examine the relationship between number of perceived barriers and reporting any telemedicine use.

Results
Table 1 reveals that the most frequently mentioned barriers to telehealth adoption were “cost of equipment” and “lack of reimbursement” (58%), followed by “inadequate technical infrastructure” and “confidentiality and security concerns” (19%). In addition, 14% of respondents cited “resistance from patients, administrator, and users” as obstacles. Last, only 3% of respondents identified “lack of usefulness of telemedicine” as an impediment. Findings from the multiple logistic regression revealed that respondents employed fewer than 5 years (p=0.003) and younger than 40 years of age (p=0.002) and working as subspecialists (p = .011) were more likely than their counterparts to report telemedicine use. Plus, the results of the chi-square test indicated that the number of perceived barriers to telemedicine usage was negatively associated with using telemedicine. Provided in Figure 1 is a visualization that manifesting that there was a strong negative relationship between the number of perceived obstructions and telemedicine utilization.

![Figure 1. Relationship Between the Number of Perceived Barriers and Telemedicine Use (n =47).](image)

Conclusion
The findings suggested that the barriers to using telemedicine existed across an array of situations and that decreasing these obstacles would be critical in encouraging future telemedicine adoption among providers during and after the pandemic. This will especially be the case for primary care practices where scarce financial resources have been a traditional problem for such providers. This complicacy is likely to be amplified owing to the inimical effects of the pandemic, during and after its potential containment or successful management of it.

Binary and Categorical Models for Automatic Acute Respiratory Distress Syndrome Detection

Kirill Lipatov, MD.1; Quan T. Do, PhD.2; Bradley J. Erickson, MD.3; Brian W. Pickering, MD.1; Vitaly Herasevich, MD., PhD.1

1Department of Medicine, 2Department of Anesthesiology and Perioperative Medicine, 3Department of Radiology, Mayo Clinic, Rochester, MN

Abstract
Early detection of Acute Respiratory Distress Syndrome (ARDS) is crucial to timely institute appropriate care and prevent adverse outcomes. The recognition relies in part on chest imaging interpretation and is hindered by delays and lack of inter-operator reliability. We derive and validate a Convolutional Neural Network (CNN) model for rapid automatic ARDS detection resulted in combined sensitivity of “probable ARDS” of 97% and specificity of 80% for “unlikely ARDS” categories.

Introduction
Acute respiratory distress syndrome (ARDS) is one of causes of respiratory failure associated with high mortality[1]. Timely recognition and institution of safe mechanical ventilation are crucial to avoid mortality. We sought to create a Convolutional Neural Networks (CNN) model that would automatically and rapidly detect ARDS with high specificity. We further combine the model with previously derived and validated ALI sniffer to improve the performance.

Methods
A cohort of 34826 chest x-ray images (15,899 unique patient admissions) were obtained, of which 3011 were used for training and testing (1002 “ARDS”, 1002 “Pneumonia”, and 1007 “Normal”). The images were used in training and testing the model with an 80% and 20% split respectively. The input size of images was set as [229x229x3]. This is the optimum input size for X-ray classification task [3,4]. Data augmentation methods were employed to avoid overfitting and therefore increases the model’s generalization ability. Convolutional Neural Network (CNN) was used to build models for “ARDS” and “Pneumonia” detection, which included 5 binary (“ARDS-Normal”, “Pneumonia-Normal”, “ARDS-Pneumonia”, “ARDS-NonARDS”) and one categorical classifications (“ARDS-Pneumonia-Normal”). NonARDS included combination of “Pneumonia” and “Normal” images.

Results
The categorical model (ARDS-Pneumonia-Normal) achieved the accuracy rate of 96%, with a testing accuracy rate of 86 %. The AUC (Area Under ROC Curve) of ARDS was 0.88, Normal 0.89, and Pneumonia 0.83. The True Positive (TP) rate of ARDS was 85%, while the TP rate of Normal and the TP rate of Pneumonia were 84% and 79% respectively. Model had Positive Predictive Value (PPV) of 0.84 with model recall of 0.83 and Negative Predictive Value (NPV) of 0.93. The results of binary classification are presented in Table II.

The validation sample included a separate cohort of ARDS patients used in derivation of the clinical sniffer and included 7,164 xray. The CNN model correctly identified 722 of 1046 images as “ARDS” and 3320 out of 3972 samples as “Non-ARDS”, resulting in overall sensitivity of 69% and specificity of 84% (PPV and NPV of 47% and 99% respectively). We further combined the more sensitive clinical parameters of the sniffer with more specific CNN-based image detection into the three-category classification: “probable ARDS” (both clinical parameters and CNN-model positive), “possible ARDS” (one of the two is positive), or “unlikely ARDS” (both negative). This resulted in combined sensitivity of “probable ARDS” of 97% and specificity of 80% for “unlikely ARDS” categories (Table III).

Conclusion
The automatic chest x-ray recognition models proved to have clinically useful performance that could accelerate detection of life-threatening respiratory conditions.
Survival Analysis of Breast Cancer from DNA Methylation Data

Guanghui Liu¹,²
¹School of Information Engineering, Nanjing University of Finance & Economics, Nanjing, China; ²Biomedical and Health Informatics, State University of New York at Oswego, Syracuse, New York, USA

Abstract

In this study, we propose a novel method for survival prediction using bidirectional LSTM network and ordinal Cox model. First, gene methylation expression data and clinical data are merged and filtered. Then, we build a deep LSTM model to predict patient survival risk. We use the leave-one-out method for cross validation and the concordance index to evaluate the prediction performance. Stringent cross-validation tests on the benchmark dataset demonstrates the efficacy of the proposed method.

Introduction

The Breast cancer is one of the most common form of dis-eases worldwide. It is reported that more than forty thousand women and four hundred men in the United States died from breast cancer annually before 2016. These data emphasize the importance of most profound understanding of factors that trigger breast cancer and contribute to its development. Gene methylation influence on cancer has been introduced with great success. Methylation of CpG sites is an epigenetic regulator of gene expression that usually results in gene silencing. Consequently, to explore the utility of methylation analysis for cancer diagnosis, we analyzed gene methylation expression of tumors from patients with breast cancer to identify potential cancer-specific methylation genes.

One long-term goal of cancer research is to identify prognostic factors that affect patients’ survival time, which in turn allows clinicians to make early decision on treatment. patients classified into a high-risk group may benefit from closer follow-up, more aggressive therapies, and advanced care planning. Cox proportional hazard¹ is among the most popular survival prediction models. Recently, based on the Cox model, several regularization methods have been proposed in the literature, e.g, LASSO-COX, RSF-COX, MLP, and DeepSurv et al. The above methods assumed that the survival information of one patient is independent from another, and thus miss the strong ordinal relationship between the survival times of different patients. Motivated by all these considerations, we thus propose a method with LSTM networks and ordinal Cox model to predict breast cancer patient's survival risk from gene methylation data.

Materials and Method

The methylation data was downloaded from TCGA² database. The benchmark dataset includes 779 patients with 20106 genes. Our proposed method has three stages, including the gene co-expression cluster stage, the bidirectional LSTM network stage, and the COX model stage. In the gene co-expression clustering stage, gene methylation expression data could be reduced in terms of feature dimension. WGCNA algorithm is used to cluster genes. So, twelve eigengenes are obtained and will serve as input features for the machine learning network. Secondly, the bidirectional Long-Short-Term-Memory (biLSTM) method is proposed to predict patient survival risk. Finally, a novel ranking loss function for the deep cox proportional hazard model is built for survival analysis to ensure that the ordinal relationship among the survival time of different patients can be preserved.

Conclusion

We assess the performance of the proposed method and carry out experiments on the training set through leave-one-out cross validation. The median risk score predicted by the cox proportional hazards model is used as a threshold to split patients into low-risk and high-risk groups. We test if these two groups have distinct survival outcomes using Kaplan-Meier estimator and rank test. The survival curves are drawn by applying different methods. Experimental results demonstrate the superiority of the proposed method over the existing four predictors. The good performances of the proposed method come from the use of the combined bidirectional LSTM predictor and ordinal information.

YouTube Video Analytics: Understandability Assessment of Diabetes Videos for Patient Education

Xiao Liu, PhD1, Anjana Susarla, PhD2, Rema Padman, PhD3
1Arizona State University, Tempe, AZ; 2Michigan State University, Lansing, MI; 3Carnegie Mellon University, Pittsburgh, PA

Introduction
Digital therapeutics that leverage mobile applications, software platforms and multi-media content have been developed for the prevention and/or management of a variety of chronic and acute health conditions, such as diabetes1. However, enhancing the effectiveness of patient education and health communication is essential to achieve improved uptake of such therapies for better health outcomes. In this study, we draw on the validated Patient Education Materials Assessment Tool (PEMAT)2 to assess understandability of publicly available user generated social media content such as diabetes-related YouTube videos.

Methods
Building on prior research1 and guided by PEMAT2, we develop a scalable, generalizable, augmented-intelligence and co-training-based machine learning approach to retrieve and assess the understandability of encoded medical content in YouTube videos on diabetes-related topics. Over 200 search keywords related to diabetes patient education are identified using literature review and clinician inputs. We collected the top 50 videos for each search term using YouTube Data API resulting in 9,873 unique videos for the study, and extract their content and metadata. Two clinicians evaluated 700 randomly sampled videos from the corpus for video understandability according to the PEMAT guideline, with inter-rater reliability assessment providing a consensus score, and used for training the classification model. We define the classification of video understandability for patient education as a multi-view learning and binary classification problem using a co-training machine learning model3. Medical terms are extracted and analyzed using a deep learning model1. We utilize the Google Cloud Video Intelligence platform to perform video data processing and extract features that are relevant for understandability. We perform object detection to obtain labels of objects in the videos at frame level and detect scene changes within the videos to examine whether videos are chunked into distinct segments. We use speech transcription to understand the narratives and extract features from them to evaluate speech clarity, and optical character recognition to detect text, tables and illustrations in the video. The confidence levels associated with these methods provide guidance on the quality of the data processing methods. All these features are subsequently used by the co-training model to assess understandability.

Results
The co-training model with logistic regression classifier initially starts with 600 labeled videos for supervision. After 12 iterations and adding 305 video annotations, the model converged, and is evaluated on 100 held-out labeled videos. Our approach achieved a precision of 0.84, a recall of 0.79, and an F1 score of 0.81 in classifying videos with high understandability. A comparison with three benchmark models, logistic regression, Support Vector Machines, and Random Forest, showed significantly improved video understandability classification by the co-training model. Furthermore, measuring average precision at K, K=1...10, for 20 random queries, a medical expert ranked 72% of top 10 videos recommended by the co-training approach compared to 40% of those based on YouTube’s default ranking.

Conclusions
In this study, we develop an automated, scalable and multi-modal algorithmic solution to evaluate whether medical information encoded in diabetes-related YouTube videos adheres to validated understandability guidelines on patient education and health promotion, and retrieve videos that meet these criteria. Ongoing research will extend the current methodologies to include critical criteria such as accuracy, actionability and quality of the video content and eventually create a repository of curated health videos. We anticipate that this approach can facilitate recommendations of highly ranked and clinically validated YouTube videos to information seeking consumers and point-of-care instructions by clinicians for improved patient education, self-care management and societal health literacy.

Engaging the disengaged: recommendations for partnering with transitional aged youth to improve mental health help-seeking in the digital age

Brian Lo, MHI\(^1\), Jenny Shi, MPH\(^1\), Howard W. Wong, MHI\(^1\), Alexxa Abi-Jaoudé, MPH\(^1\), Elisa Hollenberg, MSW RSW\(^1\), Andrew Johnson, BA\(^1\), David Wiljer, PhD\(^{1,2}\)

\(^1\)Centre for Addiction and Mental Health, Toronto, ON, Canada; \(^2\)University of Toronto, Toronto, ON, Canada

Introduction

Digital health tools, such as mobile apps, can help support transition-aged youth (TAY) between 16-29 years old navigate challenges related to finding mental health and wellness resources in Canada. Co-design approaches have been suggested to help support the development of digital health tools that meet the needs of end-users \(^1\). However, there is a lack of guidance on how to effectively engage with TAY throughout the development and optimization of these platforms. This presentation aims to share the lessons learned from engaging TAY in the development of Thought Spot, a mobile health app designed to support TAY in seeking mental health and wellness resources \(^2\).

Methods

In 2016-2019, we conducted 5 co-design workshops with TAY to develop the Thought Spot platform \(^2\). As a part of the solution development, we also explored recruitment and engagement approaches for TAY through 12 focus groups\(^3\). Based on a review of the academic literature and a reflection of our challenges and lessons learned from the workshops, we have developed seven recommendations for engaging TAY in digital health initiatives.

Results

From the activities that were conducted for the development and optimization of Thought Spot, several recommendations were identified and are described in Table 1 below.

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Address power dynamics with transparency and clear boundaries</td>
<td>Clearly establishing the scope and decision-making capacity of TAY can ensure that their perspectives are valued and issues related to power dynamics are mitigated</td>
</tr>
<tr>
<td>Language plays a key role</td>
<td>Use of non-stigmatizing language and avoiding colloquial language (e.g., the term ‘research’) can reduce stigma and language barriers</td>
</tr>
<tr>
<td>Account for diversity and foster a culture of respect</td>
<td>Project activities that are considerate of sociocultural influences can help foster inclusivity among a diverse group of participants</td>
</tr>
<tr>
<td>Involve TAY in all aspects of the project</td>
<td>TAY should be involved from planning to evaluation of all project activities to ensure appropriateness and suitability</td>
</tr>
<tr>
<td>Build upon relationships with key members and leaders of the TAY communities</td>
<td>Key community members can help researchers develop the trust and relationships needed for recruitment and engagement activities</td>
</tr>
<tr>
<td>Consider and address barriers to engagement (e.g., resources)</td>
<td>Identifying and exploring challenges that hinder engagement (e.g., time and resources) can reduce barriers for TAY to participate</td>
</tr>
<tr>
<td>Be flexible and innovative to emerging approaches favored by TAY</td>
<td>Use of emerging approaches (e.g., social media platforms) in creative ways is critical for engagement and recruitment of TAY</td>
</tr>
</tbody>
</table>

Conclusion

A set of recommendations were identified for engaging TAY in the development of a digital mental health tool. Future studies should verify these recommendations through other digital health projects for TAY.

Monitoring the Effects of the Pandemic on Cancer-Related Patient Encounters

Jack W. London, PhD¹; Elnara Fazio-Eynullayeva, MA²; Matvey B. Palchuk, MD, MS²; Peter Sankey, MBChB³; and Christopher McNair, PhD¹
¹Thomas Jefferson University, Philadelphia, PA, ²TriNetX LLC, Cambridge, MA, ³University Hospitals Plymouth NHS Trust, Plymouth, United Kingdom

Introduction

We developed an analytical infrastructure to quantify the immediate impact COVID-19 has had on deviation from normal cancer care activities, including cancer screening efforts. We leveraged an existing health research network platform (TriNetX; Cambridge, MA)¹ to analyze data from over 20 different provider institutions across the United States that represent 28 million patients and that have immediate data on relevant patient encounters. We focused on patients seen at these healthcare institutions with diagnostic codes for malignant, benign, in situ, and unspecified neoplasms. We initially looked at the number of these patients having encounters for March and April 2020 compared with the same months in 2019. Subsequently, we repeated similar analyses for the rest of 2020. These analyses include patients being seen for the first time at these institutions, possibly for screening, initial diagnosis, second opinion, or treatment initiation. Finally, patient metrics for site-specific malignancies were analyzed (lung, breast, prostate, colorectal, hematologic cancers and melanoma). Furthermore, we considered the data from a healthcare institution in the United Kingdom to initiate exploration of the global applicability of the trends we observed for our US network.

Results and Discussion

Development of this analytical infrastructure began in April 2020. The first published results² for this early period of the pandemic identified significant declines in encounters for both existing and new incidence neoplasms as well as substantial decreases in breast cancer and colorectal cancer screenings. These analyses were repeated over subsequent periods of time as the pandemic progressed through 2020, and a recovery in the numbers of cancer screenings and newly diagnosed cancers were observed.

Conclusion

Our findings indicate an initial significant decline in new incidence neoplasm-related encounters and cancer screenings as a result of the COVID-19 pandemic into April 2020, which suggests the potential for increases in later-stage disease at initial presentation and increased screening demand in the future. This decline was followed by an increase in new incidence encounters during the subsequent weeks, although 2019 levels were not quite reached. As expected, mammography and colorectal screenings did surpass prior year numbers later in 2020. Together, this confirms the need to monitor both the short-term and the long-term effects the pandemic will have on this population. The analytical infrastructure described here provides the means for this surveillance.

Oral-HPV Screening Tool for Assessing Individuals at Risk for HPV-associated Oropharyngeal Cancer

Steven D. London, DDS, PhD, MPH, MBA 1,2,3, Paul Fontelo, MD, MPH 1, Shadi Boroumand, DMD, MPH 2, Bruce A. Dye, DDS, MPH 2.

1National Library of Medicine, Bethesda, Maryland
2National Institute of Dental and Craniofacial Research, Bethesda, Maryland
3Stony Brook University School of Dental Medicine, Stony Brook, New York

Introduction: Human papillomavirus (HPV) is the most commonly transmitted sexual infection in the US and is associated with 70% of all oropharyngeal squamous cell cancer (OPC) in the US leading to significant morbidity, mortality, and cost. At the present time preventive interventions are focused on vaccinating teenagers and those up to age 26, but interventions for adults still rely on screening through clinical oral cancer examination and counseling. However, it is important for oral health professionals to inform patients of risk and screen their patients for early OPC detection. D’Souza, McNeel and Fakhry developed an algorithm for determining risk for oral HPV infections. The algorithm assigns risk based on sex, number of lifetime oral sex partners, and current smoking status. We further adapted the algorithm to include an indicator for the number of remaining natural teeth. Previous research has indicated that significant tooth loss is associated with increased likelihood of having oral HPV even after controlling for the influence of smoking. Risk for oral HPV varies for men and women, dependent upon the number of oral sex partners. For men who currently smoke, risk is even higher. Risk is also elevated for men and women with 12 or fewer teeth who do not smoke. The goal of this project is to ascertain the potential impact of oral HPV screening performed by oral health professionals using this brief screening tool in the US adult population if practice guidelines were implemented that included the use of this screening tool.

Methodology: The aim of this study is to quantify the impact of oral health professionals who provide screening for at-risk individuals using the screening tool. Data from 9183 individuals (20-59 years old) participating in NHANES 2011-2016 with valid information on age, sex, smoking status, self-reported sexual behavior information, number of remaining teeth and laboratory-assessed oral HPV status, were used. Participants were categorized into one of the six risk categories based on sex, smoking status, and having 12 or fewer teeth. Regression analysis determined that men are not at very low risk and women are not at elevated risk. The six groups are: low risk men, medium risk men, and elevated risk men; very low risk women, low risk women, and medium risk women. These six risk groups were further subdivided into three groups to reflect risk status as low, medium, and elevated for oral HPV infection. Analysis was performed using SAS statistical software 9.4 analytic routines for frequency calculations and test performance characteristics.

Results: Approximately 7% of the US population were HPV+ (10.2M) in 2011-2016. After sorting approximately 144M Americans into the 3 main risk categories using the modified screening guide, we estimate that 109M Americans would be identified as low risk (75.6%), 25.4M as medium risk (17.6%), and 9.8M (6.8%) as having elevated risk for HPV-associated oropharyngeal cancer. Among Americans, 83.5M who had dental visits in the past 12 months, 65M would have screened as low risk, 14.2M as medium risk, and 4.3M as elevated risk. Among these dental care users, 5.5M were oral HPV+, whereas 4.7M non-users were HPV+. Additionally, among those with a dental visit in the past 12 months, 23.4% received oral cancer screening advice. Among those not receiving advice, 16.4% would have screened as medium or elevated risk. If all individuals who visited the dentist had received advice and the oral HPV screening tool was used, an additional 63.9M Americans would have been screened identifying 13.4M as either medium or elevated risk for oral HPV+. Among these individuals, 3M of the 5.4M HPV+ dental users could have been referred for oral HPV testing. The performance of this screening tool yielded a sensitivity of 0.56 and a specificity of 0.78, with a 76% accuracy.

Conclusion: Findings from these analyses indicate that clinical risk screening for oral HPV could quickly identify a substantial number of dental care users who are medium to elevated risk for oral HPV (13.4M American adults) as well as more than half of all HPV+ dental care users (3M adults). Because 70% of all Oropharyngeal cancers are associated with HPV, better identification of dental patients who are medium-elevated risk for oral HPV should result in improved patient advising, referring, and decision-making with the goal of reducing OPC incidence and mortality in the US. We suggest that the screening tool could be integrated into an ICT tool for clinical use at some time in the future.

Identifying Criteria for Antonym Generation from Corpora

Chris J. Lu, PhD1,2, Amanda Payne, PhD1,2 and James G. Mork, MSc1
1National Library of Medicine, Bethesda, MD 2Medical Science & Computing, LLC, Rockville, MD

Introduction
The SPECIALIST Lexicon (the Lexicon) and Lexical Tools are enhanced with new antonym features for the 2022 release [1]. Antonym pairs (aPairs) are generated from the Lexicon, suffix and prefix derivations, collocates (CC) and semantic relations (SC) in corpora [2]. Criteria are identified from a set of common aPairs to effectively generate antonyms from CC and SC. This paper describes our systematic approach on identifying generic criteria for antonym generation from corpora.

Methods
We collected commonly used antonyms from 14 sources on the internet [3]. This collection includes 1000 unique, lowercased, single word aPairs, which are assumed to have representative characteristics of overall antonyms and is used as a training and test set (TtSet) to identify generic criteria of antonyms. APairs in the TtSet are manually tagged for canonicity, domain, type, and negation. Canonical aPairs have a generic domain, that is central to human life and ways of living across time and cultures. Computer programs are developed to 1) retrieve properties of aPairs, such as EUIs, POSs, CUIs, STIs, sources, etc. 2) compute stats among properties to identify generic criteria of antonyms. TtSet and 2021 antonym production data are used for this study.

Results – Identified Criteria
First, aPairs from TtSet and 2021’s data set have the same (10) domains for canonical antonyms and similar negation rates (9.51% and 7.14%, respectively). This conforms with our hypothesis that TtSet is representative of overall antonyms to retrieve antonym characteristics. Second, Table 1 shows the source distribution of TtSet. We observed antonyms from corpora models (CC and SC) to be worthy of further development because they contain the most aPairs (83.65%). Third, canonical aPairs must be in the Lexicon with valid EUIs and have the same POS. Fourth, canonical aPairs cannot be synonyms. This confirms the theory that antonyms and synonyms are similar in domain and different in polarity. Fifth, antonyms should have CUIs (our scope is using concepts in the UMLS-Metathesaurus) and share STIs because 67.79% of aPairs share STIs when they have CUIs. The analysis’ results are shown in Table 2 and used to retrieve antonym candidates from corpora. Our ultimate objective is to provide generic and comprehensive antonym features with completion of antonym generation from corpora models. The Lexicon is distributed with UMLS by NLM via an Open Source License agreement and is available at: https://umlslex.nlm.nih.gov/lexicon.

An exploration of information extraction models on transcribed patient visits

Kevin Lybarger, PhD, Erica Qiao, BS, Meliha Yetisgen, PhD
University of Washington, Seattle, WA, USA

Introduction

Documentation burnout contributes to clinician job dissatisfaction, and clinical notes often omit salient information. The automatic generation of notes from clinician-patient conversations, referred to here as ambient note creation (ANC), could provide an alternative, time-saving documentation process. ANC involves reorganizing dialogue content by note sections and translating the conversation to medical language. Although ANC has been pursued as a sequence-to-sequence machine translation problem, ANC may benefit from incorporating information extraction (IE) models that identify salient clinical information (e.g. signs, symptoms, treatments) and create abstractive summaries. In this work, we analyze transcribed conversations and evaluate the performance of IE models designed for clinical notes.

Methods

In a study of physician communication skills and training interventions, 1,282 primary care visits were audio recorded at clinics around Seattle, WA. The dialogue from a subset of these recordings was manually transcribed, including 144 visits at the University of Washington. We use these transcripts to explore the dialogue contents and the limitations of existing IE systems. In our previous work, we developed high performing IE models trained on clinical notes for characterizing social determinants of health (SDOH) and symptoms. The SDOH include alcohol, drug, and tobacco use, employment status, and living situation. Here, we annotate 10 randomly selected transcripts using the same SDOH and symptom annotation schemes and evaluate the performance of these extractors in this conversational domain.

Results and Discussion

Table 1 summarizes the turns, words, and questions per visit. The length of the patient and doctor contributions (words per visit) is similar, with patients making more frequent, shorter contributions. Medical assistant (MA) contributions are relatively small. In the annotated transcripts, there are 12.2 symptoms per transcript. On clinical notes, the symptom extractor identified symptoms at 0.83 F1 and predicted assertion values (present vs. absent) at 0.79 F1; however, the performance drops markedly on the dialogues to 0.64 F1 for symptom identification and 0.45 F1 for assertion. The more colloquial language of the dialogues, relative to clinical notes, is a contributing factor to the decreased symptom identification performance (e.g. “I feel crappy”). Symptom identification errors result in cascading assertion errors; however, the decreased assertion performance is also associated with the frequent coreferences to symptoms across multiple sentences and turns. The annotated transcripts only include 5 substance use and 4 employment events; however the SDOH extractor predicted 58 substance use and 18 employment events (performance < 0.04 F1). False positives related to substance use include the mislabeling of prescription drugs as illicit drugs, as well as difficult to explain errors. Many of the employment-related false positives are associated with phrases, like “works for me,” where “work” is used outside the context of employment.

ANC has the potential to reduce documentation burden and improve documentation quality. It may benefit from IE models that identify critical information. Our findings indicate existing IE models do not generalize well to conversational data. The degraded performance would be exacerbated by speech recognition errors associated with the automatic transcription of the dialogues. In future work, we plan to explore IE in this clinical conversational domain, with the goals of improving extraction performance and integrating the extracted information into an ANC pipeline.

The Real-World Trend Analysis of Cancer Drugs Empowered by Natural Language Processing

Meng Ma¹, Kyeryoung Lee¹, Yun Mai¹, Christopher Gilman¹, Zongzhi Liu¹, Mingwei Zhang¹, Minghao Li¹, Arielle Redfern¹, Tommy Mullaney¹, Tony Prentice¹, Paul McDonagh¹, Qi Pan¹, William Oh¹,², Rong Chen¹,², Eric Schadt¹,², Xiaoyan Wang¹
¹Sema4, Stamford, CT; ²Icahn School of Medicine at Mount Sinai, New York, NY

Introduction
Electronic health records (EHR) have been widely used in clinical practice and have generated a vast amount of clinical data, which has become a rich resource for quality of care and clinical research. Investigation of the trend of cancer drugs in clinical practice is an important step for the evaluation of the real-world performance of cancer drugs. This study applied natural language processing (NLP) to recognize cancer treatments from clinical notes of lung cancer patients and investigated the trend of cancer drug usage for lung cancer treatment.

Methods
The lung cancer cohort of patients was curated from the Mount Sinai Data Warehouse, and 461,098 clinical notes were extracted for this cohort (2010.01-2019.12). We built a Bidirectional Long Short Term and Conditional Random Fields (BiLSTM-CRF) based NLP model on recognizing cancer treatments. The resulting model was validated independently with an F1 score of 95%. All distinct cancer treatments recognized from the 461,098 notes by the pipeline were normalized and post-processed with a manual review (Figure 1). Time-trend analysis of the drug usage in lung cancer patients was investigated in this study.

Results
The NLP pipeline identified 2,891 more patients with detailed cancer treatments compared with the total of 1,395 patients from structured data. The approval history and longitudinal use of the most frequently appearing cancer drugs (chemotherapy, targeted therapy, and immunotherapy) are shown in Figure 2. The continuously increasing amplitude of chemotherapy use is far beyond targeted therapy and immunotherapy drugs, implying that although targeted therapy and immunotherapy have revolutionized the landscape of lung cancer therapeutics, chemotherapy remains an essential component. Compared to the first and second-generation EGFR TKI Erlotinib and Afatinib, the third-generation EGFR TKI Osimertinib shows a dramatic increase in clinical use since FDA approval in 2015. The anti-VEGF monoclonal antibody Bevacizumab is the second most frequent targeted therapy drug, while a slight decrease in use since 2017. Pembrolizumab use has rapidly grown since clinical trial KEYNOTE-024 succeeded in phase III in June 2016, while Nivolumab use has gradually decreased ever since clinical trial CheckMate-026 failed in phase III in August 2016. Atezolizumab and Durvalumab both showed an increasing trend of use in clinical practice. The data showed a consistent trend with the published revenue of the cancer drugs from structured and manually reviewed data.

Conclusion
This study demonstrates NLP is a powerful tool to enable real-world free-text clinical notes as an analyzable resource to facilitate the investigation of the use trends of cancer drugs in clinical practice.
Evaluating Social Determinants of Health in Clinical Communications Data

Diwakar Mahajan, MS¹, Jennifer J. Liang, MD¹, Ananya Poddar, MS¹, Sasha Ballen, MS², Ching-Huei Tsou, PhD¹
¹IBM TJ Watson Research Center, Yorktown Heights, NY; ²R-Health Inc, Elkins Park, PA

Introduction

Social determinants of health (SDOH) contribute to a patient’s functional status and disease onset and progression. With the shift towards telemedicine during the COVID-19 pandemic, use of secure messaging between patient and provider is becoming more prevalent and may prove to be a valuable source of SDOH information. Unlike other patient record data, communications data have the benefit of capturing the patient’s concerns in real-time in their own words. This work presents a preliminary analysis of SDOH in clinical communications data.

Methods

Our corpus consists of R-Health communications data from January 2019 to September 2020, containing a total of 672,725 messages over 11,186 patients. Starting from the core domains identified by the Institute of Medicine’s report on capturing social and behavioral determinants of health in EHRs¹, we (1) identified a subset of SDOH topics of interest: financial resource strain, stress, depression, physical activity, tobacco use and exposure, alcohol use, social connection/isolation, exposure to violence, (2) created a set of keywords for each SDOH topic, and (3) generated a keyword-based script for each SDOH topic to automatically detect topic-specific “chatter” or discussion in communications data. To evaluate this script, we annotated a total of 300 messages, half of which were randomly sampled, and the remaining selected using our keyword-based script to ensure sufficient positive instances. As the resulting dataset still contained <10 instances for financial resource strain, physical activity, alcohol use, social connection/isolation, and exposure to violence, those topics were excluded from analysis. Table 1 presents the ground truth counts and evaluation of the keyword-based script for the remaining SDOH topics. To uncover trends for different SDOH topics in communications data, we ran this script over our entire corpus of 672,725 messages.

Results

Figure 1 presents the percentage of patients with SDOH “chatter” broken down by topic and over time. Here we restrict our analysis to only those messages sent by the patient. As observed, there is a significant increase in patient-initiated messages about stress starting around March 2020 when COVID-19 was officially declared a global pandemic. The “chatter” peaked in April 2020 and has come down slightly but remained higher than the previous baseline. A similar but less dramatic trend can be observed for depression.

Conclusion

We studied presence of SDOH “chatter” in communications data for a direct primary care practice and observed interesting trends for discussions about stress in light of the current COVID-19 pandemic. In future, we plan to generate more ground truth, expand our analysis to other SDOH topics, and do a deeper analysis to better characterize the SDOH discussions in communications data.

COVID-19 as a Catalyst: Rapid Development of Usable Digital Patient Services

Andrea N. Mahnke, MS1, Jenna R. Kautza1, Emily A. Wiedoff1, Daniel P. Burish1, John B. Welch, MA1
1Marshfield Clinic Health System, Marshfield WI

Objective

Overall, the objective of this initiative was to rapidly develop digital services in order to help keep patients safe and handle increased volumes during a global pandemic. These services included a mobile app, online patient appointing and aspects of telehealth appointments. An objective of iterative user testing in parallel with development was to determine where new digital services performed well and where they failed to meet the needs of patients. A second objective of this work is to inform further design enhancements and developments of above digital services.

Background

Planning for digital patient services was underway pre-COVID-19, but the onset of the pandemic rapidly accelerated development and implementation efforts. While the imperative was to get the digital services in the hands of patients quickly, the team wanted to ensure that the services would be usable for patients. Usability is a key factor in adoption of digital services, especially for patients with complex clinical landscapes and who may also represent underserved populations.1

Methods

Pre-COVID-19 two surveys were conducted with health system patients. One was to assess patient technology use in the health system’s rural setting. The second, used the Kano Model to assess patients’ desires for mobile app features in an effort to prioritize them for development. Starting in April of 2020, we conducted iterative testing on the online patient self-appointing feature. The usability testing of online patient self-appointing included a patient portal prototype and production platform. This was followed by testing of a mobile app prototype. We also conducted a satisfaction survey of online patient self-appointing (ongoing). A card sort was conducted to help understand how patients would organize different features of a mobile app. This was followed by usability testing of mobile app home/dashboard screens and mobile app global feature navigation with four prototypes. All testing iterations were conducted with health system patients and employed remote moderated task based usability evaluations, followed by semi structured interviews. When time permitted during the semi structured interviews, we asked questions regarding patients’ perspectives of telehealth appointments, whether they had participated in a telehealth appointment or not. An extensive telehealth survey was sent to all patients that had participated in a telehealth appointment and had an email on record.

Results

The technology use survey was completed by 316 patients. The survey provided details on smart phone use and broadband access across demographics. A total of 9,865 patients completed the Kano Model survey. This identified the app features that patients most expected to see. There were three iterations of online appointing evaluations with a total of 35 patients. Feedback from patients resulted in improvements of labeling and task flows. A total of 216 patients have completed the online appointing satisfaction survey. The survey is still open and analysis is in progress. The mobile navigation card sort was completed by nine patients and provided useful information, especially about how patients expect to view and group information. The mobile app home/dashboard screens and global app feature navigation was conducted with 24 patients. Valuable information was gained regarding placement of screen elements and navigation functionality, particularly regarding the menu. The telehealth survey was completed by 2,945 patients and analysis is in progress.

Quantifying Changes in Resident-Patient Interactions During the COVID-19 Pandemic Using EHR Audit Logs

Mark V. Mai, MD, MHS¹, Naveen Muthu, MD¹, Bryn Carroll, MD¹, Anna Costello, MD¹, Daniel C. West, MD¹, Adam C. Dziorny, MD, PhD²

¹The Children’s Hospital of Philadelphia, Philadelphia, PA; ²University of Rochester School of Medicine, Rochester, NY

Problem: Curricular adaptations to limit trainees’ exposure to COVID-19, in addition to changes in healthcare utilization due to the pandemic, likely affected trainees’ participation in direct patient care. Missed clinical experiences will potentially have longstanding effects on the quality of the medical workforce. Recent methods of patient attribution, using EHR audit logs, can inform educators about trainee-patient experiences.

Methods: We performed a retrospective cohort study with year-over-year analysis of pediatric resident provider-patient interactions (rPPI) at a large academic freestanding children’s hospital. We examined cohorts of pediatrics residents during March 15 – June 15 in 2020 (Exposure), 2018 (Control #1) and 2019 (Control #2). Using previously described methods of patient attribution from EHR data, we extracted and analyzed resident shifts and rPPIs.

Results: Residents in the Exposure period had fewer shift counts than those in both of the Control periods, across all PGYs (p < 0.05). PGY1 residents in the Exposure cohort experienced the largest absolute decrease in rPPIs across all care settings (Exposure: 111, Control #1: 222, Control #2: 206), particularly in the Continuity Clinic context (Exposure 8.2, Control #1: 36.7, Control #2: 36.5), where patient continuity also decreased from 23.4% to 11.1%. Common AHRQ Clinical Classifications Software Refined (CCSR) diagnosis categories previously encountered by pediatric residents in clinic decreased during the Exposure period (Figure 1) with similar findings in ED encounters.

Conclusion: While necessary to protect trainees, curricular changes coupled with changes in healthcare utilization drastically affected clinical learning opportunities through authentic patient interactions. Patient attribution algorithms can facilitate analysis of external disruptors to traditional models of medical education, allowing educators to better support learners’ needs and development, as well as plan for potential effects on competencies of groups of trainees.

Introduction

As patient-centered care continues to grow as a cornerstone to clinical care delivery, the implementation and assessment of patient-reported outcomes (PROs) has become an area of interest for clinicians to holistically understand patients’ health statuses. Since PROs provide valuable insights into patients’ clinical pictures (e.g. symptom information, quality of life), analysis of PROs has become a common source of research studies and data analyses that aim to refine or further develop patient-centered interventions. However, recent legislation encourages increased transparency of individual health information to patients and more efforts to engage patients in their care. Part of this transparency involves the question of whether or not researchers are obligated to return this collected health information to participants to encourage transparency. Moreover, public perspectives on trust in scientific research are varied and lacking clinical context, which may influence preferences for data collection and sharing in research. Therefore, in this study, we aim to explore public perspectives on collecting, returning, and sharing their health information, and how different use cases might change their trust in research.

Methods

Guided by the Ethical Framework of Consumer-Generated Data and the Socio-Ecological Model, we aimed to conduct two surveys: one with a representative US sample, and one with a representative sample of New York State (Empire State Poll). In these surveys, we explore: 1) trust in research compared to trust in the general public, 2) preferences for researchers to return collected health information to participants, 3) desired format to receive health information, and 4) the effects on trust in research based on multiple data-use cases (based on use cases, participants rated their trust on a scale from 1 (strongly decrease trust) to 5 (strongly increase trust)).

Results

Overall, participants to date (n = 502, anticipated n = 1,300) had an average age of 46.6 years and were 51% female, 74% White, and 7% were of Hispanic or Latino origin. Most participants (66%) attended some college or had a bachelor’s degree, and 28% had limited/marginal health literacy. At baseline, most participants (60%) trust scientific researchers more than the general public. When given a scenario where health information was collected for research purposes, 84% of participants wanted access to their health information. On a scale of 1 (not important) to 10 (extremely important), most participants found it important to have access to the health information that researchers collect about them (avg: 8.0/10.0). Participants generally preferred to see their health information in E-mail (31%) or online website (17%) format. Many (85%) respondents indicated that having access to their collected health information would increase trust in research, and when knowing that the information would improve research about their own health condition, 70% of respondents indicated that their trust in research would increase.

Conclusions

It is important for participants to have access to their collected health information. Generally, participant trust in research is high when the purpose and implications of using and sharing their health information are disclosed. In future research studies, researchers should consider returning information back to participants and focus on transparency in disclosing the intended purpose and uses of their shared health information to foster trust.

Division for Cognitive and Psychological Science, Istituto Europeo di Oncologia, Italy

Introduction

Chronic pain is a burdensome condition, with high social impact, with the patients experiencing a limited working capacity, psychiatric issues, and general disability[1]. Patient’s therapeutic pathways include multiple specialists, while continuity of care and care coordination are needed to guarantee pain management. Pain is therefore considered as one of the most promising conditions in which the use of digital health technologies, ecological momentary assessments, and digital communication tools may boost patient’s engagement and coping, as well as better monitoring of therapeutic outcomes[2]. PainRE-Life is a project, financed by the Lombardy Region (Italy), aimed to develop a dynamic and integrated technology ecosystem to allow care continuity in patients with pain.

System architecture

The project is based on three main technological assets (Figure 1): first, a FHIR based cloud platform (Nu Platform, developed by the partner Nuvyta) that enables care pathway definition and data collection; second, a big data infrastructure connected to the FHIR server that analyzes data and provides inputs to an ecosystem of personalized applications for the decision support of patients and caregivers (third asset, developed by the partner Zadig). Two clinical centers (Casa di Cura del Policlinico Rehabilitation Center, and IEO Oncology Hospital), and a home-based telerehabilitation service provider (Euleria Srl) will serve as case studies for the PainRE-Life platform. The project will also provide an e-learning platform for general practitioners (GPs). Finally, the system was also designed to be integrated, in the future, to routine healthcare, through electronic health records.

Results and Conclusions

To date, the system implements three digital care pathways for the management of pain in post-stroke, early breast cancer, and fibromyalgia (treated with transcranial direct current stimulation, tDCS) patients. Each care pathway involves the execution of a workflow in the Nu platform, that allows collecting all the data (pain severity scales, pain location, psychologic assessment) to be completed by the patient/caregiver at home or by the healthcare professional in the hospital setting and the integration with devices providing patient’s related information (tDCS devices and smartbands for activity monitoring). The validation will start in June 2021, and will first include usability testing and the verification of the care-pathway integration level, by monitoring the deviations from guidelines and recommendations. A second step will be the use of the platform for the evaluation of therapeutic outcomes.

In conclusion, the system will be developed to remain as a full service for the Lombardy Region, and as a reference for all the conditions that require continuity of care, multidisciplinary approaches, and heterogeneous data collection to effectively support patients and caregivers.

Quantifying Spatial Tumor Heterogeneity Using Single-Cell Proteomics

Adriano Martinelli, MSc¹,², Aditya Kashyap, PhD¹, Anna Fomitcheva Khartchenko, PhD¹, Govind Kaigala, PhD¹, Maria Anna Rapsomaniki, PhD¹
¹IBM Research, Zurich, Switzerland; ²ETH, Zurich, Switzerland

Tumors are unique and complex ecosystems that consist of heterogeneous cancer and immune cell type populations with variable molecular profiles, different aggressiveness and proliferation potential. Understanding how heterogeneity influences tumor progression has important clinical implications for the design of effective, personalized treatment options. Towards this goal, single-cell proteomics have enabled the simultaneous quantification of dozens of proteins in millions of cells in situ, permitting a deep characterization of spatial heterogeneity at an unprecedented resolution. However, the computational analysis of the generated data is challenging, and appropriate quantitative metrics are not yet established.

We present a computational framework to quantify tumor heterogeneity in a spatial manner (Figure 1A). Starting from spatially resolved cell phenotypes, we construct a cell-cell graph that describes cell interactions and use custom heterogeneity metrics to capture the underlying tumor architecture. In a next step, we employ machine learning approaches to learn which heterogeneity scores are able to predict disease subtypes and identify the most relevant metrics driving the decision (Figure 1D). Interestingly, immune cells exhibit stronger clustering patterns in grade 3 tumors, and preliminary results indicate that immune-tumor interaction patterns are potentially prognostic for survival (Figure 1E). Our framework is extendable and applicable to other in situ approaches and has the capability to provide data-driven patient stratification or to support comparative clinical studies.

Figure 1. (A) Overview of the proposed pipeline. (B) Example tumor samples for two tumors of grade 1 (top row) and 3 (bottom row) that exhibit distinct spatial patterns and spatial entropy (C). The heterogeneity metrics used to successfully predict disease subtype (D) and linked to clinical metadata, such as grade and survival (E).

Implementation of a Clinical Decision Support System for Automated Fall-Risk Identification and Referrals in Emergency Departments

Apoorva Maru, BS1, Gwen Costa Jacobsohn, PhD, MA1, Collin Engstrom, PhD1, Frank Liao, PhD2, Margaret Leaf, MS2, Joel Galang2, Gerald Pankratz, MD1, Alexis Eastman, MD1, Maureen Smith, PhD, MPH1, Manish Shah, MD, MPH1, Brian Patterson, MD, MPH1

1. University of Wisconsin-Madison, Madison, WI, USA 2. UW Health, Madison, WI, USA

Introduction
While almost 3 million older adults are seen for fall-related injuries in United States emergency departments (EDs) each year1, EDs have played little role in falls prevention efforts. Existing interventions for fall risk screening in the ED have not been widely adopted in practice due to the time and resources necessary to perform in-person screening2,3. Our interdisciplinary team designed an automated EHR-based clinical decision support (CDS) tool to identify and refer older ED patients at high risk of future falls with minimal staff burden. Post-implementation evaluation and user feedback suggested that limitations in the EHR interface prevented ED providers from seeing the automated fall risk alert. Therefore, we evaluated the effect of implementing a forced interaction with the alert as a hard stop.

Methods
Figure 1 depicts the automated screening and referral intervention: a previously derived algorithmic screen automatically identifies high-risk patients, for whom a CDS alert prompts ED Physicians to refer to a fall risk reduction clinic. The workflow was designed with input from clinical stakeholders, patients, and IT staff using human factors principles including usability testing with a heuristic evaluation and cognitive walkthroughs. The intervention was piloted in an academic emergency department with over 60,000 yearly visits, beginning 7/8/2020. Initial results, while promising, showed a relatively low rate of physician acceptance of the CDS guidance, despite educational initiatives and academic detailing. Beginning on 11/16/2020, the CDS was altered to force physicians to either accept or explicitly reject a referral through a hard stop. Data collection began on 7/8/2020 and ran through 3/1/2021.

Results
During the overall study period, 3887 older adult patients were discharged from the ED. Of these, 392 patients were identified as high risk by the automated algorithm (10% 95% CI [9% - 11%]). Before the implementation of the hard stop, 190 patients were flagged and 46 were referred (24% [18% - 30%]). After the implementation of the hard stop, 202 patients were flagged and 77 were referred (38% [31% - 45%]). This difference was significant in a two-tailed test of independent proportions, p = 0.002. We collected qualitative data from 10 physician interviews analyzed via content analysis. Interview data suggested no increase in provider burden with the hard stop.

Conclusion
Despite a rigorous design process and user education campaign, as well as survey data suggesting high acceptance, intervention uptake was initially low when providers were able to ignore the CDS tool. The design team, despite initial hesitancy, added a hard stop to promote interaction with the tool. The addition of the hard stop resulted in significant increase in utilization (p=0.002) across all ED provider groups. Qualitative data indicated maintenance of high acceptability among users.

There is Variability in the Accuracy of Diagnosis Codes Used to Identify COVID-19 Patients

Jayson S. Marwaha, MD1,2; Elizabeth Eldridge, MPH3; Sahr Syed, BS3; Perry Mar, PhD3; Philip Ballentine, BS3; Sadiqa Mahmood, DDS, MPH3; Denis Agniel, PhD2; Nathan Palmer, PhD2; Gabriel A. Brat, MD, MPH1,2

1Department of Surgery, Beth Israel Deaconess Medical Center, Boston, MA; 2Department of Biomedical Informatics, Harvard Medical School; 3Health Catalyst, Salt Lake City, UT

Introduction: On April 1, 2020, a new diagnosis code for COVID-19 was introduced in ICD-10-CM (U07.1: “COVID-19, virus identified”).1 Recent research has found that this diagnosis code has excellent accuracy in identifying hospitalized COVID-19 patients from administrative claims data. From April to May 2020, the sensitivity and specificity of U07.1 were found to be 98% and 99%, respectively.2 While these metrics from the early months of the pandemic are encouraging, the accuracy of this diagnosis code in identifying COVID-19 patients in other types of non-inpatient healthcare interactions remains unknown. As the number of journal articles using this identifier to define their cohort grows, it is important to understand whether U07.1 reliably captures COVID-19 patients in all settings. In this study, we examined the overall sensitivity and specificity of U07.1 across all types of patient interactions with the healthcare system or electronic health record (EHR). By leveraging a unique national database, we found that a large fraction of COVID-19 patients may not be identified by U07.1, despite being clinically affected by the disease and having interactions with the healthcare system. This may affect the integrity of retrospective analyses on COVID-19 patients.

Methods: Our analysis used de-identified data on 1.6 million patients in the Health Catalyst Touchstone registry, representing 17 health systems across 24 states. Patients from January 1 to July 21, 2020 with a positive SARS-CoV-2 polymerase chain reaction (PCR) test or the ICD-10-CM code U07.1 were included.

Results: 1,564,861 patients were included. Hospitalized patients accounted for 22.1% (n=345,676) of our cohort, and non-hospitalized patients accounted for 77.9% (n=1,219,185). Among hospitalized COVID-19 patients (n=345,676), the sensitivity and specificity of U07.1 were 95.6% and 97.9%, respectively. The sensitivity and specificity from April-June 2020 was 92.8% and 99.1%, respectively; from July-September they were 95.8% and 98.9%; and from October-December they were 93.6% and 98.3%, respectively. These findings are consistent with prior studies on the accuracy of U07.1 among inpatients. Importantly, these findings also show that the accuracy of U07.1 has remained steady over time. However, we found that the accuracy of U07.1 deteriorated significantly when non-inpatient interactions were examined. When we included patients with any documented health system interaction (ex. outpatient office visits or telehealth visits), the overall sensitivity and specificity for all patients (n=1,564,861) were significantly lower at only 54.1% and 98.6%, respectively.

Discussion: In this study, we found that the accuracy of U07.1 in identifying PCR-positive COVID-19 patients varies significantly by type of patient interaction. While U07.1 is a reliable identifier among inpatients, it may miss a large fraction of COVID-19 patients in other healthcare settings. Retrospective analyses that use U07.1 codes to identify COVID-19 patients for policy, surveillance, or academic purposes need to account for the significant number of patients not captured by this code. Sample cohorts may fail to analyze an important group of patients and must consider this limitation to ensure appropriate capture of patients.

Analyzing COVID-19 Case Report Forms Data from the All of Us Program

Craig S. Mayer, MS¹, Nick Williams, Ph.D¹, Vojtech Huser MD, Ph.D¹
¹Lister Hill National Center for Biomedical Communication, National Library of Medicine, NIH Bethesda, MD

Introduction

The All of Us (AoU) program developed a survey to assess the impact of COVID-19 on its participants.¹ The program began collecting data for the ‘COVID-19 Participant Experience’ (COPE) survey in May of 2020 with the intention for each participant to complete the survey multiple times. In this study we describe how survey data are represented in the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM), how data is redacted in the ‘registered tier (level 2)’ access level of the AoU workbench and showcase selected survey research insights.

Materials and Methods

First, using the OMOP documentation and provided relationship dictionary we identified which COPE survey questions (Data Elements [DEs]) were redacted in the registered tier (level 2) of access. Second, we analyzed the format of the survey in the OMOP CDM to identify structurally how different questions and answers are adopted to the CDM including different data types, questions with multiple answers, and related DEs. Third, we analyzed the results of the COPE survey for a cohort of possible COVID-19 patients, using the 2020 fourth quarter data release.

Results and Discussion

Redaction: The COPE survey consisted of 182 DEs from 16 topics. Of the 182 DEs, 104 (57.1%) were accessible. 78 were redacted, including five complete survey sections for COVID-19 Treatment, COVID-19 Testing, Mood, Stress, and Social Support. All EHR DEs relating to COVID-19 testing and treatment were also redacted.

Data type and structure: Based on data type, 87 (83.7% of the 104 accessible DEs) are categorical, 13 (12.5%) are numerical and 4 (3.8%) are free text stings. Structurally, for questions that can have multiple answers selected, such as ‘In the past month, has the COVID-19 outbreak affected you? Please select all that apply’, there is a data row for every answer provided. If a participant selects both ‘worked remotely’ and ‘worked reduced hours’, the responses will appear on two separate rows for the one response. We also saw two types of related DEs, grouped (DEs that cannot stand alone) and branched (DEs which are dependent on the response of another DE), where the only connection between the DEs is seen in the relationship dictionary. An example of grouped DEs were ‘How long has it been since you last smoked’ and ‘Enter the number of years’, whereas an example of a branched DE is ‘Do you know someone who has died from COVID-19?’, which triggers ‘Who do you know who has died?’.

Cohort: As of the 2020 fourth quarter data release, 62,664 people have completed the COPE survey, compared to 315,297 (19.9%) who have enrolled in the AoU program so far. To demonstrate the COPE survey data research potential, we considered a cohort of 3,700 possible COVID-19 patients based on the answering of ‘Yes’ to the unredacted ‘Do you think you have had COVID-19?’. The most common reported symptoms from this cohort were ‘Unusual fatigue’ (73.5% of participants), ‘Cough’ (64.1%), and ‘Headache’ (62.6%). The biggest difference in responses from the COVID-19 cohort was in answering ‘Have you EVER been near someone that you know, or suspect, had COVID-19?’. The COVID cohort answered ‘Yes, suspected COVID-19’ (16.4% increase) and ‘Yes, known COVID-19’ (15.5% increase) far more often. Additional results are available in the project repository at https://github.com/lhncbc/CRI/tree/master/AoU/COPE.

AoU R package: We extended our previously developed R package (r4au) for frequently needed AoU workbench analytical tasks with additional functions (getCaseReportForms and getRegisteredDataDictionary) that, respectively, generate the dictionary and label the DEs with the topic and module (form) that they come from.

Conclusion: We concluded that the COPE survey data was able to be fully stored within the OMOP OBSERVATION table and the results analyzable in the research workbench. Both are significant demonstrations for other studies considering the OMOP model and adopting similar conventions used by AoU. AoU’s ability to re-contact participants also represents a powerful platform for future research as proven by COPE survey follow-ups.

Barriers to Seeking Treatment and Attitudes Towards Using Telehealth to Support Management of Depression Among Black Women

Terika McCall, PhD, MPH, MBA
1Center for Medical Informatics, Yale School of Medicine, New Haven, CT

Introduction
Approximately 1 in 5 Black women in the United States experienced mental illness in the last year (1). Furthermore, depressive disorders are the most common mental health conditions among Black women (2). Barriers to seeking treatment contribute to Black women using mental health services at less than half the rate of their White counterparts (1). Findings from numerous studies have shown that the use of telehealth interventions (eg, mobile app) can increase access to services and resources, and are effective in helping participants reduce depressive symptoms (3,4). This study aimed to identify barriers to seeking treatment and gain insight into which modalities Black women deem acceptable for use to communicate with a professional to receive support with managing depression.

Methods
The web-based survey was launched in October 2019 and closed January 2020. Black/African American women (≥ 18 years old) were eligible to participate. Participants were recruited through convenience sampling (eg, email sent via listservs). The 80-item survey included questions about barriers to seeking mental health care and the acceptability of using mobile technology to communicate with a professional to receive support for depression. Fisher’s exact test was used to determine whether an association exists between the responses to questions about comfortability with using each modality to communicate with a professional to receive help for managing depression and age group and education level, respectively. Statistical significance was determined at the 2-sided p<.05 level for all tests.

Results
Findings from the study (N=395) showed that Black women had favorable views toward seeking mental health care, however approximately 40% of respondents indicated that during the past 12 months there was a time when they needed mental health treatment or counseling but did not receive care. Identified barriers to receiving care included cost, not knowing where to access services, lack of time, and stigma. Overall, respondents were more comfortable with using voice call (69.9%) or video call (64.3%) when compared with text messaging (45.1%) or use of a mobile app (45.1%) to communicate with a professional for support with managing depression. Younger Black women (< 50 years old) were significantly more likely to endorse use of text, voice call, mobile app, or video call to communicate with a professional to receive support for managing depression (all p<.05). Furthermore, those with less than a Bachelor’s degree were significantly more likely to endorse the use of text messaging (p=.026). No significant associations were found between education and other modalities (all p>.05).

Conclusion
The findings of this study may be used to inform design of telehealth interventions for supporting management of depression among Black women. Incorporating their preferences for telehealth modalities to communicate with a professional to receive support may improve treatment outcomes.

Addressing the Social Determinants of Health and Resource Utilization Among Ambulatory Oncology Patients

Nadine J McCleary MD MPH,1,2 Ellana Haakenstad MPH,1 Sunyi Zhang MS,1 Jessica LF Cleveland MSOR,1 Michael Manni,1 Deb Schrag MD MPH,1,2 Michael Hassett MD MPH1,2

1Dana-Farber Cancer Institute, Boston, MA; 2Harvard Medical School, Boston, MA

BACKGROUND: Unplanned emergency department (ED) and hospitalizations (hospit) disrupt care for cancer patients (pt) and may be driven by SDoH needs. To develop an intervention to address SDoH in oncology, we sought to demonstrate the systematic collection of SDoH at an academic medical center. We investigate if ED/hospit rates differ based on pt demographics and SDoH needs regardless of cancer diagnosisstage.

METHODS: We conducted a cross-sectional analysis of the SDoH among new patient oncology consults from 5/30/2015 – 4/30/2020 at Dana-Farber Cancer Institute (DFCI), Boston, MA. Patients were invited to complete a New Pt Intake Questionnaire (NPIQ) eliciting SDoH including: living alone, financial distress (“How difficult is it for you to meet monthly payments on your bills”), health literacy (“How confident are you filling out medical forms”) and health numeracy (“How confident are you in understanding medical statistics”). Sociodemographics were self-reported: race/ethnicity (White, Black, Latinx, American Indian or Alaska Native (AIAN), Native Hawaiian or Pacific Islander (NHPI)), limited English-proficiency (LEP), and age (<40, 40-69, ≥70 years). Multi-ethnic was not included as a race/ethnicity option. The electronic health record was queried to identify all ED visits and hospit occurring within 30 days of the initial oncology visit. The association between SDoH and ED/hospit subsequent to the oncology visit were determined with χ² tests.

RESULTS: Of the 145,233 new consults evaluated between 5/30/2015 – 4/30/2020, 14.1% identified as Black, AIAN or NHPI; 0.7% Latinx; 5.5% LEP; and 25.8% older adults (age ≥70 years). Of these, 38,372 (42.8%) were evaluated in an MGB ED or hospital and 7,089 (0.7%) identified at least one SDoH need. ED significantly differed by race (37.2% Black vs. 10.7% white), ethnicity (59.1% vs. 17.1 % non-Latinx), LEP (33.9% vs. 17.3% non-LEP), and older adults (18.8% vs. 16.7% age 40-69 vs. 18.4 age <40). Except for health literacy, SDoH were also significantly associated with ED regardless of demographics. Except for living alone, similar findings were found for hospit.

CONCLUSION: Identifying SDoH in oncology is imperative for interventions that reduce disruptions to care and improve outcomes, particularly for pt subsets. Approximately 22.0% of pts responded to at least one SDoH question on the NPIQ. We are leading a study that will utilize a targeted, systematic SDoH needs screening tool for all pts allowing for a targeted intervention to document and intervene on SDoH needs in oncology.

Electronic Health Record-Based Risk Stratification for Recurrence of Kidney Stones: A Feasibility Implementation

Allison B. McCoy, PhD, Ryan S. Hsi, MD
Vanderbilt University Medical Center, Nashville, TN

Introduction

Symptomatic kidney stone events occur in 1 in 11 Americans, and repeated events occur in up to 50% of individuals within ten years. These recurrence episodes contribute to adverse health outcomes, detriments in health-related quality of life, and increased costs of care. Since the risk of future stone events varies for each individual, it is necessary to accurately risk stratify patients to tailor the intensity of preventative treatment to reduce stone recurrence. The current paradigm of kidney stone care relies on provider-level experience for risk stratification. Clinician-predicted stone recurrence risk varies widely among providers, and these estimates significantly differ from risk predicted by a validated nomogram (Recurrence of Kidney Stone [ROKS]). Meanwhile, adoption of nomograms in clinical practice has not occurred due to lack of knowledge on their use and high burdens of work to use nomograms that are implemented in external applications, despite clinician willingness to use such tools. We present a feasibility implementation of the ROKS nomogram into the electronic health record (EHR), which we term EHR-ROKS, to improve provider risk stratification and delivery of appropriate preventive treatment for patients experiencing kidney stone events.

System Description

In our feasibility implementation of EHR-ROKS into our Epic EHR, the nomogram is accessed from within the progress note using a text shortcut (i.e., SmartPhrase) that inserts a hyperlink into the note, as well as the predicted risk of kidney stone recurrence at 5 and 10 years, once calculated. Clicking the hyperlink will open the ROKS questionnaire in a flowsheet activity that allows clinicians to answer questions about the patient and prior stone episode and automatically calculate and update the predicted kidney stone risk in the note.

The ROKS nomogram sums total points based on 10 questions (or 14 if imaging was performed at the last stone event), then calculates risk as $1 - \alpha e^{-\alpha_5(1.84099 + \text{points} \times 0.019)}$ with defined values for $\alpha$ by stone episode and number of years since the last stone episode. The questions include age, BMI, sex, family history of kidney stones, presence of an incidental prior stone, suspected prior kidney stone, pregnant during last stone event, stone composition, number and size of prior stones, and stone location.

Within Epic, calculations for EHR-ROKS are performed using a combination of 18 logic rules that return numeric values. Two rules impute age and BMI, and one rule determines whether the patient is pregnant. Another rule determines the total number of points based on the three prior rules and the manually entered flowsheet values. To determine the $\alpha$, five rules return the $\alpha$ for 5-year risk, and five rules return the $\alpha$ for 10-year risk based on the manually entered episode number and number of years since the last stone episode. Two rules calculate the 5- and 10-year risk, respectively.

Conclusion

Our feasibility implementation indicates that the ROKS nomogram can be integrated into our commercial EHR into existing workflows, improving the likelihood of adoption in future work to improve provider risk stratification and delivery of appropriate preventive treatment and ultimately reduce kidney stone recurrence. Similar nomograms could be implemented using this approach in other clinical scenarios.

Approaches to Clinical Decision Support Alert Evaluation and Optimization

Allison B. McCoy, PhD, Adam Wright, PhD
Vanderbilt University Medical Center, Nashville, TN

Introduction
Despite extensive research into implementing and evaluating clinical decision support (CDS) alerts within electronic health records (EHRs), many continue to deliver alerts that are sub-optimal; most alerts are irrelevant and repetitive, creating additional work for clinicians and leading to considerable EHR-related information burden. This burden contributes to clinician burnout, which occurs as a reaction to long-term occupational stress exposure, and can adversely affect patient safety and care quality. Optimization of CDS and other EHR capabilities can reduce EHR-related burden, but current processes for developing, maintaining, and delivering such complex CDS alerts can be labor- and cost-intensive. We sought to review existing approaches for identifying opportunities to optimize alerts.

Methods
Through review of the literature and author experience, we identified previously applied approaches to evaluating and optimizing CDS alerts. For each approach, we determined the optimization opportunities that could be identified, the technical or build effort required to implement the approach, and the personnel effort required.

Results
One of the most frequently described approaches to automatically identify sub-optimal alerts in prior literature has involved individual or committees reviewing EHR utilization logs or dashboards, as these are very effective at identifying individual alerts with high override rates, as well as alert trends across departments or provider type. However, efforts required to develop reports or dashboards can be high, and personnel effort required to review the findings are substantial. Commercial dashboard products and analytics tools directly in the EHR can alleviate some of the technical burden, but personnel effort remains high. An initiative to optimize CDS alerts through detailed review called “Clickbusters” encouraged participants who were physicians, pharmacists, nurses, or informaticists with training or interest in CDS implementation to follow ten steps to improve CDS alerts. Additional efforts have focused on identifying opportunities for improvement by obtaining feedback from clinicians receiving the alerts, including sentiment analysis of comments entered by clinicians when overriding alerts and feedback links within displayed alerts allow clinicians to easily convey positive, neutral, or negative feedback to CDS team members about well- or poorly-performing alerts. Like EHR utilization log and dashboard review approaches, these approaches successfully identify individual alerts with optimization opportunities, but they can also identify alerts with potentially sub-optimal design, or those that are no longer functioning as designed. These approaches also have a slightly lower barrier with build and personnel effort, as they utilize a crowdsourcing approach to gaining the information and only require personnel to monitor feedback given. However, these approaches are limited in that the only evaluate alerts that clinicians see and to which they respond. Anomaly detection to identify alerts that are no longer performing as intended can successfully identify all alerts that are no longer functioning as designed, but with less personnel effort due to the machine learning approach; however, it does not identify specific opportunities for improving alerts that were sub-optimally designed at their onset. A recent tool released by Epic (“BPA TuneUp”) evaluates single characteristics (e.g., visit diagnosis, provider type) for each implemented alert and determines the number of actions that could be taken and lost by excluding that characteristic. This approach has the potential to identify all alerts with sub-optimal design with low technical and personnel effort; however, this tool remains limited in the types of features evaluated, it cannot account for multiple features or scenarios, and it is proprietary and not generalizable to other EHRs or EHR components.

Discussion
Diverse approaches for evaluating and optimizing CDS alerts exist, each with distinct advantages and disadvantages as to the types of improvement opportunities that can be identified and the requirements for adopting each approach. However, these approaches most often require significant personnel effort, and they fail to comprehensively capture potential scenarios for improvement across all alerts and all CDS implementations. Future research is needed to develop effective, efficient, generalizable methods that can better identify opportunities to optimize CDS alerts and implement these improvements to reduce EHR-related information burden and clinician burnout.
Rolling up the Sleeve: Equitable, Efficient, and Safe COVID-19 Mass-Immunization for Academic Medical Center Employees

Samuel McDonald, MD, MS1, Mujeeb A Basit, MD, MMSc1, Seth Toomay, MD1, Christopher McLarty, D.N.P., APRN, ACNP-BC1, Susan Hernandez, D.N.P., MBA, RN1, Chris Rubio, MBA1, Bruce J. Brown, Dr.P.H.1, Mark Rauschuber, MHA1, Ki Lai, MS1, Sameh N Saleh1, DuWayne L Willett, MD, MS1, Christoph U. Lehmann, MD1, Richard J Medford, MD, FRCP(C)1

1University of Texas Southwestern Medical Center, Dallas, Texas, USA

Introduction: Since the emergence of the SARS-CoV-2 virus and the ensuing global pandemic, governments of affected countries have focused on decelerating the spread of COVID-19 infection until the deployment of effective vaccines or treatments with shifting attention of US governments and hospitals to vaccine distribution, delivery, and acceptance. It is our hypothesis that a Prioritization/Invitation/Scheduling framework would 1) provide an efficient, infrastructure to optimize speed and efficiency of vaccine delivery while minimizing risk of infection during the immunization process and 2) provide insight into vaccine acceptance among health care workers.

Methods: This was an observational study with data collection occurring during the early phases of COVID-19 vaccination availability. We implemented a Prioritization/Invitation/Scheduling system that allocated vaccines based on exposure risk and stepwise invited employees to schedule the vaccine administration through the health system’s patient portal. Employees were categorized into six groups: providers, nurses, ancillary healthcare workers, facility & food services, research staff, and support staff. We measured the period from invitation to scheduling the vaccination appointment through the patient portal as a proxy measure for the level of interest in receiving the COVID-19 vaccination and stratified data by phase and job category. To assess operational efficiency, we evaluated the time from throughput and the number of vaccinations completed per hour over the first week of vaccinations.

Results: We allocated vaccines to 13,753 employees. Ultimately, 10,662 employees had or added portal access and received a vaccination invitation. During the allocation phase, we categorized 2,473 employees (18%) into the highest priority (Phase 1a.1). The majority were providers and nurses, but ancillary clinicians and administrative staff (e.g. unit clerks) were also included. While the Phase 1a.2 cohort had a similar distribution, the Phase 1a.3 cohort had 649 facility and food workers and 996 administrative staff. Out of those employees receiving an invitation, 6,483 (61%) scheduled an appointment and 6,251 (59%) employees were immunized in the first seven days of availability. Employees varied significantly by type. About 66% of invited providers were vaccinated in the first seven days, whereas only 41% of facility/food service employees received the first dose of the vaccine (p<0.001). Clinical research staff and providers had the highest uptake (68% vs. 66%, p = 0.97). Providers were the fastest group in scheduling their vaccines (92 minutes) with the longest to schedule were facility/food service employees (588 minutes). 6,251 vaccines were administered during the study period with average of 60 vaccinations per hour. Throughput was found to have average time of 5.6 minutes (IQR 3.9 – 8.3) with slightly longer wait times the first (6.8 minutes). No difference was found in wait times across any group.

Discussion: The historically short interval from vaccine development to authorization, the politicization of the pandemic and pandemic measures, the paucity of accurate data throughout the pandemic as well as historic distrust of the medical establishment in minority communities are reflected in preliminary surveys that suggest many Americans are reluctant to “roll up their sleeves” to be vaccinated. Despite this, we found an interest among healthcare workers to receive the vaccination at the earliest possible opportunity. Even though invitations were delayed, some employees realized that scheduling was available to them in the mobile patient portal and word spread quickly to others. We noticed a stark difference in the willingness to be vaccinated by the different employee groups. It is possible employees in the later phases may have received a vaccine invitation from the affiliated organizations. The dwell time for employees at the vaccination site was very short and improved to under 5 minutes (excluding observation) as the week progressed. This minimized the risk for infection during the vaccination.

Conclusion: We offer early data on vaccine prioritization, administration, and uptake in our institution with the intent of offering insight and a potential model for other health systems to adopt for not only employee vaccination but also one that is scalable to vaccinate the general populous in an efficient and safe manner. We hope that our findings are not a unique response within our health system and are instead a marker for not only other health systems but also the rest of the country.
Design and Feasibility of ACTIVATE, a Digital Health Platform for Community Health Centers in Response to COVID-19

Scott P. McGrath, PhD1; Cynthia G. Matsumoto, PhD, RN2; David Lindeman·PhD1;
Katherine K. Kim, PhD, MPH, MBA, FAMIA3,4

1University of California Berkeley, CITRIS and the Banatao Institute, Berkeley, CA, USA; 2 University of California Davis Health, Sacramento, CA, USA; 3University of California Davis, Betty Irene Moore School of Nursing, Sacramento, CA, USA; 4University of California Davis, School of Medicine, Department of Public Health Sciences/Division of Health Informatics, Sacramento, CA, USA

Introduction
Rural, low-income agricultural workers in California, many of whom are undocumented, are especially vulnerable to ill health, including COVID-19. Rural populations suffer significant health disparities arising from a variety of circumstances, notably including multiple adverse social determinants of health and inadequate access to high-quality healthcare. The recent COVID-19 pandemic has exacerbated health inequities and digital disparities in areas such as California’s rural and agricultural region called the Central Valley. ACTIVATE: Accountability, Coordination, and Telehealth in the Valley to Achieve Transformation and Equity was conceptualized and designed to bridge these specific disparities and to accomplish two key aims: co-design a digital health solution for community health centers and assess the feasibility of implementation in one center in the Central Valley.

Methods
Two stages will be focused on in this poster: a co-design stage and a feasibility pilot stage. Feasibility was determined if at least 50% of participants fulfilled an established data upload frequency within three weeks.

Results
Co-design: The co-designers informed delivery of educational material, remote patient monitoring equipment set up, and a technology assessment tool. They also tested technology. Co-designers also helped refine a technology readiness assessment tool sharing their concerns and practical considerations that might affect patient readiness.

Feasibility pilot: 12 patients recruited for the pilot (out of 15 contacted). The ages range from 38-64. 11 are female and 9 are monolingual Spanish speakers with the remaining 3 being English speakers. 3 participants have diabetes, 3 have hypertension, and 6 have both. For Internet connectivity, 11 patients have smartphones, 3 of the 11 with phones did not have a data plan and only 5 of 12 have broadband access at home. In 12 weeks of the feasibility pilot period, 1,046 unique vital measures were transmitted including 691 blood glucose values and 355 blood pressure values. 3 of 9 the patients with diabetes transmitted 18 measures in their first week and 3 of 9 patients with hypertension transmitted 14 measures in the first week. By the third week, 4 of 9 of the diabetes patients had submitted 18 entries and 5 of 9 of the hypertension patients had 14 entries. Thus, the feasibility pilot cleared the threshold of 50% of enrolled participants by week 3.

Discussion and Conclusion
Recruitment into the program in for the feasibility pilot was very high. The large number of measures transmitted and high level of patient engagement with health coaches bodes well for future expansion. A key goal of ACTIVATE is to demonstrate the program is scalable and repeatable in other underserved communities. COVID-19 only heightened existing socioeconomic inequalities and the digital divide in underserved populations. Individuals who already had difficulty visiting healthcare providers in person, were faced with additional hurdles when clinics and physicians shifted to telemedicine and remote care. The safety and convenience of telemedicine only benefited those who had the technology and connectivity to participate. ACTIVATE targets these very inequalities with direct patient engagement, hardware and Internet access solutions, and increased health literacy to improve outcomes all through a digital health based solution. Experience in the pilot indicates that delivering on ACTIVATE’s key goals are feasible. ACTIVATE is currently being expanding in the Central Valley and plans include development of tools for dissemination of the model elsewhere.
Natural Language Processing and COVID-19 Predictive Analytics to Enable and Optimize SARS-CoV-2 Pooled Testing

Stephane Meystre, MD, PhD, Paul M. Heider, PhD, Jihad Obeid, MD, Alexander Alekseyenko, PhD, James Madory, DO

Medical University of South Carolina, Charleston, SC

Introduction: As part of the COVID-19 pandemic response at the Medical University of South Carolina (MUSC), a telehealth system was implemented as the preferred option for patients interested in COVID-19 diagnostic testing. Patients would start a virtual visit, indicate their symptoms, COVID-19 exposure and travel history, and brief medical history. After completion of this virtual visit, the telehealth system exports a summary text note generated from the information entered by the patient. To enable multiple efforts supporting the care and management of patients diagnosed with COVID-19, structured and coded data was required and a new dedicated natural language processing (NLP) application (COVID NLP tool) was therefore developed, evaluated and deployed in March-April 2020. This COVID NLP tool was subsequently improved (as described below) and processes text notes stored in a new datamart focused on COVID-19 (COVID-19 datamart). Early success with using information from the telehealth system to predict positive SARS-CoV-2 results encouraged further efforts to enhance the accuracy of these predictions and enable applications supporting patient care such as a novel data-driven COVID-19 symptom checker giving patients testing advice according to their predicted test result. Further experiments with NLP and predictive analytics for SARS-CoV-2 test results prediction with various behaviors and optimization experiments followed along with applications to improve the capacity and efficiency of SARS-CoV-2 diagnostic testing by enabling pooled testing in conditions typically preventing it, as described below.

Methods: The COVID-NLP tool combines components we had developed in past efforts and could reuse with components from other local current research (rule-based or deep learning-based, not retrained) and a few new custom components (i.e., for data import/export, section detection, and key demographics). The deep learning components are based on Bi-LSTM sequence labeling models using word tokens as input and had been trained on publicly-available annotated corpora. Vector representations of words were constructed using fastText embeddings pre-trained with clinical texts (MIMIC-III). To evaluate the COVID NLP tool accuracy, a small set of 15 text notes was randomly selected and manually annotated by domain experts (two independently and a third adjudicating differences).

For the development, optimization and evaluation of predictive analytics, we included all patients using the telehealth system for virtual care visits at MUSC in April-June 2020 who had a SARS-CoV-2 diagnostic test within 14 days after the virtual visit (14,055 patients, 1,101 testing positive and 12,954 negative). Information extracted by the COVID-NLP tool was then used for predicting the SARS-CoV-2 test result. To select algorithms for prediction, shallow and deep learning algorithms were compared. The initial features used for prediction included age, a selection of 23 symptoms and deep learning components are based on Bi-LSTM sequence labeling models using word tokens as input and had been trained on publicly-available annotated corpora. Vector representations of words were constructed using fastText embeddings pre-trained with clinical texts (MIMIC-III).

Results: The COVID-NLP tool accuracy results are presented in Table 1. For predictive analytics, we focused on SVM and logistic regression models in the later stages of this work. The best logistic regression evaluated with our telehealth data had a recall of 0.9514, specificity of 0.1244, and negative predictive value (NPV) of 0.9286.

Transparency with Safeguards: Suppressing Notes from a Patient Portal

Chelsea L. Michael, MS\textsuperscript{1}, Gilad J. Kuperman, MD, PhD\textsuperscript{1}
\textsuperscript{1}Memorial Sloan Kettering Cancer Center, New York, NY

Introduction

The Information Blocking Rule (IBR) of the Cures Act has increased attention to how healthcare organizations provide electronic health information to patients\textsuperscript{1}. The IBR coincided with our phased project to add clinic notes to the patient portal (portal) at Memorial Sloan Kettering Cancer Center (MSK). For our project, the experts at OpenNotes urged us to create a feature so providers could prevent a specific note from appearing in the portal (if it would appear by default). While it was a best practice, OpenNotes had limited information about other organizations’ features and usage. They recognized a gap in the literature. Therefore, we aimed to implement and evaluate a feature to allow a clinician, when warranted, to prevent a note from appearing in the portal, within our project to post notes to the portal by default.

Methods

MSK is a dedicated cancer center. Our electronic health record (EHR) is Allscripts Sunrise and our portal is custom. To create the capability to prevent notes from appearing in the portal, we gathered version 1 (v1) requirements with input from the project team, Health Information Management, the MSK clinical documentation team and the EHR optimization committee. We created and piloted the v1 feature in 3 services for 5 months, starting in late 2020. We trained users through an email at go-live and posted additional resources to our intranet. We evaluated the feature through a discussion with Ethics, Compliance/Legal and users; user feedback; and overall use. Finally, we created requirements for version 2 (v2) in early 2021.

Results

Our v1 requirements were: (1) allow the clinician to suppress a specific note from appearing in the portal, based on risk of harm to the patient (the feature would not impact release under HIPAA); and (2) the final note in the legal record would not indicate the note was suppressed from the portal. Our EHR did not have a built-in feature to enable suppression but we were able to implement a check box the clinician could use at the time of note creation that would suppress the note from appearing in the portal. The check box would not appear on the note output. We implemented the check box with a brief description and guidance to clinicians to only use based on risk of harm to the patient.

The pilot and evaluation led to 5 changes for v2. (1) Users wanted to know if a patient had a prior suppressed note. Therefore, we will create a way for users to check for prior suppressed notes in “writing” mode or in a separate ad hoc search application. (2) Ethics and users felt patients should be involved in the decision to suppress a note, and 3 pilot patients asked for notes to be suppressed. We will update the field explanation and training to direct users to follow patient wishes. (3) Low feature use (19 notes out of 6600+ patients with 1+ note) as expected, however half was accidental use (the provider didn’t recall using feature for 9 notes). We will create advisory text that will appear in the “writing” user interface when the checkbox is selected. (4) One service chief made a policy to consider additional referrals (e.g., Social Work, Psych) to meet patient needs when suppressing a note due to risk of harm. We will include this in the advisory text and training documents. (5) Finally, due to field properties, once suppressed, a note cannot be unsuppressed (the note cannot later be sent to portal). We noted the technical limitation in v1 training, but one user tried to reverse a suppression. We will now note the limitation in the advisory text, as well. (A note that flows to the portal can be removed through a later suppression, though.)

Conclusion

While adding clinic notes to our portal, we implemented a way to prevent a specific note from flowing to the portal based on clinician judgment of a risk of harm or patient wishes. Because our EHR did not include a feature, we used its capabilities to create one. While the IBR does not require proactively providing notes to patients, our use cases and user guidance align with IBR exceptions: risk of harm and privacy (patient’s request sub-exception)\textsuperscript{1}. At submission, we are implementing v2 and expanding to the rest of the organization.

Patient-Reported Visit Modality Preferences During a Pandemic

Introduction

Telemedicine visits may offer patients convenient access to care and minimize exposure to infectious diseases. It may be unsurprising then that the COVID-19 pandemic prompted a shift toward telemedicine. However, it is unclear whether increased telemedicine use will continue post-pandemic or how experience with a telemedicine visit will impact patient visit modality preference. We surveyed patients about their visit modality choice before, and during the ongoing COVID-19 pandemic and the care settings they anticipate wanting once the pandemic ends.

Methods

This cross-sectional patient survey study was conducted within Kaiser Permanente of Northern California (KPNC). During the pandemic-related study period, patients wishing to self-schedule a visit with their primary care provider using the patient portal website or mobile app were able to choose a video or telephone visit (in-person visits required provider recommendation). We surveyed 1000 adult patients (among 1855 invited participants) who had self-scheduled a telephone or video visit in the previous month between April, 2020 and February, 2021. Respondents were 49% non-white, 40% male, 20% age 18-40, 38% age 40-60 and 42% over age 60. The survey included both structured and free-text responses. We asked patients to report their first choice visit modality before, during and (hypothetically) after the COVID-19 pandemic for a health concern that could potentially be helped by all three of the visit types and to explain their visit choice at each time point. Free-text responses were qualitatively analyzed using thematic analysis to supplement findings from structured data.

Results

Participants were more likely to report a preference for telemedicine visits during the COVID-19 pandemic than before (from 13% to 46% for video; from 18% to 31% for telephone). Expected preference for video visits after the COVID-19 pandemic was also higher than before (from 13% to 23%). About 90% of respondents provided free text responses to explain their visit modality preferences. Analysis of free text responses indicate that 63% of participants either expect to prefer, or to be open to including telemedicine visits as a care-seeking option, depending on the specific health concern and their own perceived visit barriers (Table 1).

<tr>
<td>Preference changed from in-person to Telemedicine</td>
<td>“Prior to COVID-19, I wasn’t unaware of the Video visit. Now that I’ve used it, I don’t want to go back to in-person visits unless it is necessary.”</td>
</tr>
<tr>
<td>Consistently prefers Telemedicine</td>
<td>“If I can get care with a video or telephone visit, then I do not have to get a babysitter or take young kids in the car with me to a medical facility.”</td>
</tr>
</tbody>
</table>

Discussion

Post COVID-19, more survey participants expect to prefer telemedicine visits than before, and the majority will incorporate the use of telemedicine for some health care concerns, suggesting pandemic-related exposure may lead to continued use post-pandemic. Although the survey was limited to patients scheduling a telemedicine visit during the pandemic period, our study includes participants who did not initially prefer telemedicine. Offering visits by telephone, video or in-person may support patients’ ability to choose the visit types most appropriate for their health concern.
Automated Clinical Shift Schedule Generation for Emergent Care Settings

Azadeh Mobasher, PhD, Naqi Khan, MD, MS, David Elop, BASc, Zach Griffin, MBA, MHA, Naveen Valluri, MS

1Microsoft, Redmond, WA, USA, 2Providence Health & Services, Renton, WA, USA

Introduction

Clinical departments traditionally use a series of organization-specific manual processes to determine their staffing needs. These processes can equate to weeks of manual effort, while yielding sub-optimal, costly staffing plans. We propose leveraging advances in operations research, throughput simulation, and scenario prediction methodologies to augment staffing decision-making processes.

Methods

Successful, flexible shift planning for clinical staff with varying experience levels must consider organizational staffing policies, such as shift lengths, inter-shift rest durations, total weekly working hours, among many other constraints. We propose a mixed-integer program and a constraint programming based column generation algorithm to achieve a flexible shift schedule, while accounting for business logic and practical requirements such as taking downtime, working unrealistic shift lengths, and activating staff on breaks, which are unaddressed in previous work. Figure 1 illustrates the general flow of the proposed algorithm.

![Figure 1. High level flow of constraint programming-based column generation algorithm](image)

Results

We contrasted our proposed optimal scheduling costs with manually derived scheduling costs for real-world data from three emergency departments.

Linking U.S. Administrative Claims Data and Electronic Health Records to Describe Association Between Ambulatory Care Appointment No-Show and Healthcare Resource Use and Cost

Iman Mohammadi, PhD\(^1\), Zulkarnain Pulungan, PhD\(^1\), Nathan Markward, PhD\(^1\)

\(^1\)Avalere Health, An Inovalon Company, Washington, DC

**Introduction.** Appointment no-show is a key driver of inefficiency and waste in healthcare, contributing to incomplete and/or fragmented care delivery, reduced access to preventive services, and, consequently, sub-optimal clinical outcomes\(^1\). The objective of this study is to describe the relationship between appointment no-show and critical healthcare resource utilization (HRU) and cost among patients with Bipolar Disorder I (BPD). Data. The study utilized Inovalon’s MORE\(^2\) Registry, a large multi-payor, commercial claims repository, and a nationally representative electronic health records (EHR) database. **Methods.** Enrollment and claims data were used to identify patients who were \(\geq\) 18 years of age and newly diagnosed with BPD (ICD-10 diagnosis codes: F31.xx) during 2016. Each patient’s initial BPD diagnosis date was defined as his or her index date. Patients with diagnosis of BPD 12 months prior to the index date were excluded. In turn, patients were required to have 1) one inpatient or two outpatient diagnoses of BPD; 2) \(\geq\) 12 months of continuous enrollment pre-index; 3) \(\geq\) 24 months continuous enrollment post-index; and 4) \(\geq\) 1 EHR encounter during the follow-up period. Final study sample included 3,811 BPD patients. Using EHR appointment data, appointments were grouped into ‘Show’ vs. ‘No-Show’ based on appointment status, and Cancelled appointments were removed. For each patient, the total number of appointments, number of no-shows, and no-show ratios, defined as number of no-shows divided by total number of appointments, were tracked during the follow-up period. The number of all cause inpatient admissions, emergency room visits, and total healthcare costs were measured during the 2-year follow-up period. Chi-squared and t-tests (\(\alpha=0.05\)) were used to assess whether the ‘Show’ and ‘No-Show’ groups differed significantly with respect to HRU and costs. **Results.** Table 1 shows the summary statistics. 1,770 (46.4%) patients had at least one ‘No-Show’ appointment (no-show group) in the follow up period, and 2,041 (53.6%) did not have a no-show (show group, i.e. all appointments were ‘Show’). The no-show group was slightly younger (42.2 vs. 43.5 years) compared to the show group (\(p=0.01\)). About one third of no-show patients were male. Compared to those who did not have any no-shows, no-show patients were 2.2 times more likely to utilize emergency room, and 1.6 times more likely to be hospitalized during the 2-year post-index period. Moreover, the two-year total cost of care was, on average, $10,057 higher among no-show patients compared to their show counterparts. Within the no-show group, we also explored the association between no-show ratio and ER and inpatient utilization. Patients with at least one inpatient admission had 42% rate of no-show to their appointments, compared to those without any inpatient admission who no-showed at rate of 37% (\(p=0.04\)). Similarly, no-show ratio of ER utilizers was 41% and higher than 38% for ER non-utilizers (\(p=0.15\)). **Conclusion.** In this study, we illustrated that missing a scheduled appointment is associated with increased HRU and higher costs in a cohort of BPD patients. The findings highlight the importance of ambulatory care visits, and policies designed to improve appointment adherence, especially in mental health populations. Future work will be multivariate analyses of association between appointment no-show and HRU and cost, adjusting for patient demographics, comorbidities, and social determinants of health.

Development of a Clinical Question-Answering Corpus with Realistic Multi-Answer Challenges

Sungrim Moon, PhD\(^1\), Huan He, PhD\(^1\), Jungwei W. Fan, PhD\(^1,2\)
\(^1\)Department of Artificial Intelligence and Informatics
\(^2\)Kern Center for the Science of Health Care Delivery, Mayo Clinic, Rochester, Minnesota

Abstract: We generated a clinical question-answering (QA) corpus that involves realistic, multi-answer cases by converting the concept-relation annotations from the i2b2 Adverse Drug Event extraction challenge dataset. A total of 91,440 QA entries were derived, representing a diverse array of 1-to-0, 1-to-1, N-to-1, and 1-to-N relations between the question and answer(s).

Introduction: Clinician’s thought processes and decision-making often involve a cascade of questions and answers. Achieving human-like question-answering (QA) capability is highly regarded in artificial intelligence (AI). Medical QA research has therefore gained vital momentum over the past decade. A new generation of AI scientists is updating the “state-of-the-art” at a daunting pace almost every few months, if not weeks. One of the sought-after applications is to find the answer within a given document (a.k.a. reading comprehension), which enables patient-specific QA based on the information mentioned in the clinical text. As an essential component in AI engineering, QA training data determines the likelihood of success not only in terms of annotation quality but the fidelity of representing the target scenario. Along with other issues observed in existing medical QA corpora, the mainstream annotation approach knowingly simplifies the task into a one-answer-one-document scheme. The simplification has practically made development and evaluation easier for promoting the initial growth of the field. However, it is unrealistic in the sense that medical QA can naturally have multiple qualified answers within one document – sometimes all need to be captured to sufficiently answer a question. To address this gap, we created a clinical QA corpus that involves realistic multi-answer cases by converting the concept-relation annotations from an existing AI challenge dataset.

Methods: The 2018 i2b2 Adverse Drug Event (ADE) challenge\(^2\) was originally organized for extracting ADEs and various drug-related entities in clinical text. The dataset contains a gold standard annotation of 83,869 concepts and 59,810 relations in 505 discharge summaries. Given our primary interest in why-QA, we focus on generating QA pairs from the subset of annotated Reason-Drug relations. Each Reason-Drug relation has two arguments: one Reason concept and one Drug concept. Accordingly, we can generate a question from a Drug, e.g., “Why morphine was prescribed to the patient?” and its Reason “pain” can then be made the answer. Since there exist many-to-many relations across the Reason and Drug concepts in the dataset, we can derive the corresponding N-to-1 or 1-to-N QA entries as a logical result. In addition, by leveraging the fact that some Drug concepts do not have any Reason in the text, these no-reason instances allow us to generate unanswerable questions – a critical subset in QA challenges for evaluating AI system specificity. As another value-adding feature, we inject paraphrastic questions for enhancing the generalizability of the potentially trained systems.\(^3\)

Results & Discussion: The table below summarizes the QA categories and examples in our generated corpus. We obtained a total of 91,440 QA entries, of which half (51%) are unanswerable. The answerable ones include a substantial percentage of 1-to-1 (24%), N-to-1 (15%) and 1-to-N (10%) QAs, and each has more than 9,000 entries. The results are formatted into the widely adopted Stanford Question Answering Dataset (SQuAD) 2.0 JSON, except that we now allow each 1-to-N QA to have a list of reasons under the answer block. As the major contribution of this work, these diverse and sizable annotations represent more realistic train/test data for developing robust clinical QA systems that will transcend the conventional, limited single-answer task definition. We are in the process of engaging our domain experts to quality-audit the corpus and will share it with the research community.

Characterizing Outpatient Portal Use among Women Receiving Obstetric and High-risk Pregnancy Care

Evan Morgan, BA, Shonda Vink, MPH, Pallavi Jonnalagadda DrPH MBBS, Priti Singh PhD, MS, Naleef Fareed, PhD, MBA
The Ohio State University, Columbus, OH

Introduction
Outpatient portal technology (OPP) allow patients to engage with their healthcare. For pregnant women, the level of engagement could have important implications for maternal and infant outcomes.1,2 There is a dearth in studies that characterize OPP use among pregnant women. Our academic medical center (AMC) implemented the OPP in 2011 system wide. The most frequently used OPP functions at our AMC are those that allow patients to access their personal health information (PHI), view and schedule appointments, and message their providers.3 Our study is one to the first to our knowledge that characterizes OPP use and identifies user profiles in order to explore how a historically understudied patient population engages with their healthcare electronically.

Methods
We built upon existing research using OPP server-side log files by executing a hierarchical clustering algorithm to group pregnant women based on their proportion of use for each OPP function.4 Of the 14,658 women with optional use of the OPP in our initial dataset, 7,664 women were considered active users of the OPP during their pregnancy if they used the OPP at least once within each trimester of pregnancy. Women who visited a Maternal Fetal Medicine (MFM) provider for a pregnancy were considered high-risk, while those who only visited an Obstetrics and Gynecology (OB/GYN) provider were considered having a normal pregnancy. Post-hoc analyses were performed using one-way ANOVA to further assess OPP use on key encounter and OPP use characteristics. For the cluster analysis, use of the following OPP functions was examined: Messaging (send/receive messages), Visits (manage appointments), My Record (access PHI), Billing (view bills, insurance information). We calculated proportions of use for each OPP function across a pregnancy and used these proportions as inputs for our cluster analysis.

Results
Four clusters were identified among all pregnancy episodes based on our clustering stopping rules and upon inspection of the cluster groups. The “Average Users” (AUs) cluster consists of those who primarily used the My Record and Visits functions. The “Prepared Engagers” (PEs) and “Schedulers” (SCs) focused their use on the Visits function, with use more common among SCs. Lastly, the “Intense Digital Engagers” (IDEs) used the Messaging and My Record functions most. The SCs cluster was not seen among normal risk pregnancies, whereas the same clusters were seen among those with a high-risk pregnancy. Post-hoc analyses revealed the IDEs cluster had the least sessions per pregnancy, while the clusters centered on use of the Visits function (i.e., SCs and PEs) had many sessions per pregnancy. This suggests that the Visits oriented clusters may be less focused in their use of the OPP functions in comparison to the other clusters. Likewise, SCs and PEs had many sessions per pregnancy. These women are also eager to engage with the OPP. Notably, clusters in the high-risk pregnancy group had more sessions per pregnancy, perhaps indicating the importance of maintaining a higher level of engagement with providers.

Conclusion
Characterizing OPP use among pregnant women demonstrates how specific patient populations might engage with their health. We were able to identify distinct cluster groups of OPP users among pregnancy groups. Future studies could explore whether such patterns of OPP use influence patient quality and clinical outcomes. For instance, OB/GYN or MFM teams may wish to know if they are retaining women who primarily use the Visits function, or if medication adherence is greater among those who primarily use the MyRecord function. Finally, this work can support studies of motivational themes of OPP use, which might help expand our understanding of OPFs as a beneficial tool in the effort to improve patient engagement.

Assessing CONCERN: Analysis of Application Log Files to Investigate the Utilization of a Clinical Decision Support Tool for Identifying Risky Patients

Amanda J. Moy, MPH, MA1, Kenrick D. Cato, RN, PhD,2,3 Christopher Knaplund, MPhil,1 Patricia Dykes, RN, PhD,2,4 Min Jeoung Kang,4 RN, PhD, Graham Lowenthal,1 Sarah Collins Rossetti, RN, PhD1,2
1Columbia University Department of Biomedical Informatics, NY, NY; 2Columbia University School of Nursing, NY, NY; 3Columbia University Irving Medical Center Department of Emergency Medicine, NY, NY; 4Brigham and Women’s Hospital, Boston, MA; 5Harvard Medical School, Boston, MA

Introduction
Communicating Narrative Concerns Entered by Registered Nurses (CONCERN) is a clinical decision support (CDS) tool that leverages data from the electronic health record (EHR) to make predictions about a patient’s risk for deterioration. The CONCERN risk score has demonstrated significantly better performance in predicting patient status when compared to other early warning systems.1 In this retrospective analysis, we were interested in examining whether application (app) log files were useful in uncovering usage patterns (e.g., link between risk and features accessed and risk and intensity of use, usage over time) among RNs and physicians (MDs) following its real-world implementation.

Methods
We extracted CONCERN’s app usage log file data from 6/2020 (i.e., go-live) to 1/2021. At the time, CONCERN was implemented in the acute care and intensive care units of a large Northeastern U.S. academic medical center; additional study details are described elsewhere.1 Log files comprised of all events (i.e., activity types) that RNs and MDs engaged in within CONCERN after launching it from the EHR patient list. We grouped log events into higher-level categories based on app features: clicking links to resources (i.e., contact us, FAQs, review the research, view the model, watch the video), predictive model driving factors (i.e., flowsheet comments, medication administration record, note content, note metadata and vitals) and viewing trend time window change (i.e., visualizations of longitudinal data). Log files displayed risk score (1=low to 10=high), score color (green=low, yellow=moderate, red=high), and time associated with each hourly update for each patient risk score. We restricted usage and trend analyses to 6,456 events for which time and risk data were complete. Session is defined as all events RNs and MDs engaged in per hourly score update.

Results
Among the 375 RNs and MDs included, the app was launched 1,325 times (38.9% were green, 47.5% yellow, 13.6% red) across 870 patients; 54 launches occurred within the same hourly risk score update. Across all events stratified by score color (Figure 1), predictive model driving factors were accessed at higher proportions (12.3-23.6%) compared to other categories, such as clicking links to resources (0.1-3.6%) or viewing trend time window change (0.7-5.1%). The association between event types (Figure 1) and score color (p<.001), and event counts per score update and score color (p<.001) were statistically significant; 81.5% of all RN and MD app sessions involved 0 to 5 events (Figure 2).

Discussion and Conclusion
The provision of CDS tools in clinical settings does not ensure uptake, and clinician resistance—such as lack of trust is a barrier.2 Evaluating usage patterns through app log files may be one approach to examining uptake of CDS tools among clinicians and may shed light on how to improve design and sustain usage. We harnessed information generated in CONCERN’s app log files to study utilization behaviors within the app and found that RNs and MDs were more likely to use features related to immediate patient care (i.e., predictive model driving factors) versus ancillary resources (i.e., clicking links to resources) and longitudinal data displays (i.e., viewing trend time window change) based on the app events captured; event types and score color and event counts per session and score color were statistically significant, but not attributable to increasing severity. Over 81% of the sessions represented involved 0-5 events. Future analyses will explore event duration, launch rate and how visual cues on model feature contribution impact usage.1

An Example of Leveraging State Claims Data to Evaluate COVID-19 Policy Changes regarding Substance Abuse Disorder/Opioid Use Disorder Programs

Charles Mueller, PhD1, Johnna Beane1 Tsan-Yao Huang, PhD1, Thomas Bias, PhD1, Jennifer Mallow, RN, FNP-BC, PhD2

1West Virginia University Office of Health Affairs & School of Nursing, Morgantown, WV, USA

Introduction
As the state agency responsible for the administration of Medicaid benefits, the West Virginia (WV) Bureau of Medical Services (BMS) provides health insurance coverage to nearly one third of the population (N=564,000)1. In response to COVID-19, the WV BMS introduced new and authorized changes to its Medicaid policies to minimize human to human contact and ensure continuity of healthcare services2. It is anticipated that these policy changes will have an impact on service utilization, Medicaid spending, and health outcomes during and after the COVID-19 pandemic. In order to determine the effectiveness of these policies, a set of prioritized policies are being evaluated to provide timely information and to inform decision-making on maintaining policy changes post-pandemic.

Methods
A comprehensive list of WV Medicaid policy changes that were implemented in response to the COVID-19 pandemic were compiled along with documenting the contextual reasons for implementing the change. Next, the development of evaluation strategies for each policy change were identified as well as the proposed source of data. Medicaid claims data were examined to identify patterns and trends to provide insight about cost, service utilization and health outcomes.

The nature of conducting an evaluation during a continuing public health emergency requires a flexible approach to answer evaluation questions due to time and response constraints from affected populations. In addition, many of these evaluation questions were designed to be answered using sequential mixed methods designs, meaning that claims information will further be integrated with the results of a subsequent qualitative analysis regarding the same question.

Results
The evaluation plan consisted of 32 questions with a Medicaid claims analysis component. Due to space and time limitations, we present one example from our findings. In order to look at the impacts of BMS authorizing the use of telehealth flexibilities to replace face-to-face counseling/therapy requirements, we created a set of codebooks that allowed us to extract the following indicators: Number of counseling/therapy visits per MAT recipient; MAT recipients as a percentage of total Medicaid population; Proportion of MAT counseling/therapy visits occurring face-to-face vs. via telehealth; and MAT services as a percentage of total services billed by types of facilities. Presented above (Figure 1) is the result we obtained for indicator related to telehealth utilization showing the monthly relative percent of MAT counseling/therapy services rendered via telehealth from January 2019 to October 2020.

Discussion
While the results are preliminary, Figure 1 shows the percentage of counseling/therapy services occurring via telehealth drastically increased after the introduction of this policy with peak utilization occurring in April 2020 at around 43%. This began to drop in May 2020 and has since ranged between 20-30% per month, suggesting that a substantial portion of the MAT population has been able to continue their counseling/therapy service requirements as a result of telehealth options. Starting on April 30th, 2020 the Governor of WV began removing the strictest COVID-19 precautions increasing the ability for face-to-face interactions3. Taken together the data suggests that even with increasing ability to meet face-to-face, some desire to use telehealth remains.

Conclusion
The ability to rapidly translate scientific data into easily comprehensible forms during a public health emergency helps create a decision feedback loop based on the best available information for policymakers. We demonstrate that informatic processes allow for systematic evaluation of health data (e.g. Medicaid claims data) in a way that is useful for policymakers. In the case of this project, we were able to provide WV BMS with direct feedback regarding how policy changes to SUD/OUD programs are impacting the target population during a public health emergency. This data demonstrates the successful use of telehealth modalities on delivering MAT counseling/therapy visits to address a critical need for a population of most importance in the state of WV. This information has policy implications as they consider ways to improve healthcare service delivery in rural areas of WV where in-person counseling services may not always be an option.

Title: Incorporating Health Equity into the Evaluation of Health Informatics Electronic Health Record Tickets: Design and Initial Findings

Authors: Anoop Muniyappa, MD, MS*; Colin Purmal, MD*; Jennifer Corbell, BSN, RNii; Susan Chim, DHA, MATiii; Kendall Gross, PharmDiv; Amy Kangwankij, BSN, RNii; Katie O’Connor, BSN, RN, OCNii; Kay Burke, MBA, BSN, RN, NE-BCii; Andrew Auerbach, MD, MPHii

Background: Health informatics interventions have the potential to both improve and worsen health equity.1,2 While frameworks have been proposed to guide assessment of the impact of health technologies on equity,3,4,5 few have demonstrated a practical and reproducible method to evaluate electronic health record (EHR) tools with regard to health equity.

Objectives: To describe feasibility and early experience with a system to evaluate ordersets, documentation tools, and decision support tools with regard to health equity.

Methods: The UCSF Health APeX Clinical Content Committee, the governance group responsible for overseeing provider-facing EHR tools, created an equity scoring rubric that included: 1) Classification of tickets as beneficial effect on health equity, neutral, or needing improvement, 2) Assessment of impact on potentially affected patient groups using a Likert scale (1: very low, 2: low, 3: intermediate, 4: high, 5: very high), and 3) Description of the benefit or suggestions for improvement. Using these criteria, we piloted our schema by reviewing 20 EHR change tickets, calculated descriptive statistics, and performed a thematic analysis.

Results: Three informaticists reviewed 20 EHR change tickets using our internal rubric. Of these, 6 were scored as beneficial, 13 neutral, and 1 needing improvement. Beneficial ticket impact scores ranged from 1 to 4 with an average score of 2.83, suggesting low to intermediate impact. The ticket flagged for improvement had an impact score of 3, suggesting intermediate impact. Descriptions of potentially beneficial tickets focused on improving care for conditions inequitably distributed across the population by race, ethnicity, and/or socioeconomic status, standardizing care for various conditions, and expediting mental health care. The ticket flagged for improvement provided helpful patient instructions but was only developed in English.

Conclusions: Establishing criteria to evaluate the impact of EHR change tickets on health equity represents a novel way to identify potential disparities in EHR enhancements, and can promote health equity through improved EHR governance. Our next steps include incorporating health equity scoring into enhancement prioritization, growing our list of examples representing how health equity is impacted by EHR changes, and evaluating interobserver variability in scoring.

Addressing Challenges and Strategies for Virtual Recruitment for Longitudinal Studies

Annie Myers, MA1, Meghan Reading Turchioe, PhD, RN1, Sabrina Mangal, PhD, RN1, Leslie Park, BS1, Lisa Grossman Liu2, Ruth Masterson Creber, PhD, RN1

1Department of Population Health Sciences, Division of Health Informatics, Weill Cornell Medicine, New York, NY; 2Department of Biomedical Informatics, Columbia University, New York, NY

Introduction
Since March 2020, the COVID-19 pandemic has presented unique challenges and interrupted traditional in-person recruitment strategies.1 For the past year many researchers have turned to remote virtual recruitment. Remote recruitment requires that participants have access to technology, while in-person recruitment does not. This poses a significant challenge for vulnerable populations who may not have access to email or a smartphone. We discuss a few recruitment tools and strategies that have helped us continue our patient recruitment when in-person recruitment was no longer possible.

Methods
We started virtual recruitment for vulnerable patients with heart failure in March 2020. For approaching eligible patients, we utilized flyers and phone scripts, and once enrolled, data collection was supported by the Research Electronic Data Capture (REDCap) platform.2 Flyers were designed by author LGL and were placed in the participating clinician’s offices (Figure 1). We found that it was more effective for clinician’s to directly give these flyers to patients compared to indirectly having them in the waiting room. After being given the flyer, patients were called by a research coordinator using specific phone scripts. The phone scripts included the name of their provider, explained the purpose of the study, and that it was all completed online through REDCap. REDCap is a secure, web-based software platform designed to support data collection and data tracking. We utilized REDCap’s ‘Alerts & Notifications’ feature which allows researchers to construct alerts and send customized notifications to patients for follow-up. These alerts can be scheduled to automatically send at specific times for longitudinal projects (i.e., after 2 weeks, 4 weeks, etc).

Results
Although some patients had difficulty with Internet connection, the majority were able to easily complete the enrollment process and online surveys online. Patients who reported monitoring their symptoms or using technology often had higher rates of completing follow-up surveys through email or text.

Conclusions
There are many challenges to virtual and remote recruitment. Virtual recruitment is undoubtedly more difficult, especially for vulnerable older populations. However, the tools used for this project’s virtual recruitment have allowed us to continue recruiting patients at a slower but steady rate during the COVID-19 pandemic. This recruitment is supported by NINR of the NIH under Award Number R00NR016275 (PI: Masterson Creber).

Developing Framework for Healthy Coping Feedback Messages Evaluation from Diabetes Mobile Apps

Ploypun Narindrarangkura, MS, MD1, Qing Ye, MS, PhD1, Suzanne A. Boren, MHA, PhD1,2, Uzma Khan, MD3, Eduardo J. Simoes, MD, MSc, MPH1,2, Min Soon Kim, PhD1,2

1Institute for Data Science and Informatics; 2Department of Health Management and Informatics; 3Department of Medicine, University of Missouri, Columbia, MO, USA

Introduction

The American Diabetes Association (ADA) has recommended that all individuals with diabetes should receive diabetes self-management education and support (DSMES) throughout the treatment process. AADE7 Self-Care Behaviors® (AADE7®) is a validated and widely accepted DSMES principle. AADE7® has seven principles: Healthy Eating, Being Active, Monitoring, Taking Medication, Problem Solving, Reducing Risks, and Healthy Coping. In this study, we focused on Healthy Coping, a key principle that enables people with diabetes to achieve self-care goals. Healthy Coping supports monitoring diabetes-related measures, physical exercise/activity, and mood of people with diabetes. Diabetes mobile applications with feedback messages can be used to promote Healthy Coping. Feedback messages should be designed based on behavioral change theories because a feedback message is to allow people to reflect on their progress and remind them of their goals. We aimed to analyze Healthy Coping-related feedback messages from diabetes mobile apps against the theoretical framework based on validated behavioral change theories.

Methods

There was a lack of a framework to evaluate feedback messages from diabetes mobile apps. We reviewed the literature to identify the most suitable model that we could use for evaluating feedback messages. A framework was developed based on several validated behavioral change theory-based models (Figure 1). The framework is composed of three domains and three dimensions. The three dimensions are timing, intention, and content of feedback messages. The content dimension has two subdimensions of feedback purpose and feedback response. For the feedback purpose, there are seven types of purpose: warning, suggestion, self-monitoring, acknowledging, reinforcement, goal setting, and behavior contract. The feedback response is divided into real-time and delayed responses. Real-time messages provide instant information when user input data, while delayed messages provide information at a later time after user input data. Then, we searched diabetes apps from iTunes and Google Play stores, and entered a range of values on three Healthy Coping domains: 1) diabetes-related measures including blood glucose, blood pressure, HbA1c, weight, 2) physical exercise/activity, and 3) mood to generate feedback messages. We analyzed the feedback messages against three dimensions of timing, intention, and content.

Results

We selected eligible 156 out of 1,749 diabetes mobile apps that generated a total of 473 feedback messages. The majority of messages were related to blood sugar (219, 46%) and followed by mood domain (128, 27%). For the timing dimension, most of the messages were user-initiated (336, 71%). Most of the messages across all domains had neutral intentions (358, 76%), simply confirming user activity and asking to continue the activity. More than 75% of messages among all Healthy Coping domains were real-time responses. Only feedback messages on blood sugar under diabetes-related measures and mood domains encompassed all seven feedback purposes under the content dimension.

Conclusion

We found that there was an unbalanced distribution of feedback messages across healthy coping domains and feedback dimensions. It is important that feedback messages be structured around the dimensions of the behavioral theory-based framework to promote behavior change. Our framework can be extended to evaluate feedback messages for other AADE7® principles and other chronic diseases because the backbone of the model used in this study is evidence-based.
Machine Learning Implementation Results in Reduced Variable Cost of Acute Care Visits During Radiotherapy: SHIELD-RT Cost Analysis

Divya Natesan MD1, Samantha M. Thomas MS2, Eric Eisenstein DBA3, Neville C. W. Eclov PhD1, Nicole H. Dalal MD4, Sarah J. Stephens MD4, Mary Malicki MSN ACNP1, Stacey Shields ANP-BC1, Alyssa Cobb, RN BSN1, Yvonne M. Mowery MD PhD1, Donna Niedzwiecki PhD2, Jessica D Tenenbaum PhD3, Manisha Palta MD3, Julian Hong MD MS4
1Duke University Medical Center, Department of Biostatistics and Bioinformatics, Durham, NC; Duke University Medical Center, Department of Radiation Oncology, Durham, NC; Duke University, Durham, NC3; University of California, San Francisco, CA4

Introduction: SHIELD-RT was one of the first prospective randomized studies (PMID: 32886536) to utilize ML in an interventional clinical application. SHIELD-RT implemented a ML algorithm to identify patients who were at high risk of acute care visits (ER visits or hospitalizations) during radiotherapy (RT). High risk patients who were randomized to receive supplemental visits during treatment had reduced rates of acute care utilization (12%) compared to standard care (22%). We hypothesized that acute care variable healthcare costs (impacted by patient volume and vary with usage) would also be reduced in those who received supplemental visits.

Methods: Patients who initiated RT from 1/7/2019-6/30/2019 at a Duke University Hospital were evaluated during the first week of treatment by a ML algorithm to identify high risk patients (>10% risk of acute care visit during RT). High risk patients were prospectively randomized to receive either standard weekly (S) or intervention of twice weekly (TW) visits during RT. Variable cost data (excluding fixed costs) associated with acute visits were obtained and compared between patients who underwent S or TW evaluations. Missing cost data were imputed using disease related groups. Variable costs are presented as mean (standard deviation) and were compared between arms with non-parametric Wilcoxon Rank Sum tests. Intervention costs were not included in this analysis.

Results: 311 high risk courses were identified and randomized to receive either S (n=157) or TW (n=154) evaluations during RT. 85 patients (S: 51; TW: 34) had 121 distinct acute care visits (S: 74; TW: 47). Patients in the TW evaluation arm had fewer hospitalizations (29 vs 41) and ER visits (18 vs 33) than those in the S arm. Actual cost data was available for 102 visits and imputed for 19 outside hospital visits. Variable costs associated with acute visits was lower in the TW arm ($156,066) compared to the S arm ($349,260). Mean cost per patient associated with acute visits was also lower in the TW arm ($1013, SD $3201) compared with the S arm ($2225, SD $6243) (p=0.02).

</tbody>
</table>

Discussion: Acute care visits during RT are a frequent and costly occurrence for high risk patients. ML-directed evaluations decreased variable costs of acute care. Variable costs were reduced across revenue centers, with the largest difference related to inpatient room costs. These are the first data to report on the variable cost implications of ML implementation in a clinical setting. Analyses incorporating physician and intervention costs are underway.
Diachronic Analysis of the Evolution of COVID-19 Scientific Literature

Denis Newman-Griffis, PhD1, Venkatesh Sivaraman2, Adam Perer, PhD2, Eric Fosler-Lussier, PhD3, Harry Hochheiser, PhD1

1University of Pittsburgh, Pittsburgh, PA; 2Carnegie Mellon University, Pittsburgh, PA; 3The Ohio State University, Columbus, OH

Introduction The COVID-19 pandemic has led to an unprecedented global research effort. New findings emerge constantly and are swiftly disseminated, and scientific understanding of the pandemic has evolved at a rapid pace. The COVID-19 Open Research Dataset (CORD-19),1 an actively-maintained collection of scientific literature related to COVID-19, indexes tens of thousands of new publications and preprints each month, far more than any human reader can consume. Computational analysis of changes in the literature is thus required to understand trends in how scientific understanding has developed during the pandemic, and identify patterns suggesting promising new research directions.

We developed TextEssence, a text analysis workflow with an interactive, web-based interface to explore diachronic shift in language use, as well as other semantic differences between text collections. TextEssence reflects key shifts in the COVID-19 literature between March-October 2020, and lays the foundation for further knowledge discovery in the evolution of COVID-19 research.

Methods Our analysis leverages concept embeddings to capture patterns in how medical concepts are discussed in CORD-19: i.e., which concepts play similar roles in scientific writing (such as treatments for COVID-19 symptoms). Our workflow, illustrated in Figure 1, had three phases. We used the JET software2 to train embeddings of SNOMED CT concepts from snapshots of CORD-19 containing all new publications indexed in each month from March to October 2020. These embeddings were filtered to the concepts with stable representations across multiple replicates. We built a web-based interface for qualitative analysis of the resulting embedding spaces, providing three functions: (1) Browsing a set of embeddings; (2) Inspecting how a particular embedding changes over time; and (3) Comparing how a pair of concept embeddings changes relative to one another over time.

Results The embeddings of key concepts related to COVID-19 changed across the months of CORD-19 data in ways that reflected the broader evolution of scientific understanding around the pandemic. Anosmia moved from being embedded with other otolaryngological concepts in early months to associations with other symptoms such as nausea and vomiting in October 2020, reflecting its earlier emergence as a key diagnostic variable. The corticosteroid Dexamethasone, used throughout the pandemic to treat severe COVID-19 symptoms, picked up Ruxolitinib as a nearest neighbor in September 2020, reflecting a spike in the literature on similar use of ruxolitinib for severe symptom relief. Hydroxychloroquine added nearest neighbors such as hospital-acquired infections and respiratory failure over time, reflecting the body of studies finding negative or harmful results of its usage for COVID-19 treatment.

Conclusion These results indicate that concept embeddings provide a useful lens for studying shifts in the COVID-19 scientific literature. Our work provides a strong foundation and reusable implementation for exploring the use of medical concept embeddings for discovery of new knowledge and relationships over time. The results of our CORD-19 analysis are available at https://doi.org/10.5281/zenodo.4432958, and the TextEssence system is available from https://github.com/drgrippis/text-essence. A screencast of the system is available at https://youtu.be/1xEEfsMwL0k.

Qualitative Coding Framework for Analyzing Alert Notes from the Telehealth Intervention Program for Seniors (TIPS)

Phuong Nguyen, MPH.¹, Hyung Wook Choi, M.S.², Melody K Schiaffino, MPH, Ph.D.¹, Zhan Zhang, Ph.D.³, Jina Huh-Yoo, MHCI, Ph.D.²

¹San Diego State University, San Diego, PA, USA, ²Drexel University, Philadelphia, PA, ³Pace University, New York, NY, USA

Introduction

Telehealth brings opportunities to reduce hospital readmission and emergency visits and improve chronic illness care for older adults. Alerts from abnormal monitoring during telehealth participation can generate alert fatigue for clinicians.¹ Although alert fatigue has been extensively discussed in the context of electronic health records, little is known about telehealth and the efficacy of alerts. Alert notes, which describe nurse’s detailed notes about an alert, contain a larger context than medical record data to delineate whether an alert was false, how the problem was resolved, and any recorded steps moving forward for the patient. However, much of the literature depends on the quantitative analysis of patient’s medical records. In this poster, we introduce a qualitative coding framework developed for the alert notes generated from the Telehealth Intervention Program for Seniors (TIPS)—a tri-state community-based telehealth program implemented in the states of New Jersey, Pennsylvania, and New York (N=17 sites, N=1,878 participants, N=24,933 alert notes, 2011-2019). The framework enables mapping the entire workflow and sequence of events leading from alert generation to nurse’s phone call attempts to patients and next steps. We developed keyword-matching information extraction techniques that represent the workflow of alerts and nurse calls with patients based on 352 manually annotated alert notes. We discuss the scalability of this method in the large-scale analysis of alert notes and use of the framework for future analyses.

Methods

A research team with gerontology, public health, telehealth, and text processing expertise generated the workflow model shown in Figure 1 to map the information documented in the alert notes regarding the nurse’s response to each alert. The workflow model presents multiple sequences of events that begin with an alert to the nurse’s call to the patient and resulting plan for the patient. We developed a coding framework based on the workflow model, and keyword matching information extraction approach building on manually annotated alert notes for scalable analysis of the alert notes. We iteratively refined the regular expression that would capture the notes that represent each code. For instance, we used keywords “equipment”, “issue_machine”, “malfunction”, “not_work_properly” to capture notes that present the code 1a: ‘technical error’. We then tested the keyword match results by randomly selecting 400 mutually inclusive alert notes (20 identified as false, 20 identified as negative) for 20 codes, resulting in analyzing 762 alert notes in total for precision and recall analysis.

Results and Conclusion

Using the keyword matching approach, we identified a total of 23,856 alert notes identified as belonging to at least one of the 20 codes (Precision: 0.89, Recall: 0.91, N=762). The high-performance results show the scalability of this approach. The resulting coded model can be cross analyzed with patients’ medical records, which can generate numerous predictive models, correlations, and appropriate triaging of false alerts. Furthermore, the TIPS program has a high proportion of racial and ethnic minority participants and those with limited English proficiency—all with known barriers to healthcare utilization. These socio-economic factors can be mapped with the codes to aid identifying facilitators and barriers to making successful monitoring that lead to increased health equity and continued retention.

Identifying Posts from Reddit Talking About ADRD Caring Experiences Using Machine Learning

Congning Ni1, ME; Jonathan A Hughes2; Andrew K Nam1; Zhijun Yin1,3, PhD

1Vanderbilt University, Nashville, TN, USA,
2Lipscomb University, Nashville, TN, USA
3Vanderbilt University Medical Center, Nashville, TN, USA

Background Alzheimer’s disease and related dementia (ADRD) impair memory, thinking processes, and mainly occur in older adults1. It is estimated that the caregivers of people living with ADRD provide more than 18.5 billion hours of unpaid care for their family members in the United States every year2. Therefore, it is essential for the society to understand and respond the challenges faced by these caregivers3. With the rapid development of internet, many ADRD caregivers began to seek support or share caring experiences on various social media platforms or online health communities. However, given the massive, noisy online data, it is necessary to classify the posts with ADRD caring-related content before further analysis.

Objective We aimed to build efficient classification models to identify online posts about ADRD-caring experiences from Reddit, a social news aggregation, web content rating, and discussion website.

Methods Firstly, our data consists of all the submissions collected through the pushshift.io Reddit API by using both 1) ADRD-related keyword searching (“alzheimer”, “alzheimers”, “demen” and “dementias”) and 2) collecting all the submissions from ADRD related subreddits (r/Alzheimer, r/Alzheimers, r/dementia, and r/AlzheimersGroup) from 2012 to 2020. Then, we combined the two datasets and drop the duplicates. Next, we randomly sampled 5,000 submissions and recruited four annotators for annotating whether each of these submissions was related to ADRD care or not. Finally, based on the annotated results, we built multiple machine learning models for binary classification. We embedded the submissions with various feature extraction strategies, including using vectorization of Linguistic Inquiry and Word Count (LIWC), Term Frequency Inverse Document Frequency (TFIDF), Word Count, and N-grams (counting sequences of characters, n ∈ {2,5}). We applied three common classification models: a Logistic Regression (LR), a Random Forest Classifier (RFC) and a K-Nearest Neighbors (KNN) classifier. Additionally, we also tested three deep learning-based models, BERT fine-tuning, LSTM (one-hot representation) and LSTM (word2vec representation), to enhance model performance. For each model, we applied 10-fold cross-validation to select the optimal hyper-parameters, and evaluated model performances based on accuracy, precision, recall, f1 and AUC score.

Results 68,868 submissions were collected in the initial dataset. Within the 5,000 annotated submissions, 1,914 (38.28%) were labeled as positive, which were related to ADRD caring. Table 1 presents the AUC score of all the traditional models we trained. Table 2 shows the AUC of deep learning models. Note that the AUC of the BERT fine-tuning model was 0.938, which out-performed all other models.

Conclusion In this project, we built classification models to identify ADRD-caring-related posts from massive Reddit online posts. We demonstrated that these classifiers could efficiently identify ADRD-caring related information, which could be used for further analysis of topics shared by caregivers of ADRD patients on social media. Our future research will focus on 1) improving model performance and applying the model with the best performance for ADRD-related posts collection; 2) using the same strategy to other online communities of ADRD caregivers (e.g., AlzConnected), to obtain the related discussion in a broader range; 3) conducting content analysis to the data we collect to understand the needs of ADRD caregivers.

Evaluating the Scope of Collaboration Among Primary Care Teams through Electronic Asynchronous Communication

Arianna E. Nimocks, Bryan D. Steitz, PhD, Adam Wright, PhD
Dept. of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN

Introduction
Electronic health record (EHR)-based asynchronous communication (Inbasket messaging) has emerged as a primary means of communication and care coordination among multidisciplinary care teams. Within the ambulatory setting, primary care providers (PCPs) are often tasked to coordinate patient care across numerous specialties and care teams. Previous work has found that highly connected care teams had lower costs\(^1\) and better outcomes\(^2\). Analyzing the scope of communication and connectivity between care team members involved in asynchronous messaging affords key insights into opportunities to improve collaboration between clinical teams. In this study, we conducted a social network analysis to evaluate communication patterns among all members of the care team who communicated with PCPs, including physicians, clinicians, nurses, and administrative staff.

Methods
We extracted secure clinical message logs from the Epic EHR corresponding to each message viewed or sent by an adult PCP at the Vanderbilt University Medical Center between January 1, 2019 and June 1, 2019. We identified PCPs as any physician, physician assistant, or nurse practitioner who was scheduled for independent patient appointments in ambulatory general internal medicine or family medicine clinics. Message log data included a thread identifier, message timestamp, action (view or send), a unique employee identifier, and employee role for each messaging instance. From these logs, we calculated undirected edges by taking pairwise combinations of all individuals involved in a thread. For single messages that were not part of a larger thread, we indicated a tie between the sender and readers. We calculated descriptive messaging statistics and evaluated PCP relationships by employee role.

Results
During our study period, there were 1258 PCPs who communicated about 225161 patients through 1227813 messages – an average of 334 patients (SD=297) and 990 messages (SD=1016) per PCP. In Table 1, we show PCP relationship statistics. PCPs shared 57.4% of threads with only the top 5% of employees involved in their messages. The majority (64.2% and 62.1%) of PCP relationships shared fewer than three patients and three message threads, respectively.

</tr>
</tbody>
</table>

Conclusion
Improving care coordination among primary care team members has important cost and care quality implications. Our social network analysis found that most messages sent or received by PCPs involve a small “core” group of employees who commonly communicate, and that the majority of communicative relationships involved fewer than three message threads. These results suggest an opportunity to co-locate individuals who are distributed across the organization but work together closely to allow for more synchronous communication. Future work will examine how these collaboration patterns affect PCP workflow, with the goal of reducing unnecessary tasks.

Transforming Data Capture for Clinical Care and Research: ePRO Adverse Event Reporting and Quality of Life in a Phase 2 Breast Cancer Study

Anna Northrop¹, Michelle Melisko, MD¹, Garry Peterson¹, Laura Sit¹, Anika Christofferson¹, Ebunoluwa Olunuga¹, Ananya Mittal¹, Adi Goldman¹, Ronak Ahir¹, Mitra Rocca, PhD², Lisa Weiss, MBA³, Elizabeth Prager⁴, Cal Collins⁴, James Palazzolo, MS⁵, Laura Esserman, MD, MBA¹, Adam Asare, PhD¹,³, Amrita Basu, PhD¹

¹University of California, San Francisco, CA, ²U.S. Food & Drug Administration, Silver Spring, MD, ³Quantum Leap Healthcare Collaborative, San Francisco, CA, ⁴OpenClinica, Waltham, MA

Introduction: Here we describe the development of a system for monitoring patient-reported adverse events (AE) and quality of life (QOL) using electronic patient reported outcomes (ePRO) instruments in the Investigation of Serial studies to Predict Your Therapeutic Response with Imaging And moLeCular analysis (I-SPY 2 TRIAL), a phase II clinical trial evaluating neoadjuvant treatments for locally advanced breast cancer. I-SPY 2 randomizes patients to 12 weeks of a drug treatment regimen, followed by four biweekly cycles of Adriamycin Cyclophosphamide (AC) and surgery.

Methods: An ePRO survey series was designed to assess QOL and AEs in I-SPY 2 participants using a maximum of 126 validated, branching logic questions from the Patient Reported Outcomes Measurement Information System (PROMIS®) Health Measures and the National Cancer Institute’s Patient Reported Outcomes – Common Terminology Criteria for Adverse Events (PRO-CTCAE™) instruments.

We developed rules-based logic to build an automated scheduler and survey delivery platform using the OpenClinica (OC) electronic data capture system. We piloted the ePRO system at the University of California, San Francisco (UCSF) to evaluate feasibility and usability. For each patient who consented to screen for participation in I-SPY 2 at UCSF, the clinical research coordinator (CRC) linked the patient’s email and subject ID in the OC Participate™ module. This information was encrypted in the study database. When the patient consented to treatment, the CRC entered key clinical dates in the OC Scheduler case report form including: (1) date of screening consent, (2) start of drug regimen, (3) start of AC cycles, and (4) date of surgery. This prompted the system to automatically schedule and send ePRO surveys to the patient at a predetermined frequency based on the I-SPY 2 treatment schedule. Automated reminders were also put in place to encourage patient participation and increase compliance.

Results: The UCSF ePRO pilot began in September of 2020. Over nine months, 45 I-SPY 2 patients were accrued (average age of 43.8 years), whose interactions with the ePRO system informed design modifications and technologic iterations. Of the patients who received a baseline ePRO survey at UCSF, the completion rate was 75.9%.

CRCs monitored data completeness using the OC Participate™ module and a custom report that was built to display the status of each participant’s survey history in real time. These tools were designed to enable CRCs and clinicians to easily identify patients who had not completed their ePRO survey prior to their visit, so they may be provided with a tablet computer with internet connectivity to complete the survey in the clinic. After introducing tablets into the workflow at UCSF, patient completion of the baseline survey increased from 75.9% to 80%. To increase the accuracy of reporting, a CRC training guide was developed, which integrated detailed workflow diagrams and technical solutions for cases that deviated from the traditional I-SPY 2 patient journey.

Discussion: The implementation of ePRO within I-SPY 2 has the potential to improve the efficiency and accuracy patient-reported data collection for clinical trial research, while integrating learning as a byproduct of care. As a result of the refinements made during the development and pilot phase of the project, the ePRO system was implemented at 21 additional I-SPY 2 sites in June of 2021. We will seek to demonstrate the extensibility and scalability of the ePRO platform at these sites. Future iterations will integrate updated workflows as well as SMS capabilities and patient educational materials to increase survey completion rates.
Consumer Perception of Smart Speaker-Based mHealth Tool
Hyunkyoung Oh, PhD, RN1, Min Sook Park, PhD1, Youngjoo Cho, PhD2
1University of Wisconsin-Milwaukee, Milwaukee, WI; 2Konkuk University, Seoul, Korea

Introduction
Approximately 60% of Americans have at least one chronic condition.1 Self-management (SM) is a promising strategy for managing chronic health conditions in daily lives through identifying challenges and solving problems associated with their own illness.2 Although mHealth apps have been developed to support SM, most mHealth apps have not been used routinely by patients. Barriers to use include complicated and inconvenient ways to input and output data, as well as unreliable health information and data interpretation.3-4 The use of smart speakers has rapidly increased due to their ease-of-use and convenient features with advanced voice assistant and increased demand for smart devices.5 However, we do not clearly know patients’ acceptance and adoption of a novel smart speaker-based mHealth tool yet. Recognizing end-user needs and potential barriers to the use of technology is the most important key to develop a successful technology-based infrastructure to deliver a clinical intervention.6 The purpose of this study was to identify challenging SM behaviors and useful features of mHealth tool on a smart speaker platform.

Overview of methodology
A survey was applied using Qualtrics. We recruited individuals who are 18 years old and older living with at least one metabolic health condition (i.e., diabetes, hypertension, obesity) in the US through a Facebook advertisement. The survey asked what are most difficult SM behaviors. In the survey, we provided a brief description of our proposed Voice-activated Self-monitoring (VoIS) application on a smart speaker platform to know users’ perception and use intention to this tool, which has three types of features: self-monitoring, clinical decision support, and shared decision-making features (detailed features are reported in Table 1). The VoIS is able to connect to other smart devices (e.g., smartphone, tablet) thus, it can be used on multiple platforms which increases users’ ease-of-use and accessibility. The survey also asked what are most useful features after providing this description. Descriptive statistics were used for demographic characteristics. Mean rank values (MRV) were calculated to identify the order of priorities. Low MRV indicates a higher priority.

Results
A total of 509 survey responses were analyzed. The mean of age is 40.17 years and 66.2% are male. The majority have Bachelor’s degree (81.1%) and employed (71.9%). More than half are non-Hispanic White (63.5%) and 11% have more than two conditions. Over 70% reported that they would use the proposed mHealth tool continuously if they had it. Table 1 shows the most challenging SM behaviors and the useful feature of the proposed mHealth tool. Table 1. Rank order of challenging behaviors and useful features.

Towards Identification of Opiate Use Disorder in Clinical Text

John D. Osborne, PhD1, Tobias O’Leary, MS1, Abdullateef I. Almudaifer, MS1, Whitney L. Covington, MPH1, Caleb M. Carroll, BS1, Ellen F. Eaton, MD1, Rachel A. Lee, MD1, Sue S. Feldman, PhD1, Lauren Walter, MD1,

1University of Alabama at Birmingham, Birmingham, Alabama, United States of America

Introduction

The majority of overdose deaths in Jefferson County Alabama occurred in persons who received care in the University of Alabama at Birmingham (UAB) health system underscoring the many missed opportunities for Opiate Use Disorder (OUD) identification and treatment. Experts recommend universal screening for OUD in hospitalized patients in order to prevent adverse outcomes such as opioid withdrawal, elopement, infections, and overdose death. OUD requires a clinical diagnosis, yet patients may not disclose their disease due to stigma and criminalization. A prior retrospective study utilizing Natural Language Processing (NLP) revealed that over one-third of NLP-identified patients lack codes for opiate abuse or dependence1. We annotate and plan to release the first such public data set (to our knowledge) that could be used to identify OUD cases and expand capabilities for personalised intervention for OUD.

Method

Annotation was done using BRAT 1.3 software and documents were pre-annotated with an initial set of opiate keywords identified by regular expression. OUD researchers WC and CC were responsible for all annotation. Notes were double annotated for 2 development annotation rounds, revising annotation guidelines each round after discussion with TO and JO. 3295 notes from 59 patients (25 controls) were annotated. Annotators identified 42 label types including DSM-5 OUD symptom entities, comorbidities, treatments, drug tests, opiates and events. Annotators modified entities for negation, uncertainty, subject as assigned a DocTimeRel value of before, overlaps or after. Annotators identified explicit event mentions of Opiate Use, Substance Use, OUD and Substance Use Disorder (SUD) using the same set of modifiers as entities but with the addition of a severity and an illegal use modifier. Annotator agreement was calculated using Cohen’s Kappa in scikit-learn. Work was done under IRB-300002304 Initiating Medication Assisted Treatment of Opioid Addiction in the Emergency Department: The ED MAT Protocol funded by the Al. Dept. of Public Health.

Results

Annotator agreement was 0.702 and 0.965 in the 1st and 2nd annotation round respectively. The final data set consists of 3295 notes with 27953 mentions grouped under 12 higher level labels for brevity and shown in Table 1.

Usability Testing of MedWISER3: A Novel, Card-Based Electronic Health Record Interface
Soheb Osmani1, Katherine L. Dauber-Decker, PhD1, Sundas Khan, MD1, Sera Levy1, BA, Jennifer Itty, MPH1, Thomas McGinn, MD, MPH2,3, Jan Horsky, PhD1, Yalini Senathirajah, PhD2
1. Center for Health Innovations and Outcomes Research, Feinstein Institutes for Medical Research and Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Manhasset, NY; 2. Physician Enterprise, CommonSpirit Health, Chicago, IL; 3. iQuEST Institute, Baylor College of Medicine, Houston, TX 4. Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA

Description of the Problem
The gap between the way clinicians and programmers think often results in healthcare software that does not meet the clinicians’ needs. Clinician information requirements can vary widely by specialty, individual patient type, context, and institution.1 Current software interfaces are developed to have fixed information locations, which can impose undue extrinsic cognitive load.2 To address this problem, we sought to develop a novel, customizable, “draggable cards” based electronic health record (EHR) called MedWISER3.3 In this context, cards are: self-contained interactive blocks of information similar to widgets, comparable in size to playing cards, and can be dragged in the MedWISER3 interface to be relocated for customization.4 We performed usability testing to examine how clinicians obtain, utilize, and process information from MedWISER3. Additionally, we obtained feedback on the new EHR to optimize its utility.

Methods
We performed “think aloud” usability testing of the MedWISER3 interface with 11 internal medicine and endocrinology providers (two attending physicians, one hospitalist, two fellows, and six residents) at a large academic healthcare system in New York. Participants were asked to work through four mock patient cases on the MedWISER3 interface as they would with a real patient, providing a diagnosis and treatment plan at the end of each case. We performed thematic analysis of session notes and recordings to develop suggestions for improving MedWISER3.

Results
We identified three recurring themes in our usability testing sessions: functionality, content and usefulness, and visibility and navigation. The participants expressed that the functionality of MedWISER3’s card-based system could be further developed to be more refined and less clunky. The cards often overwhelmed the participants because of the vast quantity of information they immediately provided. The participants noted that the content and usefulness of MedWISER3 were improved compared to existing EHRs; however, the MedWISER3 interface lacked information standardization, which would allow rapid information processing. As expected, the participants expressed that the card-based EHR improved the overall visibility of content and the speed at which users could navigate through the EHR. Most participants expressed a strong interest in seeing reformed and improved EHRs.

Discussion
Several participants remarked on the patient notes in MedWISER3, reporting that it was difficult to follow the patient’s medical history. Furthermore, participants noted that using an EHR in which multiple patients’ charts could be open at the same time could cause confusion. A rework of the note tab would be most beneficial to the overall usability of the MedWISER3 interface. Our findings highlight clinicians’ need for a modernized EHR and how a card-based interface could streamline information processing. Importantly, several participants noted that this interface decreased the total time spent in the EHR. Reducing time and number of clicks in the EHR is crucial for providers who are moving quickly from patient to patient. Our future work will involve comparing MedWISER3 to an existing EHR.

Conclusion
Our observations highlighted several important areas in which EHR usability can be optimized for clinician use. There is a clear need to modernize EHR interfaces. MedWISER3’s card-based software could help bridge the gap between the clinician’s needs and the programmer’s development due to its layout and customizability.

Methodologies of Nursing Workflow Studies: A Scoping Review
Yennuten Paarima, MPhil, RN, Po-Yin Yen, PhD, RN, FAMIA, FAAN
Goldfarb School of Nursing, Barnes-Jewish College, BJC HealthCare & Washington University in St. Louis, St. Louis, MO

Introduction
Workflow is defined as “the set of tasks grouped chronologically or arranged sequentially into processes” that describes the procedural and sequential aspects of processes and offers a methodical narration of how work is conducted. Since the adoption of electronic health records (EHR), it has led to essential nursing workflow changes which may potentially affect patient care and safety. This has necessitated a critical need to examine the approaches employed in workflow studies. As a result, we conducted a scoping review to investigate how nursing workflow studies were conducted and interpreted and identify knowledge gaps that could inform future workflow studies examining the impact of the EHR.

Methods
We conducted searches in PubMed, Embase, CINAHL, Scopus, and Cochrane Library to retrieve articles published between 2005 and 2020. We used keywords such as “electronic health records” OR “electronic medical records” OR “computerized medical record”, AND “nursing workflow OR work process”, OR “task performance”, OR “time and motion studies”. We included studies with an explicit goal of examining the impact of the EHR on nursing workflow. We excluded non-English studies, editorials, and literature reviews.

Results
We identified 2289 articles in the initial stage. After de-duplication, a total of 15 studies were included. Disagreements for exclusion were resolved through discussion. Among the 15 studies, we found that twelve used time and motion (T&M) design, two used mixed-method design, and one used qualitative design. These designs allowed the continuous observation and analysis of the movement of nurses as they perform clinical tasks with particular attention to the amount of time required to perform each task. Fourteen studies used clinician-centered approaches to identify role-specific clinical activities, and one used patient-centered which focuses on services arranged around patient needs. The T&M approach was used to measure nurses’ time spend with the EHR in comparing to their time spent on performing other clinical tasks. We found that T&M studies measured the time nurses spend on both direct and indirect care activities. Nurses spend 18%-27% of their time charting and documenting in the EHR. However, we did not find any study investigating or reporting the changes in the sequential flow of nurses’ tasks which is suggestive that the impact of EHRs on nursing workflow has been mostly focusing on time efficiency.

Discussion
Several approaches as identified in this review have been used to assess how nurses distribute patient care activities with the EHR. The clinician-oriented approach focuses on a single nurse’s work instead of collaborative work, which is essential in healthcare delivery. However, observation of role-specific clinical activities will not likely represent the patient care provided. On the other hand, the patient-oriented approach captures various roles of the healthcare team in care delivery which promotes coordination and defining more meaningful care boundaries. Though workflow is defined as a set of tasks chronologically or the processes of care, we did not find any study investigating nursing workflow relative to the sequential order of tasks. Understanding the sequential order of nurses’ tasks will allow for proper streamlining and prioritizing of nurses’ activities and minimize interruptions. Nurses are spending more time with the EHR, but currently, there is no evidence of whether the time spent with EHR would impact other patient care activities. Understanding EHR activities along with patient care activities outside of the EHR may be the key to complete the whole picture of the nursing workflow. This will also allow for the investigation of nurses’ work fragmentation, multitasking, and interruption due to the EHR.

Conclusion
Existing workflow studies focused on nurses’ time spent in the EHR and did not directly address workflow changes. Future studies should consider using mixed approaches with data triangulation to explore the extent to which EHR can help restructure nursing workflow.

2. Sanofi, Cambridge, MA and *Bridgewater, NJ, USA

INTRODUCTION
The proliferation of real-world health data (RWD) has provided opportunities to understand people’s natural health evolution and care seeking behavior. A typical form of RWD for health is electronic health records (EHR) data, which contain detailed information on a patient’s health encounters. RWD sources differ in their underlying characteristics creating distinct advantages and disadvantages depending on the health question. Differences include size, geographic coverage and availability of source data.

Given these differences, an important uncertainty is the extent to which findings from one RWD source can be transported or replicated in another RWD source. In this project we sought to examine this question within the context of developing a predictive model for hospital admission for individuals with Type II diabetes.

METHODOLOGICAL APPROACH
Data Sources. Data were derived from Duke University Health System (DUHS); a large academic medical center that serves as the primary provider in Durham County, North Carolina, and a large national health plan that organizes EHR data and makes it available for research.

Data Extracted. We first defined a population of patients having Type II diabetes. We extracted information on demographics, service utilization history, comorbidities, procedures, medications, vital signs and lab test results.

Analytic Approach. We created Table 1 and compared the defined cohort using standardized mean differences (SMDs). For each data source, we used LASSO regression to derive a predictive model for hospitalization. We cross compared the model fit in independent test datasets.

RESULTS
We identified 18,355 diabetic patients from DUHS and 967,499 diabetic patients from the national data source. There were meaningful differences (most SMDs > 10%, with many > 20%) in the demographic and clinical characteristics of the patient groups. Of note, the DUHS cohort was younger and contained more females and African Americans than the national cohort. After limiting the national data set to just those living in the South, these differences attenuated but still persisted with many SMDs still greater than 10%, suggesting that differences were not solely due to geographic differences.

Predictive model results are shown in table below.

<table>
<thead>
<tr>

</tr>
<tr>
<td>African Americans</td>
<td>0.82</td>
<td>0.69</td>
<td>0.69</td>
<td>0.58</td>
</tr>
</tbody>
</table>

DISCUSSION
While the national data are larger and arguably more nationally representative, the DUHS data have clearer data provenance and follow the PCORnet CDM. The DUHS data appeared more clinically accurate and ultimately produced a better performing predictive model that showed more transportability. The results suggest that a relatively well performing model built from a single center performed moderately well in a national dataset. Conversely, the nationally derived model did not perform as well in this same single center.
Applying NLP to extract clinician recorded affect to advance depression clinical research: A proof of concept

Vanessa Panaite, Ph.D., Dezon Finch, Ph.D., Andrew R. Devendorf, B.A., Lina Bouayad, Ph.D., Stephen L. Luther, Ph.D., MA, Susan K. Schultz, M.D. Research & Development Service, James A. Haley Veterans’ Hospital, Tampa, FL; Department of Psychology, University of South Florida, Tampa, FL; College of Public Health, University of South Florida, Tampa, FL

Problem addressed: Affective theories of depression suggest that affect marks the depressed state and is associated with depression severity, course, and outcomes [1]. Clinical practice is still in need of clinical markers that better capture patient desired outcomes. Current practice guidelines for depression use a symptom-management approach to gauging recovery [2] while patients place more value on achieving psychological well-being [3]. Affective flexibility has been linked to psychological well-being [4]. In the current pilot we proposed that clinician documented patient affect is reliably observed during mental health encounters and reliably extracted using natural language processing (NLP) to assist in the future with tracking patient desired depression outcomes over time. We piloted an information extraction vocabulary to test the feasibility and reliability of identifying clinician recorded patient affective states in clinical notes from electronic health records (EHRs).

Methods: Affect and mood were annotated in 149 clinical notes write by mental health providers for 109 patients. Annotations were completed by two independent coders. Affect was defined as a session specific emotional state that could be defined by emotion related behaviors and expressed or clinician observed emotional experiences. Mood was defined as affective behaviors and experiences over weeks or longer outside of session. Agreement statistics and frequency of the concepts were examined. Intercoder disagreements were settled by a third clinical coder. This reference annotation set was used to test a proof of concept NLP system using a Named Entity Recognition approach.

Results: Annotated data demonstrated that affect characteristics were identified in 88% of the notes; mood was identified in 97% of the notes. Reliability of affect and mood annotation was established across three coding waves. The intercoder reliability was consistently good across the three pilot coding waves (Inter-Annotator Agreement (IAA) = >70%) showing substantial agreement. The final NLP system showed good reliability with the final reference annotation set: affect IAA = 80.9%; mood IAA = 85.8%.

Conclusion: Concepts describing in session affect and general mood were frequently addressed in templated format and free text in clinical notes both by psychiatrists and psychologists. These findings show that concepts of affect and mood can be reliably identified in clinician reports and that they are good targets for NLP. This work has multiple implications: 1) it provides a solid springboard for a larger scope NLP to capture patient affect relevant to mental health treatment across multiple session; 2) supports the effort to better capture patient desired outcomes such as psychological well-being.

Predicting Breast Cancer Treatment Outcomes for Minority Women in California Using Machine Learning

Jung In Park, PhD, RN¹, Doyub Kim, PhD², Kai Zheng, PhD³, Sunmin Lee, ScD, MPH⁴
Alpesh Amin, MD, MBA⁵

¹Sue & Bill Gross School of Nursing, University of California, Irvine, CA; ²NVIDIA, Santa Clara, CA; ³Donald Bren School of Information & Computer Sciences, University of California, Irvine, CA; ⁴University of California-Irvine, Department of Epidemiology, School of Medicine, Irvine, CA; ⁵School of Medicine, University of California, Irvine, CA

Breast cancer is the second leading cause of cancer-related deaths of women aged 40-55 in the United States. The National Cancer Institute (NCI) estimated that about 276,480 women would be diagnosed with breast cancer in 2020, and about 42,170 will die of the disease. Although white women have higher cancer incidents, minority women have a higher mortality rate. California has the largest ethnic/racial minority population in the United States – about 20% of the total national minorities live in California. Several studies have compared the breast cancer treatment outcomes, but few studies predict the treatment outcomes for minority women residing in California using large datasets. A large dataset allows robust modeling for individualized treatment decisions. This study aimed to build prediction models for breast cancer treatment outcome, which was 5-year survival, for minority women residing in California using a machine learning approach. The minority populations included in this study were Hispanic, Asian or Pacific Islander, Black, American Indian/Alaska Native.

We used the data from the Surveillance, Epidemiology, and End Results (SEER) program, which the NCI supports. SEER collects cancer incidence data from the cancer registries covering nearly 35% of the U.S. population. The data include patient demographics, primary tumor site, tumor morphology, stage at diagnosis, and the first line of treatment, and patients’ vital status. We developed prediction models using random forest (RF), XG Boost, SVM, and Logistic Regression, and these models were evaluated using precision, recall, and Area Under the ROC Curve (AUC). The grid search algorithm was used with 10-fold cross-validation to find the optimal hyperparameter set.

A total of 119,392 minority women who had breast cancer diagnoses between 2000 – 2017 were identified. After data preprocessing, the number of features used for modeling was 582. Most of them were Latino (48.1%), Asian or Pacific Islander (35.5%), Black (17.0%), and American Indian/Alaska Native (1.2%). The RF model found that HER2 positive, surgical primary site, summary cancer stage, whether surgery was performed, median household income, regional nodes positive were the predictors of the outcome. The most patients had localized stage (59.7%) followed by regional (35.5%), and Grade II (41.7%) followed by grade III (39.2%). The precision, recall, and AUC for each model were RF (87%, 69%, .86, respectively), XG Boost (87%, 70%, .86), SVM (86%, 70%, .85), and LR (86%, 71%, 0.85). Based on the evaluation results, the XG Boost model slightly outperformed the other models.

This study has developed highly accurate models to predict the breast cancer survival of minority women in California using large datasets and machine learning. It can work as an evidence-based decision support tool that is tailored to individuals for better patient outcomes. Future work is required to validate this algorithm in other health care systems to test its generalizability.
Technology and Data Sharing Preferences in mHealth Research Interventions
Leslie Park, BS1, Sabrina Mangal, PhD, RN1, Meghan Reading Turchioe, PhD, MPH, RN1, Annie C. Myers, MA1, Brittany Taylor, BS, RN2, Ruth M. Masterson Creber, PhD, MSc, RN1

1 Dept. of Population Health Sciences, Health Informatics Div., Weill Cornell Medicine, New York, NY; 2Columbia University School of Nursing, New York, NY

Introduction
The ubiquity of mobile devices enables an unprecedented level of accessibility to information, which has created an opportunity for mHealth interventions to empower patients to understand their health status and improve communication between patients and providers. As mHealth interventions grow, there are critical challenges in data governance, transparency, and accessibility that impact patients’ agency over health decisions and vulnerability to data misuse. The objectives of this study were: (1) to explore Heart Failure patients’ technology experiences in a mHealth intervention and (2) to gauge public trust and data sharing preferences regarding clinical research studies.

Methods
This is a two-part mixed methods study. Part 1 included qualitative interviews with patients with heart failure who had participated in an mHealth intervention that evaluated patient symptoms over eight weeks. These interviews were audio-recorded, transcribed, and deductively coded by a team of three trained researchers. Part 2 was a survey that focuses on a representative U.S. population’s technology experiences and attitudes about data access and sharing. The survey includes focused questions that were generated from our interview themes about attitudes towards technology use, data sharing, and trust in various institutions involved in delivering mHealth interventions.

Results
Part 1) Interviews with heart failure patients (n=16; average age: 63.6 years old, 81% male, 75% White, 19% Hispanic/Latino) participating in our mHealth intervention generated four emerging themes and illustrative quotes:

<table>
<thead>
<tr>
<th>1) Mobile devices make research participation convenient</th>
<th>“The phone makes it easy because it’s with me and I can do it whenever I want [...] I don’t have to worry about where I am or what type of day it is.”</th>
</tr>
</thead>
<tbody>
<tr>
<td>2) Email is a preferred mode of communication and record keeping for health information, but is often lost</td>
<td>“Email [is preferred], I probably wouldn’t go on any website because it’s difficult to track passwords. If I had a PDF and an email, I would dump it in a folder and leave it there. I have 10,000 emails from [years ago]”</td>
</tr>
<tr>
<td>3) Barriers to data sharing include concern about provider-burden and time constraints</td>
<td>“If [my provider] is okay with receiving [my symptom results], I would gladly share it, but I know she has a lot of patients. I don’t want to be a burden. When I do call her, I want an answer.”</td>
</tr>
<tr>
<td>4) Altruistic motivations for sharing their data with providers, researchers, and tech companies</td>
<td>“I figured [participating and sharing data] couldn’t hurt. It could only help if someone else is going through what I’m going through. It’s pretty scary going through it and not knowing what the outcome is going to be.”</td>
</tr>
</tbody>
</table>

Part 2) Survey (n=502; average age: 46.6 years old; 49% male; 74% white; 7% Hispanic of Latino) results revealed three key findings: 1) the internet, tech companies, large corporations, and government are significantly less trustworthy than health policy makers and healthcare providers; 2) mixed feelings of trust in sharing data with health tech companies for mHealth interventions (15.9% decrease trust, 52.4% no change in trust, 31.7% increase trust) with 36% preferring to share none of their health information with health tech companies in context of an mHealth study; 3) 72% felt that they should be paid for sharing data with health tech companies.

Conclusion and Discussion
This study raises important design and ethical considerations for implementing mHealth interventions, especially those involving tech companies either directly as partners or indirectly as intermediaries that provide the devices, applications, data, and systems infrastructure necessary for implementing scalable solutions involving mHealth. Future mHealth studies should consider implementation design choices, protocols for supporting information accessibility and actionability, patient-provider communication, as well as equitable and ethical data access and use.

Assessing the Predictive and Ecologic Validity of Geographic Indices for Social Determinants of Health
Yoonyoung Park, ScD1, Frank Yoon, PhD2, William Kassler, MD, MPH2
1IBM Research, Cambridge, MA; 2IBM Watson Health, Cambridge, MA

Introduction The growing interest in social determinants of health (SDoH) that affect public health and well-being has led to development of geographic deprivation indices (GDIs) that characterize SDoH based on geography. While most component measures are sourced from population statistics, GDIs largely differ in concepts and analytic methodology. This work is motivated by lack of evidence on the comparative performance of popular GDIs to inform analytic choices for health policy research and practice. We evaluate the predictive performance of four existing GDIs and examine the threat of ecological bias to inform the choice of GDI in practice.

Methods The four candidate GDIs examined in this study are: Area Deprivation Index (ADI), Community Need Index (CNI), Social Deprivation Index (SDI), and Social Vulnerability Index (SVI). Conceptually, the ADI captures health inequity, the CNI the demand for health services, the SDI the relative levels of social disadvantage, and the SVI the vulnerability and preparedness for natural disasters. Except for SVI which is based on percentile ranks, the three other GDIs were developed using factor analysis. All four indices are available at county level. The area under the receiver operating characteristic curve (AUROC) was calculated by logistic regression models predicting the worst decile of life expectancy, diabetes prevalence, and preventable hospital admissions. To assess ecological bias, we obtained health measures from County Health Rankings & Roadmaps (county-level data) and IBM Watson Health™ PULSE® Healthcare Survey and Claritas PRIZM® Premiere Segmentation (block group-level data) for the state of New York. Using generalized linear models, we incorporated the ADI at different geographic levels in predictive models for emergency room (ER) utilization to assess at what geographic level the ADI becomes less informative or changes the direction of effect, with or without adjusting for other SDoH measures (18 chronic condition indicators, insurance type, and SDoH such as income level, household composition, home ownership, education, and employment).

Results The GDIs exhibited strong pairwise correlations (0.73-0.86). In predictive models, ADI consistently showed the best performance in terms of AUROC values (Table 1). Adding ADI to the models adjusting for age categories and subsequently additional variables, we observed that the signs of ADI coefficients change when block-group or tract level ADI is used compared to when county level ADI is used (Table 2). The magnitude of ADI coefficients generally decreased as the aggregation level increased or as additional SDoH variables were added.

Table 1. AUROC of county-level GDIs

<table>
<thead>
<tr>
<th></th>
<th>Bottom 10% life expectancy</th>
<th>Top 10% Diabetes prevalence</th>
<th>Top 10% Preventable hospital stays</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADI</td>
<td>0.904</td>
<td>0.875</td>
<td>0.792</td>
</tr>
<tr>
<td>CNI</td>
<td>0.782</td>
<td>0.752</td>
<td>0.651</td>
</tr>

<td>0.692</td>
</tr>
</tbody>
</table>

Discussion We observed differences in predictive performance across four GDIs based on AUROC. In general, ADI performed well and reliably across experiments. But the impact on performance in practice, such as in risk adjustment models, may not be as strong if GDIs are used as one of many features in a model. The differences in concepts, components, and associated face validity should be considered when choosing a GDI for an analytic task. One important factor to consider is the aggregation level, as we can see some evidence for the presence of ecological bias when county-level data is used in place of individual or more granular data. We suggest that GDI should be used at the highest geographic resolution whenever possible to avoid such limitations.

Use of a Widely Available Electronic Health Record to Facilitate COVID-19 Vaccinations

Mark A. Parkulo, MD 1,6; Windell Smith, MHA 2, Luanne Williams, MSN RN NE-BC 3, Marites E. Sayo, MBA 2, Jason Buckmeier 4, Jodi Rinken 4, John C. O’Horo, MD, MPH 5

1Mayo Clinic, Jacksonville, FL: Division of Community Internal Medicine, Department of Medicine, 2 Department of Administration, 3 Department of Nursing, 4 Mayo Clinic, Rochester, MN: Department of Information Technology, 5 Division of Infectious Diseases, Department of Medicine, 6 Mayo Clinic Robert D. and Patricia E. Kern Center for the Science of Health Care Delivery.

Background  On December 23, 2020 Ron DeSantis, governor of the state Florida, issued an executive order authorizing COVID-19 vaccination of healthcare workers, patients over the age of 65 and other patients who were extremely vulnerable. A process to prioritize the highest risk patients was implemented at Mayo Clinic in Florida. 1,2

Methods  Initial evaluation of patient data generated by our Electronic Health Record (EHR) (Epic Systems, Inc.) revealed 182,265 unique patients from the state of Florida had at least 1 visit/encounter in 2020 with 61,488 of those patients being over age 65 and living in the surrounding 5 counties. Utilizing a COVID Risk Score3 (based on demographic, medication and comorbid risk factors) to predict risk of severe complications of COVID19 infection, we were able to further segment the population and invite highest risk patients first.

Results  Between January 4 and January 7, 2021, we invited 11,000 patients (Table 1) and were rapidly able to fill 4,093 scheduled appointments with 3,156 patients able to self-schedule online or via the Mayo Clinic app. (Table 2). Between January 5 and January 14, 2021, we administered 4,093 scheduled vaccines to patients until our vaccine supply was exhausted. We were able to rapidly fill schedules utilizing this process and placed invited patients requesting vaccine on a waitlist when appointment calendars were filled (Table 1). We halted the process when our vaccine supply was exhausted. We reinitiated the process when more vaccine was delivered to us by the State.

Core Outcomes Sets Development in COVID-19 Clinical Trials
Irena Parvanova and Joseph Finkelstein
Icahn School of Medicine at Mount Sinai, New York, NY, USA

1. Introduction
A novel coronavirus disease (COVID-19) has caused a worldwide pandemic outbreak [1]. As of January 2021, the virus affected the population of 222 countries, with 83,910,356 confirmed cases at the time. Outcome reporting and standardization in COVID-19 clinical research depends on the use of a core outcome set (COS), collected and compared across all COVID-19 trials [2]. The growing research data are currently being integrated in data repositories, including publicly available repositories, such as ClinicalTrials.gov.

2. Methods
Primary and secondary outcomes from COVID-19 trials in ClinicalTrials.gov were analyzed using analytical query, combining “COVID-19” in the “Other terms” field with “United States” in “Country” and “NIH” in “Funder Type” fields, generating 120 studies at the time of our inquiry. We performed detailed analysis where we examined common data elements based on the studies outcomes.

3. Results
We examined the outcomes for the 120 clinical trials and ranked each outcome for the COVID-19 clinical trials by calculating the percentage of the appearance of each outcome in all 120 trials. For quantification purposes, we considered outcomes that were present in more than 1% of the studies. The most common COVID-19 clinical outcomes are: Mortality due to COVID-19 (16%), Mental health impact due to COVID-19 (12%), Anti-SARS-CoV2 Antibodies (10%), Proportion of patients that required hospitalization due to COVID-19 or died (8%), SARS-CoV-2 PCR/RT-PCR test results/nasal swabs samples (6%), Severity of COVID-19 (6%), and others (Figure 1).

4. Discussion
ClinicalTrials.gov contains enormous quantity registered clinical trials information, including COVID-19-related clinical trials. Our findings provide standardized approaches for representation of COVID-19 research to allow for cross-trial comparison of the results and building a comprehensive core outcome sets in COVID-19 clinical trials. Synchronization of common data elements and data exchange standards is necessary to facilitate data harmonization approaches in COVID-19 research.

5. Conclusion and future work
Future plans include implementing ontology-driven automated metadata extraction pipeline from ClinicalTrials.gov, combined with crowdsourcing for engaging multidisciplinary researchers in ranking COS candidates [3].

Optimizing Clinician Alerts for Concerning Symptoms in an Electronic Patient-Reported Outcomes (ePRO) System in Community Oncology

Amila M. Patel, PharmD¹, Lalan S. Wilfong, MD², Ethan Basch, MD, MSC³, Angela M. Stover, PhD⁴ Max Franklin¹, Ben Pearson¹, Debra A. Patt, MD, PhD, MBA²

¹Navigating Cancer, Seattle, Washington; ²Texas Oncology, Austin, Texas; ³University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Introduction

Successful implementation of electronic patient-reported outcomes (ePROs) tools in cancer care is highly dependent on integration with routine clinic workflows for symptom management. This includes appropriate and timely notification to clinical staff for symptom intervention. However, there is a risk of clinician burden and both patient and provider dissatisfaction if ePRO symptom notification algorithms fail to prioritize symptoms warranting attention. Identifying patients who need acute symptom intervention may help optimize staffing and improve time to symptom resolution.

Methods

Texas Oncology, a large multi-site community oncology practice, partnered with Navigating Cancer to implement an ePRO technology across 210 sites of service for symptom monitoring among patients initiating a new systemic therapy. Patients were sent symptom assessments on a weekly basis to characterize 14 common cancer-related symptoms for presence, frequency, severity, and/or interference with daily activities based on NCI’s PRO-CTCAE instrument, with responses based on a 5-point Likert scale. Participating patients self-reported via email or text and moderate-severe symptoms triggered a real-time notification to nursing staff. We systematically tracked clinician alerts and interventions, and continuously collected user feedback. These data were reviewed by a multi-disciplinary stakeholder group and practice leadership to modify the alert algorithm based on consensus.

Results

6,867 patients completed 61,688 symptom assessments between July 2020 and January 2021. 68% of reported symptom items triggered an alert. 46% of alerts were associated with a single symptom, with the most common being fatigue in the absence of other symptoms (13%). These fatigue-only alerts resulted in no direct clinical intervention by nursing staff, but rather reinforcement of lifestyle and behavior modifications for fatigue management. A decision was made to remove fatigue-only alerts from the algorithm, but to continue providing patient-reported fatigue data to providers at clinic visits.

Discussion

A high volume of clinician alerts for concerning symptoms occurred, and thus we created a framework to optimize the alerting algorithm, with a specific focus on fatigue-related alerts. Although fatigue is a significant patient burden, it did not elicit immediate intervention by nursing staff, possibly because there are limited available acute interventions for fatigue. An algorithm prioritizing symptom alerts based on clinical actionability enables nurses to focus on symptoms that warrant acute intervention.

Conclusion

Systematic analysis and multi-disciplinary review of ePRO alerts and resulting nursing actions enables a deliberate approach to improving alert algorithms and optimization of clinician time. Further evaluation of the influence of predictive algorithms to tailor alerts to clinically significant criteria coupled with the use of automated tailored patient education materials on utilization, efficacy, and clinical staff feedback will be studied.
From Emergency Department to Admission: mapping reasons for visit and admit diagnosis using Natural Language Processing

Olga V Patterson, PhD1,2, Hannah Eyre, MS1,2,
Kelly S. Peterson 1,2, Scott L DuVall, PhD1,2
1VA Salt Lake City Health Care System; 2University of Utah, Salt Lake City, UT, USA

Introduction

Even with a broad spectrum of medical imaging and laboratory tests that provide accurate and objective information about a patient’s state, the importance of symptom-oriented research was highlighted during the COVID-19 pandemic. The Veterans Affairs (VA) electronic medical record system contains data collected at the point of care, which are aggregated nightly into the Corporate Data Warehouse and made available for research. Among a number of other data elements, the reasons for Emergency Department (ED) visits and the inpatient admit diagnoses are entries that indicate patients’ presenting symptoms or diagnoses. These entries are implemented as 50 character-fields with free text entries or automatically populated text that represents ICD10-CM codes if specified by the user.

Methods

In order to map free text entries to a standard vocabulary we developed a natural language processing (NLP) system* that contained the following modules: 1) for text preprocessing, we adapted patterns from the Emergency Medical Text Processor (EMT-P)1 by adding or removing some patterns to perform initial spelling correction and abbreviation expansion, 2) for UMLS concept mapping, we utilized cTAKES 4.0 Fast Dictionary Lookup module2 with UMLS 2020AA dictionary, and 3) for context detection, we utilized ConText algorithm3 expanded to VA specific terminology. The NLP pipeline was implemented within Leo infrastructure4 that is based on UIMA AS 2.9.0. The system was validated on 500 distinct presenting symptom statements through double annotation.

Results

Validation showed that the system achieved 91.4% precision and 83.4% recall in identifying mentioned concepts and their contexts. As of Dec 31, 2020 the VA COVID-19 Shared Data Resource5 had 449,117 patients who had 854,699 ED visits in 2020. The concept mapping NLP system was used to process 1,504,319 statements of ED visit reasons and 644,487 of inpatient admit diagnoses. The most frequently reported ED symptoms were dyspnea (11.7%), COVID-19 (8.1%), and chest pain (6.7%). The most frequently negated symptoms were homicidal/suicidal ideation, COVID-19, and dyspnea. In most cases, patients were released home (59.7%). Out of those who were admitted to the hospital, the most frequent admit diagnoses were COVID-19 (5.8%), pneumonia (4.2%), and chest pain (3.9%).

Discussion

Biosurveillance requires real-time recognition of emerging infections and symptom-based research depends on accurate detection of symptoms. We built a lightweight high-performing NLP system and deployed it in April 2020 for comprehensive tracking of presenting symptoms for the Veterans who were tested for COVID-19 within the VA system. Over 140 studies are currently in progress that utilize the chief complaints recorded in the VA EDs.

Conclusion

We developed a scalable, high-throughput system that provides concept mapping for patient visit reasons and inpatient admit diagnoses. The system was implemented in April 2020 and has been in use to provide data for the VA COVID-19 Shared Data Resource with weekly dataset updates.

Identifying erosive disease from radiology reports of veterans with inflammatory arthritis using natural language processing

Shaobo Pei, PhD1,2, Gopi K. Penmetsa, MD1,2, Brian C. Sauer, PhD1,2, Bingjian Feng, PhD3, Kevin Douglas, MD3, Jerry Clewell, PharmD3, Jodi Walker, PharmD3, Jessica A. Walsh, MD1,2
1George E. Wahlen Department of Veterans Affairs Medical Center, Salt Lake City, Utah; 2University of Utah, Salt Lake City, Utah; 3AbbVie, Inc., North Chicago, Illinois

Introduction
The presence of erosive disease influences diagnosis, management, and prognosis in inflammatory arthritis (IA). Observational research of IA in large datasets has been limited by a lack of methods for identifying erosions. We developed methods for identifying articular erosions in radiology reports from veterans with IA.

Methods
Included veterans had ≥2 ICD9 or ICD10 codes for ankylosing spondylitis (AS), psoriatic arthritis (PsA), or rheumatoid arthritis (RA) between 1/1/2005-12/31/2019, in the Veterans Affairs Corporate Data Warehouse. Chart review and annotation of relevant radiology notes produced the reference standard, and identified erosion terms that informed classification rule development. A rule-based natural language processing (NLP)1 model was created and revised in training snippets. The NLP method was validated in an independent reference sample of IA patients at the snippet (sections of text containing 30 words before and 30 words after the meaningful term) level and patient level.

Results
In 168,667 veterans with IA, the mean age was 63.1 and 90.3% were male. These IA patients involved 2,926,113 radiology notes with 35,141 note titles. Based on 11 root terms (ero*, pencil*cup, cort*, irreg*, etc.), we found 1178 variations (erosion, erotic, etc.), and selected 179 possible terms (erosion, erode, etc.). Within 5000 randomly selected erosion snippets, we identified 6 meaningful terms representing erosion (pencil* cup, erosion, erosive, etc.), 28 terms representing erosive process irrelevant to joint(s) (i.e. gastric erosion), 5 terms representing non-IA processes (i.e. infection, trauma). Based on annotated data, 83 rules were developed for assigning the target concept “erosion” using the surrounding contextual language (i.e. classifying as negated vs. affirmed, related vs. unrelated to a joint or bone, due to vs. not due to IA). NLP models on snippet level or patient level were built and optimized on training dataset with 817 snippets (AS 417, RA 200, PsA 200) and testing dataset with 200 snippets (AS 100, RA 50, PsA 50). The models were validated on independent dataset of 60 randomly selected IA patients (20 AS, 20 RA, 20 PsA) with 254 snippets (53 AS, 122 RA, 79 PsA). The accuracy of the NLP model was 96% at the snippet level and 93% at the patient level, for all IA patients (Table 1).

Modernization of the Intermacs Data Warehouse: Moving Data Management from SAS to SQL Server for Analytics

John K. Pennington, MSHI¹, Nicholas Timkovich, MSHI¹, Bunyamin Ozaydin, PhD¹
¹University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

The Kirklin Institute for Research in Surgical Outcomes (KIRSO) mechanically assisted circulatory support device (MCSD) registry named Intermacs utilizes monthly flat-file data extraction from Microsoft SQL Server. Extraction is executed through a web interface triggering a series of SQL Server Views denormalizing stored data, and culminating resulting records in text files containing a comprehensive snapshot of data. A series of SAS Analytics Software programs are then executed against those text files rendering formatted and labeled SAS datasets for use in statistical analysis and outcomes reporting to contributing hospitals for benchmarking. This poster will present a rework of the extract, transform, and load (ETL) process such that data are not extracted from SQL Server as flat text files and manipulated by SAS. Instead, information within SQL Server is transcribed into a set of denormalized SQL tables structured to match those resulting from the existing SAS datasets. This workflow transformation ensures the ETL and data management processes are executed wholly within SQL so that KIRSO sees operational benefits via streamlining code management and personnel responsibilities, and creates a path towards further optimization and implementation of additional features through automation and business intelligence software integration¹.

Methods

The data warehouse utilizes a sample of over 25,100 adult patients receiving mechanical assisted circulatory device (MCSD) treatment for advanced heart failure from one of 181 participating Intermacs hospitals within the United States. The ETL process redesign consists of four main phases: SQL DDL, SQL DML, SQL Data Processing, and a SAS Macro. The SQL DDL phase creates table shells for denormalized data extracted from SQL Server. The SQL DML phase moves those data from their storage locations on SQL Server, denormalizes them, and renames columns in accordance with SAS variables. The SQL Data Processing phase derives new columns necessary for reporting that are not stored or calculated via the web application, as well as making corrections to some of the problematic data manager created data records. The SAS Macro is a SAS program acting as its own mini-ETL by allowing SAS users to extract SQL tables, transform them into formatted and labeled SAS datasets, and load them either into SAS working memory or a network location by an Open Database Connectivity (ODBC) connection².

Results and Conclusion

The Intermacs data mart was validated as a successful process redesign by cross comparisons, including row and column counts as well as SAS proc tabulate of key dates and SAS proc freq of adverse event and outcomes variables, ensuring equilibrium between data created through the legacy SAS workflow with data created in the new SQL workflow. The data mart and data management redesign expedited data preparation, reducing the lag time between date entry and retrieval for research and made data accessible to a broader audience. The process redesign allowed for a simpler process when updating and creating research datasets by eliminating some of the personnel and existing manual interim steps in the ETL process that were artifacts of the legacy system. Legacy workflow averaged 32 minutes of SAS run time compared to an average of 17 minutes of SQL query time. This data processing time reduction of 47% becomes a 100% reduction in personnel resources via off-hours automated execution as nightly SQL stored procedure data refreshes. The data that were subsequently available also facilitated the future roll-out of timelier reporting as data are now stored in the KIRSO EDW on SQL Server and may be refreshed nightly instead of quarterly. This more frequent refresh narrows the reporting window from previous one to three month gap from data entry by a participant until those data were delivered in reports. Lastly the warehouse redesign also laid the groundwork for future real-time interactive reporting, where sites might request customized cohorts and exhibits through the web interface in addition to receiving exhibits based on cohorts as designed by the KIRSO Data Collection and Coordinating Center (DCCC).
Comparison of Population-wide Explanations for Predicting the Outcomes of Patients with Community-Acquired Pneumonia

Eddie Pérez, M.S.¹, Shyam Visweswaran, M.D., PhD¹, and Harry Hochheiser, PhD¹
¹University of Pittsburgh, School of Medicine, Department of Biomedical Informatics, Pittsburgh, PA

Introduction
Wider adoption of machine learning (ML) models in healthcare settings requires model explanations that are human interpretable, locally accurate, and globally consistent (1). Shapley Additive Explanations (SHAP) is a novel tool that theoretically guarantees the local accuracy of these explanations (2). To effectively guide patient care, explanations will ideally provide consistent insight into patient state, independent of the models used. However, the consistency of explanations across different types of models has thus far not been a topic of significant investigation.

Methods
In this study, we evaluate the consistency of explanations across popular ML models (Logistic Regression (LR), Random Forest (RF), and Gradient Boosted Machines (XGBM and LGBM)) when predicting clinical outcomes for community-acquired pneumonia (CAP) patients. Lundberg et al. showed that LR and GBM’s can weigh features differently resulting in differing explanations (1). These results were attributed, in part, to differences in each model’s bias/variance balance. Thus, hypothetically, the different models compared in this study could yield differing explanations.

The models were trained on a subset of the dataset collected by the Pneumonia Patient Outcomes Research Team (PORT) (3). Our pneumonia dataset contains 2,287 patients and has been studied extensively with the goal of training models to predict a dire outcome (i.e., serious complications, including death) of CAP (3). We used the following python libraries: [1] scikit-learn, xgboost, and lightgbm for training models, [2] SHAP for explanations, [3] Scipy to calculate Kendall’s W coefficients and p-values.

Results
Pairwise explanation consistency ranged from 0.45 to 0.78 (Table 1). Maximum consistency was 0.78 LGBM and XGB, both of which are GBM algorithms. RF had the minimum average consistency 0.47.

Conclusion
Model explanations differ across training algorithms. There was more agreement between LR and the GBMs than between RF and the GBM’s. Further research is necessary to understand how these differences affect the relevance of the model explanations to the clinical problem.

Early Prediction of Positive Clostridioides Difficile Test Results

Anh Pham, MS1, Robert El-Kareh, MD1, Lucila Ohno-Machado, MD, PhD1, Tsung-Ting Kuo, PhD1

1 University of California San Diego, La Jolla, CA, USA

Keywords. Machine Learning, Data Mining, Clinical Decision Support

Introduction. Clostridioides difficile infection (CDI) caused by the Clostridioides difficile (C. difficile) bacterium may lead to serious complications, especially in older, antibiotic-treated patients.1 While early detection of carriers could help manage outbreaks,2 current guidelines do not recommend broad screening at admission.3 A CDI risk-score model can identify at-risk patients for targeted testing. Past models are subject to issues of generalizability and feasibility.4,5 We sought to predict positive CDI test results (which may differ from true CDI diagnoses) with high accuracy, interpretable results, and a reasonable number of covariates, adding to the physicians’ decision-support toolbox with other testing strategies.

Materials and Methods. Our models predict C. difficile test results up to one calendar day before the first actual positive test, using 104 covariates of 157,493 UCSD Health patients from 01/01/2016 – 03/07/2019 (our IRB date). There were 1,541 cases which had at least one positive C. difficile lab test. Predictors include (a) race/age/gender, and (b) medication used in the timeframe, grouped by pharmacologic classes. We chose Logistic Regression (LR) and Random Forest (RF) algorithms, evaluated by the Area Under the Receiver Operating Characteristic Curve (ROC AUC). We held out 10% of the dataset for testing and tuned hyper-parameters via grid search using 10-fold cross validation on the remaining 90%. From selected hyper-parameters, the LR and RF models were retrained on 90% of data. Afterwards, an ensemble model averaged the LR and RF predictions to find the final scores and compared them to a threshold of 0.5 to decide outcomes. We performed significance analysis on the model covariates, recording their LR odds ratios and corresponding p-values, and RF Gini importance.

Results. The ROC AUCs are 0.839 (LR), 0.851 (RF), and 0.866 (ensemble). Among the significant factors (p < 0.0001), the clinically seen risk factors are age, use of anti-infectives,6 and gastrointestinal (GI) tract medications.

Conclusion. Our models using patients’ medication history and demographic can predict first positive CDI tests. For infectious diseases, early prediction of positives may aid clinical practices.

Integrating Molecular and Clinical Data for Real World Evidence Research in Precision Oncology

Scott Phillips, B.S.¹, Xiaojun Xu Ph.D.¹, Paulina Paul, M.S.², Wenhong Zhu PhD³, Michael Hogarth M.D.²,³, Olivier Harismendy, PhD ¹,²

¹Moores Cancer Center, ²Division of Biomedical Informatics, Department of Medicine, ³Altman Clinical and Translational Research Institute, University of California San Diego School of Medicine, CA

In precision oncology, Real World Evidence (RWE) research depends on clinicopathological data (stage, grade, diagnosis, outcome), which is not often available as structured data and hence requires manual curation of Electronic Health Record (EHR) data. Moreover, the practice of precision oncology increasingly relies on the results of DNA sequencing assays (NGS), which are available only as narrative text reports and not adequate for large-scale research use. Research initiatives such as the AACR GENIE consortium are aggregating data, relying on their members to share de-identified test reports accompanied with a minimal set of clinical information. Similarly, prospective clinical studies have collected molecular data and curated the clinical information to evaluate predictive biomarkers. Here we present an alternate approach that minimizes curation in the assembly of molecular and clinical data and which was used to create the Aggregated Registry for Molecular Oncology Research (ARMOR), a large-scale registry supporting RWE research in precision oncology.

Structured NGS report data were collected directly from the laboratories, extracted, and transformed to flat files following the cBioportal extended formats. The associated meta-data including laboratory, assay-type and version, diagnosis, specimen site and primary organ at order, Tumor Mutational Burden, or Microsatellite instability are added to sample and patient tables. The clinical and demographic data is obtained from the UCSD Health Clinical Data Warehouse for Research and included antineoplastic prescriptions and start dates, which were abstracted to their main ingredient using the Anatomical Therapeutic Chemical (ATC) classification. The data is anonymized, and all dates converted to duration since first report and made available to approved investigators via a local cBioportal server.

A total of 6,098 DNA sequencing test reports from 4,900 patients were collected between 2012 and 2020. The distribution of cancer types was consistent with the prevalence of cancer diagnosed at more advanced stages and more likely to be subjected to molecular testing (Lung: 10%, Colon: 9%, Breast: 7%, Prostate: 5%). We identified medication prescriptions and their dates for a subset of patients (N=3,970). A total of 360 antineoplastic medications, mapped to 145 ingredients. A total of 64 ingredients were classified as targeted therapy (TT), including 40 protein kinase inhibitors and 24 monoclonal antibodies. The usage of antineoplastic compounds across cancer type was consistent with the disease specific treatment (e.g. temozolomide in brain cancer) and highlighted frequent combinations (e.g. fluorouracil, irinotecan and oxaliplatin in colorectal cancer). The majority of the molecular tests were gene panel sequencing from tumor DNA (5,090, 83%) or cell free DNA (971, 16%). A total of 895 (18%) patients received results from multiple tests within a median time of 76 days. A subset of 2,877 patients tested by one laboratory and with available treatment and survival information was used for biomarker validation and analysis. Twenty-seven combinations of alterations in 12 genes across 13 diseases were associated with prognosis including ARID1A in Brain cancer (HR=0.2, p<10⁻⁶) or NFI in Ovarian cancer (HR=2.06, p<5.10⁻³). The rate of TT matching was high in approved settings (88% of EGFR-mutated lung cancer or KIT-mutated Gastro-Intestinal Stromal Tumors), but low in settings with alternate TT (19% of ERBB2-mutated colorectal cancers). Furthermore, out of 239 combination of genes (N=25), cancer type (N=17) and treatment (N=34) eligible for investigation (N>10 patients in each arm), we identified 20 significant associations (log-rank p-value < 0.01). While most were also prognostic, ARID1A mutations predicted response to oxaliplatin in Gastric cancer (HR=0.17, p<5.10⁻³) and PIK3CA mutations predicted poor response to docetaxel in Breast cancer (HR=7.7, p<3.10⁻³).

ARMOR faithfully captures a snapshot of a molecular oncology clinic using automated and real time collection of both molecular and clinical information. Despite inherent limitations, including phenotypic depth and heterogeneity of the source of the molecular data, ARMOR provides a platform to evaluate the practice of precision oncology at a high-level, rapidly validate matching therapy findings in an independent, real world patient population, document patients’ trajectories, develop predictive models and test novel therapeutic paradigms.
Online health information seeking, health literacy, and human papillomavirus vaccination among transgender and gender diverse people

**Introduction** Transgender and gender diverse (TGD) people report a higher prevalence of poor health and experience stigma and discrimination in healthcare, resulting in poor health outcomes from delaying necessary health care. Although health information seeking and eHealth literacy (the ability to use electronic health information to make health decisions) has been explored among cisgender sexual minority people, these topics have not been explored among TGD people (e.g., individuals whose gender identities or gender expressions that may not align with those commonly associated with their sex assigned at birth).[1] There is a paucity of research that explores online health information seeking among TGD people and how this may be associated with health decision-making. The purpose of this study is to describe online health information seeking among a sample of TGD people compared with cisgender sexual minority people to explore associations with HPV vaccination, and whether general health literacy and eHealth literacy moderate this relationship. **Methods** We employed a cross-sectional design to explore the association of online health information seeking and HPV vaccination among TGD and cisgender sexual minority people. Between February and May 2020, we launched an online survey to an existing cohort. Invitations to participate were sent to 17,036 participants in The Population Research in Identity and Disparities for Equality (PRIDE) Study, a longitudinal, U.S.-based, national health study of sexual and gender minority people. The PRIDE Study recruits adults aged 18-years and older, who are English speaking, reside in the U.S. or its territories, and who self-identify as a sexual and/or gender minority person. We employed logistic regression to model the association of health information seeking on the vaccination outcome and interaction terms were entered to test for moderating effects of general and eHealth literacy. Models were adjusted for age, race/ethnicity and education. Alpha for significance was set at .05 with Bonferroni-Holm post hoc correction for adjusted alphas. **Results** The online survey yielded 3,258 responses, of which 1,172 (36%) were classified as TGD and 2,086 (64%) as cisgender. After adjusting for age, race/ethnicity, and education, TGD participants had increased odds of reporting HPV vaccination (aOR=1.5; 95% CI, 1.1-2.2) but decreased odds when they had searched for information about vaccines online (aOR=0.7; 95% CI, 0.5-0.9). TGD participants had over twice the odds of reporting HPV vaccination if they visited a social networking site like Facebook (aOR=2.4; 95% CI, 1.1-5.6). No moderating effects from general or eHealth literacy were observed. **Conclusion** TGD participants had decreased odds of reporting vaccination when they had searched online for vaccine information, but increased odds of vaccination when they reported using social media. Future studies should investigate potential deterrents to HPV vaccination in online health information to enhance its effectiveness and further explore which aspects of social media might increase vaccine uptake among TGD people.

Leveraging Transformer-based Sequential Sentence Models for Clinical Information Extraction
Ananya Poddar, MS, Venkata Joopudi, MS, Bharath Dandala, PhD, Ching-Huei Tsou, PhD
IBM TJ Watson Research Center, Yorktown Heights, NY

Introduction
Popular machine learning models for clinical information extraction primarily use context within the current sentence without considering the surrounding context in which the sentence appears. As a step toward better document-level understanding, recent work on applying a pre-trained transformer-based language model in a sequential sentence classification (SSC) setting has shown promising results on scientific abstract sentence classification tasks. Inspired by this research, we experiment with two clinical information extraction tasks, namely, note section recognition and clinical summary categorization, that can potentially benefit from inter-sentential context. We demonstrate that a pre-trained transformer-based language model in a SSC setting significantly outperforms that of a single sentence classification setting in these two clinical natural language processing tasks.

Methods
We use expert-labeled annotations from two different datasets for two information extraction tasks: 1) 63,016 sentences from the i2b2 corpora for the note-section recognition task, and 2) 63,594 summary sentences from an internal dataset for clinical summary categorization, to evaluate the usefulness of a SSC setting in comparison to a single sentence classification baseline, widely established in 4.

Results and Conclusion
We achieve state-of-the-art performance on the i2b2 note-section recognition task with a micro-F1 score of 0.822 in the SSC setting, in comparison to 0.710 in the single sentence classification setting. For the clinical summary categorization task, we achieve a micro-F1 score of 0.751 using SSC, an improvement from 0.748 micro-F1 using single sentence classification setting. Our work demonstrates that pretrained transformer-based language models in a SSC setting has the potential to improve state-of-the-art on clinical information extraction tasks. In the future, we plan to explore methods for encoding longer sequences that overcomes context window size limitation and better model interdependencies between consecutive context windows.

*We map the labels of the phrase to that of the current sentence and treat this as a sentence classification task.
A Return to Workplace Health Advisor Implementing Public Health Guidance for Safe Re-Opening During a Pandemic

Anita M. Preininger PhD1; Fernando S. Suarez MD1; Jaimie Gorman BS1; Brian Gibbemeyer BBA1; Gretchen P. Jackson MD, PhD1,2

1IBM Watson Health, Cambridge, MA, USA; 2Vanderbilt University Medical Center, Nashville, TN USA

Introduction The COVID-19 pandemic prompted widespread economic shutdowns to contain spread of disease. As science about the novel pathogen emerged, public health agencies provided guidance for returning to work. Return to Workplace Health Advisor (RWHA) was developed to support safe business reopening in accordance with public health recommendations. This poster describes the system implementation and reports early adoption.

Methods RWHA included an employee-facing application that enabled self-screening based on Centers for Disease Control guidance, assessing symptoms, exposures, travel, testing, and risk factors, and generating a work pass (green to allow entrance, red to deny), with capability for employer override (e.g., with medical clearance). The system also featured an employer command center (Fig. 1B), which displayed worksite disease-transmission risk, based on employee-reported diagnoses, symptoms, exposures, and community risk, calculated with data from The Weather Company COVID-19 dashboard, which determined county-level COVID-19 trends using data from national and regional public health authorities. The system was launched in June of 2020 and was incrementally implemented by three medium-large employers and one university in the United States (US). We report initial adoption and work pass results from July to December 2020; data were extracted from the RWHA database. We calculated the proportion of approved passes from the total number of pass requests across all four organizations for the study period, as well as by month. The Western Institutional Review Board determined this study exempt.

Results A total of 75,553 work passes were generated (Jul 2686; Aug 15,895; Sept 15,552; Oct 17,277; Nov 16,123, Dec 8030), with 72,475 (96.2%) of passes allowing workplace access (green) during the study period. The number and proportion of work passes that were not approved for workplace access (red) were: July, N = 78 (2.9%); August, N = 749 (4.7%); September, N = 485 (3.1%); October, N = 723 (4.2%); November, N = 828 (5.1%); December, 218 (2.7%).

Discussion RWHA demonstrated robust adoption and supported thousands of employees in returning to work in the latter half of 2020. The trends in work pass rejection generally paralleled national COVID-19 trends, with the exceptions of an increase in August and decrease in December, likely due university users on an academic schedule.

Conclusion A RWHA with employee self-screening and employer command center allowed thousands of individuals to return to work in accordance with public health guidelines during the global COVID-19 pandemic. Such applications may support businesses maintaining safe workplaces during future infectious disease outbreaks.
Mining for parameters in literature: the case of defining electrical stimulation protocols

Marco Prenassi, PhD¹, Roberto Prandin, Ms¹, Viviana Paolini, Ms¹, Annamaria Caruso, Ms¹, Sara Marceglia, PhD¹
¹Dipartimento di Ingegneria e Architettura, Università degli studi di Trieste, Trieste, Italy

Introduction

Electrical stimulation to the human body is a wide, heterogeneous and ever-evolving research field. Stimulation parameters have wide ranges, due to the type of methodology applied and to the physiological variability between patients. New studies with specific outcomes require to design well-defined protocols; but this task usually involves multiple degrees of freedom due the numerous possible combinations of parameters (electrode location and shape, amplitude, stimulation impulse shape, frequency, pulse width and pulse duration) other than the physiological variability between patients. To help the researchers and the doctors to narrow down the best parameters’ ranges, thus reducing the degrees of freedom of the problem, it is useful to quickly extract and order the data from the latest research. This work aims to help the professionals in this task. We developed a Pubmed-abstract data mining tool that focuses on the four most used electrical parameters: frequency, amplitude, pulse width, and duration, regardless of the specific methodology, and ranks for novelty and subject numerosity the studies that contain that information. The algorithm could be easily customized to accept other parameters (e.g. patient age) and search terms.

Methods

The system architecture is made to be compatible with Python 3.6+. The first module is a custom Pubmed web scraper, based on Requests and BeautifulSoup¹ libraries. This module searches the site using the search terms provided and extract titles, PubMed identifiers (PMID), and abstracts. The second module, based on nltk library² for natural language processing (NLP), tokenizes the text of the abstracts and selects the sentences containing measure units (regular expression string: (\d+.?\d+)s?!(\w+) ). A small custom corpus containing the most used measurement units (i.e. hertz, voltage, ampere, seconds, minutes and relative prefixes) is used to classify the various measurements. Another custom corpus containing the words “patients” and “subjects” and their variations is used to extract the sample size of the study. The algorithm classifies the studies extracted by year, and then by subject number displaying the results as PMID, title and extracted parameters. The algorithm extracts other parameters for further machine learning assisted analysis, as a word frequency counter and, most importantly, orders the extracted sentences as nltk tree with a custom grammar. The human interface is based on PySimpleGui module (version 4.34.0).

Results

To validate the preliminary algorithm, we searched 10 pages of PubMed abstracts each (total: 100 abstracts per query) with the search terms: “Deep Brain Stimulation frequency”, “Transcutaneous electrical nerve frequency” and “Transcranial direct current stimulation voltage”. The algorithm selected the best five articles ordered by year and subject numerosity containing the given parameters. Our team manually ordered the abstracts by year and patient numerosity retaining only the ones with useful parameters (e.g. stimulation frequency, “Hz”) given by the same search terms. The algorithm top five articles matched the manual ranking every time.

Conclusion

Albeit the architecture is in its early prototype stages, it is already usable for preliminary parameter research for targeted electrical stimulation and these functionalities already benefit the design of our protocols. In the future the platform is scalable in two directions: (1) using dedicated modules to search multiple databases and extract even full text articles, where accessible, and implementing a FHIR research-study resource reader. (2) The implementation of machine learning to analyze the natural language sentences surrounding the parameter extraction, to better classify the useful studies.

Multi-Site Testing of a Prolonged Opioid Prescribing Electronic Clinical Quality Measure Following Elective Primary Total Hip and/or Total Knee Arthroplasties

Avery Pullman, BS1, Mica Curtin-Bowen, BA1, Ania Syrowatka, PhD1,2, Alexandra Businger, MPH1, Michael Sainlaine, MS1, Stuart Lipsitz, ScD1,2, Tien Thai, BS1, Troy Li, BS1, David W. Bates, MD, MSc,1,2 Patricia Dykes, RN, PhD1,2

1Brigham and Women’s Hospital, Boston, MA; 2Harvard Medical School, Boston, MA

Introduction and Background: The objective of this measure is to provide a tool to assess the prolonged opioid prescribing (POP) rate in opioid-naïve patients following elective primary THA/TKA surgery using routinely collected electronic health record (EHR) data to help drive high quality, evidence-based care. This electronic clinical quality measure (eCQM) will leverage opioid prescription and patient demographic information from EHR systems to compile a risk-adjusted rate of patients who are prescribed opioids for >42 days following elective primary THA and/or TKA procedures. The rate, measured at the clinician group level, is expressed as a percentage where a lower POP percentage is indicative of higher quality care.

Methods and Materials: Alpha and beta testing was conducted at two geographically distant large healthcare systems (referred to as ‘Site 1’ and ‘Site 2’) using EHR data. Alpha testing was comprised of reliability and validity testing to assess the feasibility of implementing the eCQM into EHR systems, and beta testing was conducted to assess the unadjusted and risk-adjusted POP rate across both sites. Site 1 used the EHR vendor ‘Epic’ from six clinician groups from 2016-2019, and Site 2 used the EHR vendor ‘Cerner’ from eight clinician groups from 2017-2019. This measure is stratified, meaning that separate POP rates were calculated for THA and TKA patient populations to reflect the differences in postoperative prescribing practices by procedure type. The same methodology is used for both THA and TKA POP rates.

Discussion: This manuscript outlines the testing of an eCQM intended to assess opioid prescribing practices at two geographically distant sites with distinct patient populations. This study highlights the differences in both data availability and prescribing practices between the two sites. Site 2 recorded notably less data regarding their patient’s opioid episodes (68% in site 2 compared to 100% in site 1) and, in the data recorded, demonstrated patients with a markedly higher rate of prolonged opioid use following surgery.
Introduction:
The use of EHRs has been cited as a key factor in physician burnout, yet few attending physicians, fellows, residents, or medical students ever receive additional didactic or simulated training after their initial onboarding. Current trainees are relatively technology-savvy compared to senior medical providers and could demonstrate new EHR tools. We piloted multispecialty EHR efficiency training targeted for residents, fellows, and faculty attending physicians in graduate medical education (GME) programs.

Methods:
Based on input from faculty and trainees, a 60-minute EHR skills workshop was provided to GME programs at a multi-site healthcare system with a focus on demonstrating skills to improve chart review, documentation, and order entry. Due to social distancing restrictions, workshops were delivered virtually and divided into an instructor demonstration followed by participants practicing the skill in a live EHR environment with support from instructors. Participants received a reference handout and recording of the workshop following the teaching session. Pre- and post-surveys were compared, as well as the number of saved documentation shortcuts in a participant’s account.

Results:
Specialty tailored EHR efficiency workshops were virtually presented to 11 GME program groups (average of 12 participants per session) over fall and winter of 2020, and covered a variety of unique tips (over 20 tips per session) to improve EHR efficiency. Pre-surveys regarding comfort and knowledge of EHR tools were similar between groups. The post-surveys reflected significant increases (p < 0.01) in EHR comfort, efficiency, and tool awareness. The session was recommended by 98% (79 of 81) of the survey participants. Crucially, participants frequently felt this type of training would help reduce burnout (68.5%) and improve work satisfaction (75.4%). In addition, attending providers that participated in training showed a decrease in time spent in chart review (1.8 minutes/day/provider), documentation (3.3 minutes/day/provider), and orders (2.2 minutes/day/provider) post-training. Shortcut use increased in certain subgroups provided training.

Discussion:
Providing EHR Efficiency Workshops is successful in improving providers’ overall comfort and satisfaction with the EHR and appears to show an initial decrease in provider time spent in the EHR. Overall, the program was well received, with both trainees and senior providers requesting the workshops be given earlier and more frequently in training. The forced virtual delivery method limited the ability to correct for technical issues and instructor speed of delivery during the sessions. The reference handout and session recording were appreciated resources by session participants.

Conclusion:
Residents, fellows, and practicing providers find value in learning EHR skills especially related to chart review and documentation efficiency. This type of training should begin early in medical education and reinforced at key intervals throughout training and practice.

Introduction

One of the options for treating locally advanced breast cancer is Neoadjuvant Chemotherapy (NAC), in which chemotherapy and optionally targeted treatment are administered prior to surgery. An important clinical issue to consider when selecting NAC treatment is the likelihood of future cancer recurrence. We present multimodal AI models for predicting cancer recurrence within five years from diagnosis, using both clinical data and multiparametric magnetic resonance imaging (mpMRI) taken prior to treatment. Predicting treatment outcome using multimodal features is an important enabler of precision medicine.

Methods

We work with an anonymized dataset composed of clinical data for 1738 patients and MRI data acquired prior to NAC initiation for a subset of 567 patients. From this dataset, we separated a cohort of 100 patients that had clinical and MRI data for holdout evaluation. The remaining patients were considered for our five-fold cross-validation experiments. Given that we have different sizes of datasets for the different modalities, we divided our model in two branches. The clinical branch was trained using clinical data and the Random Forest classifier. The imaging branch used multiple MRI volumes and a combination of CNNs and classical 3D image processing. We then combined the two branches into one final ensemble model by calibrating the models using Platt’s method and averaging the scores.

The figure shows the imaging mpMRI branch model architecture. It uses multiple MRI volumes of the same study and consists of two components.

Top - Subtraction component in which 7 adjacent MRI slices (3 pre-significant slices, 1 significant slice in which the tumor is the largest, and 3 post-significant slices) form the input to seven 2D-CNNs that have the same weights. The features are aggregated into a 3D-CNN followed by an average global pooling layer.

Bottom - Dixon-ADC component in which three 3D MRI volumes form the input to 3D image processing that generates volumetric features.

Finally, the features from the two components are passed through an FCNN to create the mpMRI score.

Results and Conclusion

We evaluated the individual models, as well as the final ensemble model on cross-validation and on holdout. The mpMRI model achieved 0.700 [0.646, 0.749] AUC and specificity of 0.315 at sensitivity operation point 0.95. In the holdout test, the mpMRI model achieved 0.642 [0.586, 0.695] AUC and 0.213 specificity. The clinical model achieved in cross-validation 0.711 [0.657, 0.759] AUC and 0.263 specificity. On the holdout, the clinical model obtained 0.707 [0.652, 0.756] AUC and 0.196 specificity. The final ensemble model achieved in cross-validation 0.750 [0.698, 0.796] AUC and 0.466 specificity, while in the holdout test it achieved 0.734 [0.680, 0.781] AUC and 0.413 specificity.

In conclusion, we showed that prior to NAC treatment, each individual model shows the ability to predict five-year recurrence, and the multimodal ensemble model offers even better results and clear improvements in specificity.

Automatic Data Curation from Unstructured Text

Protiva Rahman, Ph.D., Daniel Fabbri, Ph.D.
Vanderbilt University Medical Center, Nashville, TN

Introduction

Informatics research often relies on data present in unstructured text such as biomedical literature and electronic health record (EHR) notes. As a result, the first step of many projects is curating data from free-text documents. Curation is often a tedious and time-consuming task where curators manually fill out structured data fields, i.e., curation forms. While tools exist for interactive labeling and annotation of medical concepts [1], the underlying models are for niche tasks that cannot be generalized to any given set of fields. In this work, we present our vision for a data curation tool that accelerates and guides curators. Preliminary results of our extraction model show 7% and 16% improvement in accuracy over baseline methods in biomedical literature and electronic notes, respectively.

Methods

Manually curating data into form fields from long documents is a laborious task. To accelerate data curation, we need a tool that learns to automatically extract data and populate curation forms. To this end, we frame the extraction problem as a separate classification task for each form field. The text (from the notes or biomedical article) is the input and the value for the form field is the output or “class”. Keyword search with regular expressions was used as a baseline. The baseline was compared against variations of the BERT algorithm [2], which is a state-of-the-art natural language algorithm. We first use the raw BERT embeddings trained on the Google News corpus. Next, BERT was fine-tuned for one epoch, i.e., one pass through the training dataset, individually for each form field. To overcome the length restriction, the RoBERT [3] model was used. Finally, the performances of BioBERT [4] (trained on PubMed articles) and ClinicalBERT [5] (trained on the MIMIC III notes) were also compared.

Results

Two data curation tasks were used for evaluation. The first is data curation from EHR notes for American Association for Cancer Research GENIE’s BioPharma Collaborative (BPC) [6]. The second use case is data curation for the Preclinical Science Integration and Translation (PRESCIANT) method. The PRESCIANT method aims to extract information from biomedical literature on animal models of human diseases and translate the findings to humans. We report average results across all fields for the two datasets. BERT without finetuning does very poorly. Clinical BERT performs the best for EHR notes, while BioBERT does the best for the literature dataset, as expected.

</tbody>
</table>

Conclusion

Data curation is an integral and time-consuming part of informatics research. Accelerating data curation is vital for widening the bottleneck in the research data pipeline. Our preliminary extraction results show promise, but there are multiple avenues for further improvement. Currently, each form field is extracted individually. However, form fields have dependencies which can be learned if they are trained together, improving overall extraction performance. Moreover, extracting the location along with the value can provide more transparency into the model. Allowing curators to seamlessly and symbiotically work with the system is crucial to the success of informatics research.

Primary Care Providers’ Needs for Usable Clinical Prediction Rule Presentations

Ivan Rahmatullah, MD MPH1,2, Kari A. Stephens, PhD2,3, Allison M. Cole MD2, Andrea L. Hartzler, PhD3.
1Faculty of Medicine, Universitas Airlangga, Surabaya, Indonesia; 2Family Medicine, University of Washington; 3Department of Biomedical Informatics & Medical Education, University of Washington, Seattle, Washington, United States

Abstract

Clinical prediction rules (CPRs) can improve the accuracy of clinical diagnosis and prognosis and increasingly depend on electronic presentation to clinicians. Yet we lack design studies of CPR presentations based on clinician needs that can improve the usefulness of CPRs. This survey study reports on clinicians’ CPR needs (i.e., preferences, motivations, and barriers) to inform human-centered design of CPR presentations in the primary care context.

Introduction:
Diagnostic and prognostic errors prevent patients from getting timely testing, treatment, and optimal health outcomes. CPRs, such as CENTOR score for the diagnosis of streptococcal pharyngitis and Framingham Score to estimate cardiovascular disease risks could improve the accuracy of clinicians’ diagnoses and prognoses. A review study of 400 CPRs identified primary care as the most targeted study settings. However, CPR presentations that are designed to drive high usability for CPR implementation based on clinician needs remain largely unexplored.

Methods: To characterize clinician needs for CPR presentations, we recruited primary care providers (PCPs) from the WWAMI region Practice and Research Network to participate in an online survey. The survey was executed using REDCap supported by the University Washington. The survey asked about PCP characteristics (i.e., type of provider, years of practice, and CPR experience), preferred CPRs, and motivations and barriers to using CPRs.

For CPR preferences, we presented 11 validated and commonly used CPRs in primary care in the US and asked respondents to rank the top three as most useful. Respondents then ranked their top three motivations out of seven options (i.e., CPRs improve diagnostic/prognostic accuracy, are easy to use, save time for diagnosis/prognosis of a disease, avoid unnecessary costs, improve shared decision-making with patients, are recommended by guidelines, are used by many colleagues). Finally, respondents identified barriers to use of CPRs based on seven options (i.e., CPRs disrupt clinical workflow, don’t improve diagnosis/prognosis accuracy, give results that are difficult to interpret, consume unnecessary time during patient consultation, give results that can be difficult to communicate to patients, interfere with clinician autonomy, increase the risk of being sued). We drew these motivation and barrier options from published reviews and qualitative studies. We summarized survey responses with descriptive statistics.

Results: Of the 25 respondents (34.7% response rate), 80% were MDs (others were PAs, DOs, ARNPs, and Residents), 56% had more than 10 years of primary care experience, and 72% had at least moderate CPR experience. CPRs for diagnosis of depression (i.e., PHQ9/PREDICTNL) and stroke risk (i.e., CHADS2) were preferred as the most useful CPRs, both selected by 84% of respondents. The next most preferred CPRs were CENTOR Score and Framingham Score that were both selected by 44% of respondents. The other CPRs (e.g., CURB score Bacterial pneumonia score, BCRAT, Diabetic foot screen tool, PredictAL, Marburg heart score, and Flu score) received between 0 to 32% selections. For motivation, respondents prioritized ‘easy to use’ (64%), improve diagnostic and prognostic accuracy (56%). For the barriers, the most selected items were disruption to clinical workflow (52%), difficulty communicating CPRs to patients (48%).

Conclusion: Finding identified several targets to address PCP needs for successful implementation of CPRs in practice (i.e., preferred CPRs and prioritized motivations and barriers to use CPRs). Highly ranked CPRs in our sample align well with prior research showing stroke risk (i.e., CHADS2) and depression (i.e., PHQ9) as the most preferred and easy to use CPRs. Findings add prioritized barriers (i.e., workflow disruption and communication difficulties). In addition to supporting prior work, findings add a well-defined list of CPR preference, motivation, barriers from a well-defined target population of PCPs who could benefit from CPR presentations in practice. Findings can inform future design research on CPR presentations that are easy to use, avoid workflow disruption (e.g., by integrating CPR presentations into electronic health records) and address patient communication.

Informatics to Power Post-COVID Care: A Framework for Patient Care and Secondary Data Use

Sritha Rajupet MD MPH, Rachel Wong MD MPH MBA, Donna Moller RN-BC, Lisa Maldonado, Tricia Weisse, Tahsin Kurc PhD, Janos Hajagos PhD, Hasit Shah MBA, Mary Saltz MD, Joel Saltz MD PhD, Veena Lingam MD
Stony Brook University Hospital, Stony Brook, NY

Introduction
With over 2 million cases of COVID-19 in New York, approximately 30% of patients have persistent symptoms after infection1-2. Stony Brook Medicine (SBM) launched a Post-COVID multidisciplinary clinic to support patients with Post-Acute Sequelae of SARS-CoV-2 infection (PASC) with primary care and specialty services3-4. Data from PASC forms needed to be integrated into a pre-existing SBM COVID-19 Data Commons, with the goal of identifying a cohort for future researchers to investigate clinical characteristics of PASC, symptom course, and their impact on management and treatment.

Methods
To capture Cerner Millennium™ EHR data in a structured format, we identified Powerforms™ and e-Clipboard™ functionalities that enabled integrated EHR forms to be sent via the patient portal. While building these tools, we leveraged Microsoft Forms™ for interim data collection. With the PASC clinic director, we designed and validated the forms, and developed pipelines to extract, transform, and integrate forms data into the COVID-19 Data Commons. Workflows were developed for forms that required urgent vs. non-urgent review, formalized using swim lane diagrams and approved by risk management and the forms committee for patient safety.

Results
Ten Post-COVID Clinic questionnaires were developed, which could be filled out asynchronously through the patient portal or synchronously by clinical staff using Powerforms™. Both options allowed data to be reconciled by clinicians, integrated into clinical documentation and extracted as discrete data elements. As of July 14, 2021, the SBM Data Commons has incorporated 261 Post-COVID form responses using MS Forms, and 121 using the e-Clipboard. Data quality was evaluated by 1) cross validating visits in the scheduling system with data capture of the associated forms in the Cerner Millennium database to make sure that all responses were recorded and 2) by manual review of 10 sample data extracts to ensure data quality by the clinical informatics team.

Discussion
The PASC clinic was a perfect use-case to develop tools and workflows to collect discrete data on patient-reported outcomes over time. The front-end effort of building integrated EHR forms allowed easy integration into the local Data Commons, future generalizability of the EHR forms functionalities and the ability to scale up data-sharing to national databases with minimal pre-processing.

Factors Historically Influencing Telehealth Use in Six Medical Specialties:
A Systematic Review and Narrative Synthesis

Pavani Rangachari, PhD1, Swapandeep S. Mushiana, M.S.2, Krista Herbert, M.A.3
1Augusta University, Augusta, GA, USA; 2 University of California, San Francisco, CA, USA; 3 Rowan University, Glassboro, NJ, USA

Background: Recent studies preceding the COVID-19 pandemic in the US, have identified wide variations in telehealth use across medical specialties. This is a problem-of-interest, because the US has historically lacked a standardized set of telehealth coverage & reimbursement policies, which in turn has posed a barrier to telehealth use across all specialties. Although all medical specialties in the US have been affected by these macro (policy-level) barriers, some specialties have been able to integrate telehealth use into mainstream practice, while others are just gaining momentum with telehealth during COVID-19. Despite accelerated use of telehealth services during the pandemic, owing to the temporary removal of federal coverage restrictions, uncertainties remain regarding future sustainability. Since macro (policy-level) factors do not serve to explain the variation in telehealth use across specialties, it would be important to examine meso (organizational-level) and micro (individual-level) factors historically influencing telehealth use across specialties, to understand underlying reasons for the variation and identify implications for widespread sustainability.

Methods: This paper draws upon the existing literature to develop a conceptual framework on macro-meso-micro factors influencing telehealth use within a medical specialty. The framework is then used to guide a systematic review and narrative synthesis of the specialty-level telehealth literature, to identify factors historically influencing telehealth use across six specialties in the US, including three “lower-using” specialties (Allergy-Immunology, Gastroenterology, Family Medicine) and three “higher-using” specialties (Cardiology, Psychiatry, Radiology). Article searches were conducted on PubMed. The PRISMA checklist was used to guide reporting of literature reviewed. Three reviewers worked to develop a preliminary synthesis, identify eligibility criteria, explore themes in the data, and assess robustness of final synthesis.

Results: Fifty-three articles were reviewed across six medical specialties. The review identified 12 factors across 3 layers, including: 1) macro-layer (policy-level, legal, structural factors), 2) meso-layer (specialty-level historical telehealth rationale, hospital-organizational, specialty-society, treatment, technological, research, cultural factors) and 3) micro-layer (individual-level provider-and-patient-specific factors). There was limited variation across the six specialties, with respect to factors influencing telehealth use in the macro layer. However, distinct themes emerged among “lower-using” and “higher-using” specialties in meso and micro layers. For example, the historical rationale for telehealth use in “lower-using” specialties, was ‘improving access to care.’ By contrast, “higher-using” specialties had progressed beyond using telehealth to improve access, to using it to ‘improve patient experience/outcomes,’ ‘reduce costs,’ or ‘promote population health’ (Triple Aim). Another key finding was that among “higher-using” specialties, the specialty-societies and hospital-organizations in the meso-layer, proactively promoted telehealth use by influencing both macro-layer factors (e.g., advocating for consistent payment policies) and micro-layer factors (e.g., enabling provider practices to be more tech-savvy & patient-centric).

Conclusions: By identifying a comprehensive set of policy, organizational, individual (and interaction) factors influencing telehealth use across six medical specialties, this review addresses a gap and provides a foundation for future research. Importantly, it identifies: 1) strategies for reducing variation in telehealth use across medical specialties, and 2) implications for ensuring widespread sustainability in the post-pandemic era. For example, to secure sustainable support for telehealth services from hospitals and payers, providers in “lower-using” specialties could undertake telehealth initiatives in line with the Triple Aim framework (e.g., allergy providers could develop capacity for remote monitoring of asthma management to demonstrate reduction in hospitalizations and costs). Likewise, specialty societies and hospital organizations could play a significant role in promoting telehealth sustainability, by advocating for better telehealth reimbursement from public and private payers; and educating & training providers in the effective design and implementation of telehealth services.
Generalizable Gated Recurrent Neural Network based model to predict COVID-19 patient outcomes on admission

Laila Rasmy, MSc¹, Bijun Sai Kannadath, MBBS, M.S², Masayuki Nigo, M.D³, Ziqian Xie, Ph.D¹, Bingyu Mao, MA¹, Khush Patel, MBBS¹, Yujia Zhou, MSc¹, Xiao Dong, MSc¹, Hua Xu, PhD¹, Degui Zhi, PhD¹

¹School of Biomedical Informatics, UTHealth, Houston, TX; ²College of Medicine, University of Arizona - Phoenix, AZ; ³McGovern Medical School, UTHealth, Houston, TX.

Introduction

Though multiple machine learning based predictive algorithms have been developed using secondary electronic health record (EHR) data, these models have rarely been widely implemented or validated in practice despite their high reported accuracy. During the pandemic and by July 2020, Wynants et al reviewed 107 COVID-19 prognostic predictive models, out of which they only found one promising model that deserves further validation. The common challenge for the majority of the studies is the high risk of bias. Training and evaluating models on large diverse data, reporting calibration results, and external validation are among the methods that can help reduce the risk of model bias. Additionally, such models mostly need complicated data preprocessing pipelines that impact their transferability, reliability, and sustainability. In our study, we propose a gated recurrent neural network (GRU) based algorithm that utilizes EHR structured data to predict patient outcomes with minimal need for data preprocessing. We trained our model using a cohort of 243,785 patients from 85 different health systems available through the cloud-based, de-identified COVID-19 patient data derived from the Cerner® Real-World Dataset (CRWD). For external validation and transferability evaluation, we evaluated the model on two held-out hospitals' data from Cerner RWD as well as a cohort of 36,140 patients extracted from de-identified patient data derived from the Optum® COVID-19 EHR-based dataset (2007-2020) was employed for external validation of our model.

Methods

We extracted all patient information available on and before the day of admission, including demographics, diagnosis, medication, procedures, laboratory results, and observations. We trained our model embedding layer on standards commonly available in EHRs such as ICD9/10CM, ICD9/10PCS, SNOMED-CT, LOINC, Multum, CPT-4, and HCPCS. We split our primary cohort into training, validation, and test sets using the ratio of 7:1:2 respectively. We reported the discriminatory prediction accuracy measured by AUC on a held-out test set of 48,781 from 85 health systems. For external validation, we evaluated the model on two held-out hospitals from different Census regions, Hospital 1 from the south and Hospital 2 from the west. We further tested the transferability of our proposed model on the OPTUM cohort.

Results & Conclusion

Our GRU-based model achieved a high discriminatory prediction accuracy measured by AUC as well as good calibration for different tasks including in-hospital mortality (93%), need for mechanical ventilation (93%), long hospital stays (>7 days) (87%), as well as a good calibration. External validation showed a consistently good performance with AUC of 91% and 97% for Hospital 1 (3,469 patients) and Hospital 2 (706 patients) in CRWD, respectively, and 90% on OPTUM cohort for in-hospital mortality. Our results were consistently better than baseline models such as logistic regression by around 3%. To the best of our knowledge, We are the first to train an RNN-based model utilizing medical code embedding for the prediction of COVID-19 outcomes from EHR data on admission. Trained on a large heterogeneous dataset from 85 health systems, our model showed one of the highest reported prediction accuracy, transferability, and consistently good performance on multiple external datasets.

Cardiac patients’ and healthcare providers’ telehealth experiences during the COVID-19 pandemic in Queens, New York

Meghan Reading Turchioe, PhD, MPH, RN\textsuperscript{1}, Alexander Volodarskiy, MD\textsuperscript{2}, Jessica S Ancker, PhD\textsuperscript{3}, Joshua Vapnik, MD\textsuperscript{2}, Sushant Sunkaraneni, MD\textsuperscript{3}, David Slotwiner, MD\textsuperscript{1,2}

\textsuperscript{1}Weill Cornell Medicine, Dept. of Population Health Sciences; \textsuperscript{2}NewYork Presbyterian Hospital-Queens; \textsuperscript{3}Vanderbilt University Medical Center, Dept. of Biomedical Informatics

Introduction: Emerging research suggests that federal policy changes aiming to expand access to telehealth in response to the COVID-19 pandemic may be widening health disparities among racial/ethnic minority and low income individuals\textsuperscript{1}. Cardiac patients are more likely to contract and suffer worse outcomes from COVID-19, and racial/ethnic minority and low-income cardiac patients are at the highest risk\textsuperscript{2}. An understanding of cardiac patients’ and providers’ experiences with telehealth is lacking, but critically needed to tailor telehealth delivery in ways that close disparities.

Objective: To compare experiences with telehealth during the COVID-19 pandemic among cardiac patients and providers at a hospital in Queens, New York, a highly diverse county that has been severely impacted by COVID-19\textsuperscript{3}.

Methods: We conducted a cross-sectional study from August-October 2020 involving a one-time survey with questions about experience with two common types of telehealth, video visits and remote patient monitoring, based on the Technology Acceptance Model. Data from remote monitoring included blood pressure, blood glucose, weight, and cardiac rhythms from wearables or implantable cardiac devices. Cardiologists and internal medicine physicians were recruited by email and completed the survey online. A convenience sample of cardiac patients who recently received care were recruited and completed the survey by phone to avoid biasing the sample towards higher technology comfort. An interpreter service was used as needed. We compared cardiac patients and healthcare providers responses using chi-squared or Fisher’s exact tests as appropriate. The Weill Cornell Medicine IRB approved this study.

Results: Fifty-four participants completed the study. Most providers (n=26) were cardiologists (72%). Patients (n=28) had a mean age of 61.6 (SD 17.7) years, and were 64% female, 25% Black, 39% Asian, 21% Hispanic/Latino, and 28% non-English speaking. Additionally, 32% of patients reported inadequate financial resources and 36% received Medicaid insurance. More than half of participants had experience with both video visits and remote monitoring (Table 1). Compared to patients, significantly more providers had experience with video visits before March 2020. Providers reported significantly higher ease of use and comfort making medical decisions over video visits, while patients reported significantly higher ease of use and perceived treatment quality using remote monitoring data.

| High perceived better treatment*               | 8 (44%)      | 14 (64%)         | 0.37   | 11 (69%)     | 6 (27%)          | 0.01   |
| High perceived usefulness overall*             | 8 (47%)      | 16 (73%)         | 0.19   | 12 (75%)     | 15 (68%)         | 0.33   |
| High comfort making major treatment decisions* | 4 (22%)      | 13 (59%)         | 0.04   | 12 (75%)     | 15 (68%)         | 0.33   |

*Among participants with any experience

Conclusion: Patients perceive remote monitoring significantly improves the care they receive and are comfortable working with their providers to make major treatment decisions based on the data obtained from remote monitoring. Patients are less confident than providers that video visits are useful for their care and they are less comfortable making major treatment decisions during a video visit. Improved technical support and patient education regarding what types of medical decisions may be appropriate to reach during a video visit may improve patient acceptance.

Piloting FDA SHIELD’s LOINC to In Vitro Diagnostic (LIVD) Specification in Five Medical Centers: Implications for Interoperability

Greg Rehwoldt, PhD, MBA¹, Raja Cholan, MS², Andrew Sills, BS³, I. Khalil Appleton, BS⁴, Tim Williams, BS⁴, Natalie Scott, BS⁴, Gregory Pappas, MD, PhD⁵

¹Deloitte Consulting LLP, ²Food and Drug Administration

Introduction: To address laboratory data challenges, the Food and Drug Administration (FDA) sponsored the Systemic Harmonization and Interoperability Enhancement for Laboratory Data (SHIELD) workgroup focused on improving the interoperability of IVD data. One of SHIELD’s solutions is the LIVD (LOINC to IVD) mapping specification, which harmonizes how IVD is represented using LOINC and SNOMED CT. The FDA is funding a SHIELD demonstration program to assess the effectiveness of the LIVD specification in five medical centers’ laboratory settings. In this paper our goals are to (1) describe the laboratory coding information collected from the five pilot sites, (2) assess the extent to which LOINC codes in the LIVD catalog files from IVD manufacturers compare to LOINC codes chosen in information systems in five pilot medical centers, and (3) discuss lessons learned and implications for the SHIELD workgroup.

Methods: We sought to identify gaps and similarities between LOINC codes from the manufacturer LIVD files versus LOINC codes from the medical centers. First, we recruited five medical centers to participate in FDA’s SHIELD pilot. Each medical center was asked to extract 100 LOINC Codes from LIS systems for prioritized tests of interest focused on high risk conditions and SARS-CoV-2 / COVID-19. For each selected test (e.g., SARS-CoV-2 RNA COVID-19), we collected the following data elements: test names/descriptions (e.g., SARS coronavirus 2 RNA [Presence] in Respiratory specimen by NAA with probe detection), associated instruments (e.g., IVD Vendor Model), and LOINC codes (e.g., 94500-6). Next, we collected manufacturer LIVD catalogs containing the LOINC codes per IVD instrument per test from manufacturers. Finally, we compared the overlap between the LOINC codes from manufacturers versus medical centers for the same tests. We evaluated the gaps and similarities by the two sources (IVD manufacturers versus medical centers) to determine what tests/codes were mismatched.

Results: Five academic medical centers were onboarded from five distinct states throughout the United States, ranging in size from 500 to 1,500 hospital beds. Three IVD Manufacturers have submitted 15 LIVD catalogs representing 26 distinct devices, 6,956 tests, and 686 LOINC codes. Table 1 summarizes the data collected from the pilot sites and the matches/mismatches between LOINC codes from the manufacturer LIVD files versus LOINC codes from the medical centers.

Conclusion: The five medical centers vary in how they organize, categorize, and store LIS catalog information. We identified mismatches in how medical centers use LOINC to encode laboratory tests compared to how IVD Manufacturers use LOINC to encode the same laboratory tests in the LIVD catalogs. A summary of key findings include the following: (1) Medical Center LIS test catalogs include data quality inaccuracies with LOINC, such as using codes that are not proper LOINC codes, deprecated LOINC codes, discouraged LOINC codes, and trial LOINC codes; (2) Medical Center LIS catalogs can contain duplicative tests or tests that change meaning over time (identifiers/descriptions change over time); (3) Medical centers expressed that the LIVD catalog is helpful as a centralized platform, taking away LOINC coding guesswork and reducing LOINC coding variation between systems. There is potential for the LIVD catalogs to help improve semantic interoperability and data quality of LIS data; there is also room for improvement of the LIVD catalog data elements and accessibility of LIVD files by labs. Enhanced program support for SHIELD is necessary to effectively rollout LIVD in medical centers and promote lab data interoperability nationally. Suggested next steps include additional collaboration among key players in the laboratory ecosystem including standards development organizations, device manufacturers, and medical centers.
Usability Study of a Decision Support Website to Support People Living with Cystic Fibrosis in Shared Decision Making about Lung Transplant

Nick Reid, MHI1, Kathleen J. Ramos, MD MSc2, Mara R. Hobler, PhD2, Lauren E. Bartlett, BS2, Siddhartha G. Kapnadak, MD2, Andrea L. Hartzler, PhD1
1Department of Biomedical Informatics and Medical Education, School of Medicine, University of Washington, Seattle, WA, USA; 2Division of Pulmonary, Critical Care, and Sleep Medicine, Department of Medicine, University of Washington, Seattle, WA, USA

Introduction: Although individuals with advanced cystic fibrosis (CF) lung disease can benefit significantly from lung transplant, many are apprehensive, lack information, and experience barriers to transplant discussions with providers. Patients with advanced CF lung disease often experience ambivalent and complex feelings regarding lung transplant, with some wanting all available transplant information and others preferring to moderate the information they receive. There is a need for shared decision-making tools that help this range of patients prepare for discussions with providers about lung transplant.

Our preliminary focus groups in people with CF indicated that a shared decision-making tool should include didactic educational materials, patient stories, and frequently asked questions (FAQ). Despite the potential benefits of such content, it is unknown what design options CF patients find most usable. Some shared decision-making tools adopt an “author-driven” design that guides readers through content and recommends content that is appropriate. Conversely, “reader-driven” designs present content uniformly and allow the reader to choose independently. This study aimed to delineate which design people with CF find most usable and useful for learning about lung transplant.

Methods: We conducted individual sessions with CF patients to compare the usability of two alternative website prototypes. The reader-driven prototype displayed each content type (didactic, stories, FAQ) as separate sections, allowing participants to freely browse the available content. The author-driven prototype guided the user to complete a survey before displaying recommended content from all three types. During each session, participants interacted with both author-driven and reader-driven prototypes to complete scenario-based usability tasks, then completed the System Usability Scale (SUS) for each prototype. We summarized SUS scores with descriptive statistics, and then compared scores between prototypes with paired t-tests. Website usage logs for each prototype were compared to identify which content type was viewed first by participants and frequencies were summarized.

Results: Fourteen people with CF who had not received a lung transplant completed the study. Table 1 compares SUS scores and frequency counts from website usage logs. The mean SUS score for the reader-driven prototype was significantly higher than the author-driven (90.0 vs. 81.6, p=0.002.) Analysis of website usage logs showed that participants first viewed a wider variety of content types in the reader-driven prototype when compared to the author-driven prototype.

Table 1. Comparison of two prototype shared decision-making tools, author-driven and reader-driven

<table>
<thead>
<tr>
<th>System Usability Scale Score Mean (SD)</th>
<th>Content type viewed first (n)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Overall</td>
<td>Usability</td>
</tr>
<tr>
<td>Author-Driven</td>
<td>81.6 (9.9)</td>
</tr>
<tr>
<td>Reader-Driven</td>
<td>90.0 (8.7)</td>
</tr>
</tbody>
</table>

Conclusion: This usability study demonstrated that people with CF, when learning about lung transplant, found a reader-driven design more usable. This design allowed them increased control to access more varied content within a shared decision-making tool. The reader-driven prototype had a significantly higher mean SUS score than the author-driven prototype (90.0 vs 81.6, p=0.002), indicating that participants perceived the reader-driven prototype more usable. These results can inform the design of a shared decision-making tool for people with CF considering lung transplant.

Relationship Between Social Determinants of Health and Total Joint Arthroplasty Complications

Lauryn Remmers¹, Edward Kalpas, MD, MAS, MPH¹,², Priya Radhakrishnan, MD, FACP², Anita Murcko, MD, FACP, FAMIA¹

¹Arizona State University, Tempe, AZ; ²HonorHealth, Scottsdale, AZ

Research Objective
Social determinants of health (SDOH) are the conditions in one’s living environment that affect health, functioning, and quality of life¹. Total joint arthroplasty (TJA) is a surgical procedure to replace a damaged joint with an artificial joint. TJA complications include acute myocardial infarction, pneumonia, sepsis, surgical site bleeding, pulmonary embolism, or periprosthetic joint infection². Previous research demonstrates that Black race, Hispanic ethnicity and poverty were negatively associated with TJA outcomes in veterans³. The goal of this mixed methods quality improvement study is to determine if SDOHs affect TJA complications at a health system in the Phoenix metropolitan area.

Methodology
For this study, records from patients who underwent hip or knee TJAs at any of the five system facilities between 2/2019-2/2020 were included. Demographics and clinical data were extracted from the electronic health record (EHR) via Midas® Care Management with SDOH variables from case manager notes corresponding to food, utilities, housing and transportation insecurities, and interpersonal safety. Complications were identified using ICD-10 codes. SDOH for individuals with and without complications were compared. A multinomial logistic regression was performed in SPSS to identify significant variables. Semi-structured interviews with case managers (n=2), orthopedic surgeons(n=5), and primary care physicians (n=4) were performed to explore care team interactions with SDOH. Interview notes were coded and analyzed based on response frequency and themes.

Results
Of 2,520 patients who underwent TJA, 50 (1.98%) experienced a TJA complication. Of those, 38% screened positive for an SDOH. For those without a TJA complication, 27% screened positive for an SDOH (p=0.093). Most interview participants identified a correlation between socioeconomic status and surgical outcomes. They also recognized that language barriers for Spanish-speaking individuals and family involvement post-discharge are significant factors in TJA outcomes.

<td>0.049</td>
<td>1.050</td>
<td>0.611</td>
<td>0.936</td>
<td>0.317-3.479</td>
</tr>
</tbody>
</table>

Conclusions
This single system mixed methods retrospective quality improvement study demonstrates that patients who screen positive for an SDOH are more likely to experience a TJA complication. We recommend that SDOH assessments be obtained for all patients undergoing TJA, be available to care teams, and be incorporated into care plans to improve outcomes.

An Evaluation of Solor and ANF Assignment to HL7 Knowledge Artifacts Using High Definition Natural Language Processing

Melissa P. Resnick, PhD, MLS, MS¹, Frank LeHouillier, MA¹, Steven H. Brown, MD², Keith Campbell, MD, PhD², Diane Montella, MD², Peter L. Elkin, MD¹²

¹University at Buffalo, Buffalo, NY, USA,
²U.S. Department of Veterans Affairs

Introduction

Standards, such as terminologies, assist with important tasks including, natural language processing (NLP) and semantic interoperability. Unstructured notes written by healthcare providers in the electronic health record (EHR) are often difficult to access. This unstructured text is critical for providing healthcare, data analysis, and research. One can access this text by utilizing a terminology together with an NLP program and a standard statement model, such as, ANF¹. Solor is an integrated terminology constructed in collaboration with the U.S. Veterans Affairs (VA)². Solor combines SNOMED CT (for diseases, findings, and procedures), Logical Observation Identifiers, Names, and Codes (LOINC) (for laboratory test results), and RxNorm (for medications)²,³. A single integrated terminology, such as Solor, allows clinical data to flow between clinical documentation, decision support applications, and physician order entry at the point of care. ANF is a type of information model designed to be independent of the content in the clinical statements. The objective of ANF is to provide a simple and consistent information model for clinical statements. This makes it easier for analysts to understand the data and the manner in which it is stored. The HD-NLP program, previously known as HTP-NLP, is software developed at the University at Buffalo⁴. The HD-NLP is a name entity recognition type of program⁵. The unstructured text from the EHR is input into the HD-NLP program, which then uses a terminology to output tagged text⁶. The HD-NLP can also provide Solor terms in the ANF output.

Methods

HD-NLP was used to process 694 clinical narratives previously modeled by human experts into Solor and ANF. The HD-NLP output was compared to the expert gold standard for 20% of the sample. Each clinical statement was judged "correct" if HD-NLP output matched ANF structure and Solor concepts, or "incorrect" if any ANF structure or Solor concepts were missing or incorrect. Judgements were summed to give totals for "correct" and "incorrect".

Results

113 (80.7%) correct, 26 (18.6%) incorrect, and 1 error. Inter-rater reliability was 97.5% with Cohen’s kappa of 0.948. of 80% with these complex constructions needed for input to clinical decision support.

Conclusion

This iteration of the HD-NLP program provided an acceptable level of accuracy.

Are Smartphone-based Interconnected Personal Health Records Achieving Their Promise?

Tera L. Reynolds, MPH, MA¹, Meghna Kaligotla¹, Kai Zheng, PhD¹
¹University of California-Irvine, Irvine, CA, USA

Introduction

Smartphone-based interconnected personal health records (PHRs) are mobile applications (apps) “through which patients can maintain and manage their health information (and that of others for whom they are authorized) [from multiple electronic health record systems] in a private, secure, and confidential environment.” This type of PHR has the potential to integrate a patient’s clinical data such as laboratory test results from multiple healthcare organizations and to make that data accessible to other health apps to potentially improve their user experience (e.g., by automatically importing medication information). Ultimately, this empowers patients through opportunities to leverage their clinical data (e.g., to improve their health). Through this study, we aimed to investigate the landscape of third-party apps that claim to be able to connect to Apple Health Records, the most commonly available smartphone-based interconnected PHR, or to CommonHealth, the Android-based app developed to serve a similar purpose as Apple Health Records.

Methods

We first generated a list of health-related iOS apps using the Apple App Store’s ranking of the top apps in their Health and Fitness and Medical categories as of October 2020. This resulted in a list of 601 unique apps. In addition, we did targeted searches using keywords based on the initial Apple-defined use cases of apps that may benefit from using clinical data in their functioning—medication, disease management, nutrition, and research—resulting in 199 additional unique, health-related apps. For the final list of 800 apps, we extracted pre-defined elements, including app name and price. To identify relevant apps—those that can use Apple Health Records’ API to import clinical data—two researchers reviewed the title and short description of each app to determine the ‘potentially relevant’ apps (i.e., those that may use clinical data). We identified 81 potentially relevant apps and extracted full descriptions for these apps. We then performed a keyword search of the descriptions using terms such as “apple health” and “apple health records,” and identified 43 apps with at least one keyword. We followed a similar process for the Google Play Store in January 2021, resulting in a list of 611 health apps; three of the descriptions had the keyword “commonhealth.” Finally, TLR and MK manually reviewed the full descriptions of potentially relevant apps. In all phases of manual review, any disagreements were resolved through discussion.

Results

Thirteen of the 800 iPhone health and medical apps reviewed were not available in the U.S., had no description available, and were, thus, excluded. Among the remaining 787 apps, there were only five apps that claim to be able to import clinical data from Apple Health Records (0.6%). These apps fell into four different categories: medication management (MediSafe), condition self-management (Livongo), standalone telehealth (MDLive), and research (All of Us Research and All of Us Research Program). In addition, while three health apps from the Google Play Store were identified as potentially relevant, upon manual review of the descriptions, none of these apps appear to be able to connect to the CommonHealth PHR app.

Conclusion

While there is great potential in computable electronic medical records via apps connected to smartphone-based interconnected PHRs, among the most popular health apps in Apple’s app store, few seem to offer this feature. This suggests that the vision for a robust digital health ecosystem that offers patients flexible solutions to better meet their health and healthcare needs has yet to come to fruition. In addition, care needs to be taken to avoid digital health disparities based on the type of smartphone one owns.

An Interactive Data Extraction System to Create the Living Systematic Reviews and Meta-Analysis

Irbaz Bin Riaz, MD, MS  1,4*, Huan He, PhD  2*, Syed Arsalan Ahmed Naqvi, MBBS  3  
Rabbia Siddiqi, MBBS  3, Noureen Asghar MBBS  3,  
M. Hassan Murad, MD, MPH  4, Hongfang Liu, PhD  2

2Department of AI and Informatics Research, Mayo Clinic, Phoenix, AZ, USA  
3 Dow University of Heath Sciences, Karachi, Pakistan  
4 Mayo Clinic Evidence Based Practice Center, Mayo Clinic, Rochester, MN, USA

Introduction: It takes months to years for conducting rigorous systematic review (SR) and meta-analysis (MA), and it involves developing a search strategy, screening for relevant citations, extracting and analyzing data and ironically the review can be outdated as soon as it published. The current process of creating SRMAs is inadequate to keep pace with rapid influx of evidence as seen in COVID-19 pandemic and dynamic fields like Oncology. Thus, living SRs (LSRs)—which are updated as soon as new evidence becomes available—are necessary to overcome the limitations of conventional reviews. Previously, we have described semi-automating the screening process and analyses, and here we describe our innovative method for data extraction to decrease the effort for creating and maintain LSRs.

Methods: We designed three major modules to facilitate the data extraction: the outline module (Fig. 1(A)), the table module (Fig. 1(B)), and the interactive extractor (Fig. 1(C)). The purpose of outline module is to create a skeleton of tables for data extraction. In the outline module, the users specify the outcomes of interest as well as the structure of the data format required to analyze each outcome. Users are provided with a range of standard options to create summary and data tables and are also provided with the flexibility to generate new variables as necessary. The tables in the table module are automatically populated with studies to be included in the review with the meta-data such as year of publication, author and journal name and rest of tables are completed with the help of extractor module. The studies are listed row by row. Users could select the “check” option and select each particular study for extraction. When a study row in this table is clicked, the interactive extractor would show its text details, including the abstract and full-text PDF files. The extractor module allows user to extract data from associated text. The user simply needs to highlight the text, right-click on the highlighted text, select which attribute the highlighted text belongs to. Then the highlighted text would be saved as the value of the selected attribute for this study. Thus, the tables generated from these modules can be presented to summarize the results of the systematic review or perform further analyses such as pairwise or network meta-analyses, create summary of findings tables and evidence maps.

![Figure 1](image)

Figure 1. The screenshots of our extraction tool. (A) the outline module; (B) the table module; (C) the interactive extractor.

Discussion: Extracting data for LSRs is particularly challenging as it requires management of the key information from meta data and unstructured free texts such as PDF files and web pages. Although existing tools, such Rayyan and Covidence, work well on independent tasks (e.g., screening, data retravel) and generate data files, linking those isolated data files correctly is challenging and requires tedious manual operations in multiple tools. Thus, to ease the burden of using we created a user-friendly interface which brings together data from multiple sources and facilitates data extraction and creation of summary tables and data tables for analysis. Next steps include integrating this data extraction system with our previously created modules for screening and analyzing the data thereby creating a pipeline for true, living systematic reviews which will be updated in “almost” real time.

AI Assisted Mobile Triage App: Assessment of Time to Decide, Choice of Course of Action, Confidence Level, and Perceived Usability

Adam Rich, RN\textsuperscript{1}, Camille Whicker \textsuperscript{1}, Phung Matthews, PharmD\textsuperscript{1}, Charlene Weir, RN, PhD \textsuperscript{1}; Damian Borbolla, MD, MS \textsuperscript{1}.

\textsuperscript{1}Department of Biomedical Informatics, University of Utah, Salt Lake City, UT

Introduction
With advancements in technology, and the ease with which information is readily available online, individuals are utilizing websites and applications to self-diagnose, prior to seeking medical care/advice in a clinical setting. Artificial intelligence (AI) assisted applications are surfacing, with aims of providing accurate diagnoses and courses of action to their users. In this study, we assess the triage decision and accuracy, time to arrive at a decision, the user’s confidence level in their decision, and the usability of the AI assisted symptom triage application.

Methods
The study followed a mixed method design, assessing participant’s decisions regarding medical course of action after reading four clinical case scenarios. Participants were recruited through a snowball technique. Zoom evaluations were utilized to engage with participants. Each participant read through each scenario before deciding their “course of action”. The outcome measures included: 1) chosen course of action (\textit{Go to the ER/Urgent Care}, \textit{Call your Provider}, or \textit{Stay at home and monitor}); 2) time to arrive at that decision; 3) participant’s confidence level in their decision; and 4) perceived usability with the AI app.

Results
Eighteen participants, ranging from ages 20-60, were included; 67\% (n=12) female and 33\% (n=6) male, with over 80\% having completed a higher education. The AI app outperformed the participant’s “usual course” in triage recommendations, when the expected outcome was, “go to ER/Urgent Care” (cases A and D; p values 0.015 and 0.029, respectively), but was not statistically significant in the cases with more conservative expected outcomes (B: call your provider, and C: stay home and monitor; p values 1.000, and 0.173, respectively). The time to completion—the point at which the participant was comfortable deciding when and where to seek medical treatment—using the AI app was greater, resulted in a 2.227-point increase over the participant’s “usual course” of action (Coef. = 2.227, p = 0.000, CI = 1.44 to 3.00). The correct course of action (expected outcome) was different, based on the case. When participants utilized the AI app, there was an increased chance of the participant taking a more cautious approach in seeking medical care (i.e., going to ER/Urgent Care) (odds ratio = 2.37, 95\% CI: 0.94 to 5.96, p = 0.66). The difference in level of confidence, with the decision made, was not statistically significant. (Control: 8.63 vs AI: 8.97, p = 0.250). The System Usability Scale score averaged to 85 among the participants and only 4 out of 18 participants gave a rating of 67.5 or below.

Conclusion
In this study, we found that participants would spend more time making a decision about their care when using the app, but in riskier cases, where the recommendation was to go to the ER, participants made the correct decision. Our results suggest that, while using the AI app, participants were twice as likely to choose a more cautious route of action, such as going to the ER or Urgent care. While our research findings demonstrated a noticeable increase in both time to completion as well as likelihood to seek medical attention at an ER, the level of granularity achieved through the additional questions provided by the AI seems to have the potential to increase the level of confidence experienced by users, when utilizing the application instead of a query via a search engine.
Action-oriented Artificial Intelligence for Suicide Risk Prediction: Prospective EHR-based Validation in a Large Clinical System

Michael Ripperger1, Drew Wilimitis1, William W. Stead1, Kevin Johnson1, Colin G. Walsh1
1Vanderbilt University Medical Center, Nashville, Tennessee

Introduction
Suicide prevention begins with risk identification. Numerous risk models using complex combinations of factors have been published internationally. Almost none have been implemented into clinical systems because of challenges including generalizability, data availability, reliability, transparency, and complexity. The notable exception is REACH VET, a fully-fledged prevention program with integrated predictive model. Following a five-phased framework, Action-Informed Artificial Intelligence, we completed multiple phases of validation and silent deployment within a vendor-supplied electronic health record (EHR) to predict suicide attempt risk—reaching phase five which rigorously tests system readiness for a trial of clinical decision support to enhance suicide prevention.

Methods
We analyzed prospective and concurrent validity of research-derived risk models on EHR data. Predictions were generated silently for the risk of thirty-day suicide attempt at the time of visit registration for all Vanderbilt University Medical Center (VUMC) inpatient, emergency department (ED) and ambulatory surgery encounters over ten months (6/2019-4/2020) using past diagnoses, medications, and demographics. We ascertained suicidal ideation and attempts via reference diagnostic codes. Cause-of-death data were unavailable. Statistical analyses included discrimination, e.g., number needed to screen (NNS), c-statistics, positive/negative predictive values (PPV/NPV) and Spiegelhalter’s Z-statistic for calibration. Logistic recalibration was applied using the first five months of data.

Results
The system calculated 115,905 predictions for 77,973 patients over 296 days. Performance was good across VUMC (c-statistics for ideation and attempt, respectively: 0.84 [0.84-0.84] and 0.80 [0.80-0.80]); in the Adult Hospital (0.77 [0.77-0.77] and 0.84 [0.84-0.84]); and ED (0.78 [0.78-0.78] and 0.70 [0.70-0.70]). Performance was poor in psychiatric settings (0.63 [0.63-0.64] and 0.54 [0.54-0.55]). NNS to prevent one episode of ideation and attempt in the highest predicted risk deciles were 23 and 271, respectively. NNS for attempt was 256 for men and 323 for women. NNS was 373, 176 and 407 for white, black, and non-white/non-black patients, respectively. In settings with universal screening (ED) and without Universal Screening (non-ED settings), NNS in the top risk declines were 225 and 450. Predictions were miscalibrated (S. Z statistic -3.1, p-value 0.001 across VUMC) in the first five months and improved after recalibration (S. Z statistic 1.1, p-value 0.26).

Discussion
The utility of AI for clinical practice depends on context, setting, and resource-constraints. Settings with universal screening might prioritize NPV to reduce face-to-face screening burden. Clinics with sporadic screening might prioritize PPV to direct prevention to those at-risk. Naturally high NPV and low PPV will be expected given suicidal rarity. Our study demonstrates feasible NNS in the top declines—the number who must receive a test to prevent one event. Unlike a lab test, this model relies on passively collected data and no invasive testing. Performance was best in non-psychiatric areas that resembled the research validation setting and poor in psychiatric settings where risk factors were more prevalent and patients were more likely to be treated for suicidality. Recalibration is necessary to prevent false positives and was a critical step to ensure that predictions potentially shown to providers will reflect reality.

¹University of Saskatchewan, Saskatoon, Saskatchewan, Canada; ²Centre for Addiction and Mental Health, Toronto, Ontario, Canada

Introduction

As efforts are made around the world to triage the damaging effects of the global COVID-19 pandemic, the mental health and wellness of the global population has become a critical area of focus. Loss, isolation, and a multitude of unrelenting stressors have resulted in an unparalleled mental health challenge, placing added strain and burden on overwhelmed healthcare systems and providers. The rapid development of digital health technologies over the last decade has created opportunity to employ these solutions in addressing rising mental health and wellness needs. The purpose of this study is to develop and measure the adoption of a two-way texting service, SaskWell, to improve individual awareness of and connection to existing mental health and wellness supports. As a relatively low-tech intervention with widespread reach, texting is seen as an opportunity to bridge known digital divisions in Saskatchewan communities in delivering improved access to these supports.

Methods

A three-phase mixed-methods approach was used to develop, initiate, and explore the impact of SaskWell. The RE-AIM Framework, a wide-spread implementation tool for planning and evaluating public health initiatives was used to establish three consecutive 10-week iteration cycles of texting over the course of the project. The repeated cycles allow the team to focus on the Reach, Effectiveness, and Adoption of the two-way texting service during Implementation before a concluding exploration of Maintenance. SaskWell is intended for residents of Saskatchewan 16 years of age or older who have access to a mobile device and can understand English and was developed in collaboration with a provincial patient and community advisory committee (PCAC). Users of SaskWell will be recruited through snowball sampling techniques (e.g., organizational listservs, social media, posters, news advertisements etc.). To examine the reach, effectiveness, and adoption of SaskWell, quantitative usage (i.e., engagement, click rate, response rate), polling and demographic data will be collected by users of the service and summarized through descriptive statistics and frequencies. Additionally, qualitative semi-structured interviews and focus groups with users of the service will be conducted following the end of each iteration to further explore the user experience. Interview and focus group transcripts will be analyzed using a qualitative thematic approach.

Results

SaskWell connects users with established digital mental health tools via text messaging along with cueing wellness behaviour through weekly prompts for evidenced based self-care, such as reminders of the benefits of physical activity for mental health or seeking creative outlets as positive coping mechanisms. In addition, weekly text polling questions provided additional data, including items related to the RE-AIM exploration and others tied to understanding service use and acceptability (e.g., How did you hear about SaskWell; Why did you choose to sign up; Have you used digital mental health wellness resource before?). This poster will present data from the initial phase of the project including participant recruitment numbers, initial usage data, and qualitative themes arising from both PCAC and initial user interviews. The data will provide insights into the uptake and use of service, and the benefits of delivering both low- and high-tech mental health and wellness tools via a two-way texting service.

Conclusion

As the world continues to navigate the impact of the COVID-19 pandemic, it is essential that mental health and wellness supports be accessible to all. SaskWell, a two-way texting service, is meant to connect Saskatchewan residents with tools and resources for their mental health and well-being during the COVID-19 pandemic and beyond. Building on the SaskWell foundation, the research team plans to expand this project into a national two-way texting service to support Canadian mental health and wellness as the long-terms effects of COVID-19 continue to be revealed in the months, and possibly years ahead.
Towards Measuring Real-World vs. Theoretical Impact: Evaluating Health Information Exchange (HIE) Using an Enhanced Method

Rebecca L. Rivera, PhD, MPH, CPH1,2, Heidi Hosler, BS1,2, Saurabh Rahurkar, BDS, DrPH3, Richard J. Holden, PhD, MS2,4, Joshua R. Vest, PhD, MPH1,2, Jeong Hoon Jang, PhD1,4, Jason T. Schaffer, MD4, Julia Adler-Milstein, PhD5, FACMI, Titus K. Schleyer, DMD, PhD, FACMI, FAMIA2,4

1Indiana University Richard M. Fairbanks School of Public Health, Indianapolis, IN; 2Regenstrief Institute, Inc., Indianapolis, IN; 3CATALYST Center, The Ohio State University Wexner Medical Center, Columbus, OH; 4Indiana University School of Medicine, Indianapolis, IN; 5Department of Medicine, University of California, San Francisco, CA

Introduction
At #AMIA2019 we presented the development, and #AMIA2020, the implementation, of an enhanced method to evaluate the causal effects of HIE on healthcare processes and outcomes (1,2). Combining quantitative data, such as emergency department (ED) site, HIE use logs, provider roles, visit reasons and dates with qualitative clinician survey and focus group data offers a comprehensive method to evaluate HIE implementations. It allows organizations that implement HIE across multiple sites to evaluate its outcomes in a pragmatic, meaningful way.

Objective
The objective of this study was to apply this enhanced method to evaluate the impact of implementing Health Dart, a Fast Healthcare Interoperability Resources (FHIR)-based app, on HIE use across multiple EDs within a healthcare system. Health Dart integrates clinical information related to the 7 most common ED chief complaints directly into Cerner from an HIE that was previously only accessible via web portal.

Methods
In a stepped-wedge causal study design, 14 EDs were assigned to 4 waves of 3-4 EDs based on geographic regions. This practical and robust study design allowed for each ED to serve as a control before the FHIR app was implemented between August 2019 and October 2020, thus controlling for validity threats due to historical trends (e.g. COVID-19 disruptions). HIE use, measured as FHIR app or web portal access during a patient encounter, was linked to provider and patient data. The unit of observation was the patient-level encounter clustered at the ED level (n=209,207). A logistic regression model based on a generalized estimating equations approach (GEE) was used to estimate and compare the odds of HIE use between pre- and post- app implementation, while accounting for within-ED correlation and adjusting for ED waves. Data from focus groups with clinicians examining their experience with the intervention will be conducted from April 2021 to June 2021 and presented with quantitative data in this poster at #AMIA2021.

Results
The odds of HIE use was 48% higher in ED encounters after implementation of the FHIR app than in encounters before implementation (OR=1.48; SE=0.20; 95% CI: [1.13, 1.94]; p=0.004). Among 14 EDs, the median increase in HIE use after the intervention was 2.5% (IQR: [1.9, 3.2]), with a nearly 5% increase observed for some EDs.

Conclusion
Implementation of Health Dart and an enhanced evaluation method revealed increased HIE use among ED clinicians after leveraging FHIR to integrate HIE data directly into Cerner.

Recommendations on Building a Sustainable AMIA Centered Around Diversity, Equity and Inclusion Practices—A Preliminary Report
Rubina Rizvi MD, PhD⁰¹; Casey Taylor Overby PhD²; C. Erwin Johnson MD, EdM,MSc³; Tiffani J. Bright PhD, FACMI¹
¹IBM Watson Health, Cambridge, MA; ²Division of General Internal Medicine, Johns Hopkins University; ³Merck CORE, Policy Evidence Research

Introduction
The topic of diversity, equity, and inclusion (DEI) was in the forefront of 2020. The initiatives to strengthen DEI-related structures and policies are relevant, now more than ever, both in the USA and globally. However, it is imperative that these DEI-related activities are long-term and sustainable, as they come with numerous challenges that are often deep-rooted, reflecting systematic and organizational problems. To further DEI efforts, AMIA must redesign the infrastructure of the systems that delay the progression and ensure sustainability of DEI within the organization. We identify and propose a list of strategic shifts and recommendations that when incorporated into DEI practices, better equip AMIA and its leaders to manage, foster, and sustain DEI.

Methods
In the context of ‘AMIA Strategic Visioning Final Report’ (SVFR), created in July of 2020, the AMIA DEI task force (TF) created three themes and corresponding subcommittees to achieve the following three targets: (1) ‘Make AMIA Diverse’—promote and build diverse representation within the AMIA membership; (2) ‘Make AMIA Inclusive’—empower AMIA members to build an inclusive professional organization; and (3) ‘Make AMIA Sustainable’—optimize the infrastructure to sustain AMIA’s DEI development and focus. We report the work of the Make AMIA Sustainable subcommittee. Each subcommittee member (COT, RR, CEJ) independently reviewed the AMIA SVFR that illuminates specific strategic and tactical suggestions based on feedback from AMIA members. Each subcommittee member created a list of strategic shifts and recommendations along with additional input from other subcommittee AMIA TF members. The Make AMIA Sustainable subcommittee met bimonthly for seven months to discuss and brainstorm ideas and learnings. All recommendations were compiled into a comprehensive document to report the goal of each proposed shift, how to implement proposed shifts, and possible outcomes. The recommendations were mapped to each subcommittee (Diverse, Inclusive, and Sustainable), along with existing AMIA committee/working groups to operationalize the recommendations. A final, full report was generated.

Results
A total of 21 unique strategic shifts were identified. Each proposed shift describes how it can be achieved, possible outcomes of each recommendation, alignment with DEI themes, and which AMIA working group can help to facilitate action. Some of the proposed shifts were applicable across more than one theme i.e., Diverse AMIA (N=8), Inclusive AMIA (N=11), and Sustainable AMIA (N=11). Key recommendations for the Governance task force (N=5) were also identified. The three major recommendations approved by the AMIA Board of Directors are listed in Table 1.

Conclusion
The Make AMIA Sustainable subcommittee comprehensively identified ways that AMIA can advance, promote, and sustain a culture of inclusion and belonging through a DEI strategy. To promote, sustain and promote a culture of DEI requires interconnected and explicit DEI goals throughout the organization.
Designing a Clinical Decision Support Framework from Primary Care Quality Performance Metric Dashboard to Individualized Patient Recommendation

Amy Robinson*, PharmD1, Tanya Podchiyska*, MS1, Samson W. Tu, MS1,2, Justin G. Chambers, BS1, Omar A. Usman, MD MBA1, Vishal Duggal, MD1, Anju Sahay, PhD1, Susana B. Martins, MD MS1, Michael Ashcraft MD1, Mary K. Goldstein, MD MS1,2 1VA Palo Alto Health Care System, Palo Alto, CA; 2Stanford University, Stanford, CA

* These authors contributed equally to this work.

Introduction
Integration of clinical quality metrics (CQM) and clinical decision support (CDS) is needed to close the quality gap between patient outcomes currently achieved in routine clinical practice and those theoretically possible when best practice treatment options are applied. Both CQM and CDS aid clinical decision making and can contribute to a unified, yet multi-faceted, quality improvement strategy. In order to provide actionable, patient-specific, evidence-based CDS for patients failing CQM, we designed a CDS framework incorporating CQM and CDS. We used CQMs to focus clinician attention on patients in need of care – those not meeting specific clinical quality targets – via CQM dashboards and actionable patient panel reports. Then we built upon our existing CDS tools to deliver the relevant assessments and clinical recommendations for bridging the quality gap and achieving optimal outcomes for these patients. The CDS provided by our system goes beyond the one-size-fits-all approach used in clinical quality measurement to incorporate individual clinical characteristics, draw upon clinical practice guidelines, and address patient complexity in multimorbidity management. Our design was informed by interviews with stakeholders, discussions with clinical advisory groups, surveys, and follow-up qualitative evaluation.

Methods
We designed a CDS framework to aid the decision-making of primary care teams in chronic disease management. The framework spans population health management and individual patient care and includes: (1) CQM dashboards to assess performance across a number of CQMs and patients, (2) drill-down reports to patient lists with actionable data, and finally (3) a patient-specific view with CQM assessments, relevant CDS clinical data, and detailed patient-specific treatment plan recommendations. The CDS is triggered by the population-based business rules of the CQM. Once triggered, our CDS tools use formalized knowledge from clinical practice guidelines and drug information resources as well as up-to-date patient electronic health record data to evaluate multiple clinical characteristics of the patient and support their multimorbidity management with individualized patient recommendations.

Results
The CQM dashboards support primary care by providing easy-to-view displays of aggregate data with respect to performance measures and may be viewed and compared at different levels: Veterans Integrated Service Network (e.g., region), medical center, clinic, and provider panel of patients. The actionable patient lists provide a population view of patients who are not meeting clinical quality targets, displaying select clinical data and information for following up with the patient. The patient-specific view allows for a more in-depth look at the patient’s clinical status and provides recommendations for clinical practice guideline-based interventions.

Conclusion
Our CDS framework enables chronic disease surveillance and management from the population to the individual patient and delivers actionable, patient-specific, evidence-based advisories for chronic disease control.

PROBLEM OVERVIEW

There has been a massive shift towards telemedicine given the coronavirus disease 2019 (COVID-19) pandemic with the aim to minimize viral spread, and to promote care continuity. However, it is known that older US adults experienced delays in care; therefore, to understand possible factors associated with healthcare delays, we evaluated the effect of chronic medical conditions in both telemedicine readiness and unreadiness during the COVID-19 pandemic using a nationally representative sample.

METHODS

3,379 US elders (≥ 65 years old) from the National Health Trends Study (NHATS) cohort were interviewed in 2018 prior the COVID-19 pandemic, including participants from every state except Alaska, Hawaii, and Puerto Rico, participants reported diagnosis of medical conditions. Telemedicine readiness was defined as reporting any of the following features: able to contact provider online, handle medical insurance online or getting medical information online. Reporting one of the following was indicative of telemedicine unreadiness due to a physical factor: difficulty hearing, watching TV or reading even with glasses or problem making self-understood. Lastly, technical factors leading to telemedicine unreadiness included one of the following: Not owning a telecommunication device, not being aware of how to use such device, or no recent email, text or internet use in the past month. Multivariate regression models adjusted by demographic characteristics were developed to examined telemedicine implementation across medical conditions.

RESULTS

Models were adjusted for age, gender, race/ethnicity and marital status. Telemedicine readiness was associated with cancer, hypertension, and arthritis (odds ratio [OR] ranging from 1.21 to 1.60). Most conditions were associated with telemedicine physical unreadiness (OR ranged from 1.27 to 2.48); lastly, heart disease, diabetes, and mood symptoms to technical unreadiness with OR ranging from 1.45 to 2.52.

CONCLUSIONS

Our findings highlight the importance of chronic medical conditions in telemedicine implementation. Therefore, measures to improve telemedicine implementation should involve education, guidance, and communication with healthcare workers minimizing the gap of care across medical comorbidities. As noted in participants with cancer; where the cancer continuum model has played a crucial rule in telemedicine care while improving healthcare outcomes.
Identifying Open-Source Health Information Technology Tools for Healthcare Researchers

Ronald E. Romero Barrientos1, Siddhartha Nambiar, PhD 1, Tracy Kim 1, Julia Sheehan 1, Laura C. Schubel 1, Sadaf Kazi, PhD 1,2, Kristen E. Miller, DrPH, CPPS 1,2

1MedStar Health National Center for Human Factors in Healthcare, Washington DC, USA
2Georgetown University School of Medicine, Washington, DC, USA

Introduction

Advances in provider and patient facing health information technology (IT) such as electronic health records (EHRs), and personal connected devices have contributed to a rapid explosion of healthcare data. However, the technical and research communities already face challenges related to the scale and reproducibility of these healthcare data. Therefore, it is essential to understand the current landscape in terms of challenges and opportunities related to maintaining the capacity to collect, transform and analyze these data. To help bridge this gap and to better equip researchers with accessible tools that aid in the collection, transformation, and analyzing of healthcare data, our research attempts to identify and present the current state of open-source health IT tools.

Methods

Our research team conducted a comprehensive scoping review of open-source health IT tools leveraging a modified York framework2. Librarians, technical subject matter experts (SMEs), and healthcare researchers were consulted to produce an extensive list of open-source tools that would be screened against inclusion criteria. We developed a codebook to characterize information about each tool’s licensing, documentation quality, community, longevity/pedigree, functionality, security, and support. Tools were also classified into tool types, assigned to a stage in the data lifecycle, and assessed as to whether they enabled interoperability.

Results

Abstracts (n=2,707) and tools (n=636) were retrieved and screened against the inclusion criteria. After screening, a final list of tools (n=121) were identified for domain extraction. A sample of the extracted tools (Table 1) illustrates a brief example of information collected through the scoping review. Regarding the data lifecycle, 54% (n=66) of tools involved data analysis, 31% (n=37) involved data maintenance, and 21% (n=26) involved data capture. Additionally, the tools encompassed more than 13 different open-source licenses and were categorized into 4 different tool types.

Table 1. Sample of popular open-source tools identified through our scoping review.

Conclusion

The goal of our research was to explore, identify and describe open-source health IT tools to be used for research. Through our scoping review we were able to establish a repository of 121 open tools to assist the research and technical communities. By compiling, identifying, and describing a large repository of open-source tools, the research team plans to build on this research by conducting a needs assessment to gauge the gaps in the current state of open-source health IT tools. In its current state, this research may inform technical and research communities of tools that can assist them in collecting, transforming, and analyzing the abundant amount of healthcare data being produced.

Evaluating Brain Age Models in Adolescents with CHD

Joy Roy, B.S. B.A.¹, Ashok Panigrahy, M.D.¹,², Rafael Ceschin, Ph.D.¹,²
¹University of Pittsburgh School of Medicine, Pittsburgh PA; ²UPMC Children’s Hospital of Pittsburgh, Pittsburgh PA

Introduction:

Term-born neonates with Congenital Heart Disease (CHD) have been shown to have developmental trajectories that are more akin to healthy preterm neonates¹. Incidentally, new research shows that adults with CHD are significantly more likely to develop early-onset dementia, suggesting accelerated aging and cognitive decline². Together, it is apparent that there is an aberrant rate of neurological development in patients with CHD during the lifespan. We will attempt to model this development and identify abnormalities through the “BrainAge” framework.

Accurate modeling of a healthy individual’s age based on structural brain imaging has the potential of providing a non-invasive biomarker of aging³. There are several approaches for modeling the normal aging process in humans, which can be used for the early identification of pathologic brain development. Over the past 10 years, the estimation of a Brain Age has gained traction as a robust and reproducible approach to this problem. These “BrainAge” models attempt to predict chronological age, or time from birth, from a large normative sample, and in doing so learn the characteristic brain morphologies that best correspond to relative ages in a general population. Subsequently, these models can be used on a sample population to estimate an individual’s deviation from a normative rate of development, measured as the difference between the predicted (phenotypic) age and the individual’s chronological age.

A significant subset of adolescents with CHD have higher incidence of executive function disorders⁴. Here, we will adapt the brain-age model to investigate the pattern of aging at the critical development period of adolescence, with the secondary goal of developing potential biomarkers predictive of executive function disorders.

Methods:

Preprocessing: Preprocessing of images is done with the use of the FMRIB Software Library (FSL) and Python 3.6. All T1-weighted images have their brains extracted, with bias field correction and tissue segmented within the same generative model (FSL FAST). The images are then registered with an affine registration to a common space. To reduce noise and search space, images are passed through a Gaussian smoothing filter and then downsampled. Principal Component Analysis (PCA) is then used to further reduce the dimensionality of the input data, with the added benefit of standardizing inputs from varying scanner sources.

Prediction: To predict the ages, we implemented a number of machine learning tools and benchmark their effectiveness independently. This study employs a supervised learning approach where we supply the models a training set of images and their corresponding chronological ages and measure their prediction accuracy with a test set. The models include Random Forest Regression, Linear Regression, and finally a 3Dimensional Convolutional Neural Network. To compare performances, we compute a Mean Absolute Error for each tool and compare them to the performance of a Relevance Vector Regression model used in the original framework³.

Content Analysis and Development of a Taxonomy for Value Set Issues

Elise M. Russo, MPH,1 Arianna E. Nimocks, BSc,1 Dean F. Sittig, PhD,2
Adam Wright, PhD1

1Vanderbilt University Medical Center, Department of Biomedical Informatics, Nashville, TN; 2School of Biomedical Informatics, University of Texas Health Science Center, Houston, TX

Introduction

Value Sets are “lists of codes and corresponding terms, from National Library of Medicine (NLM)-hosted standard clinical vocabularies (such as SNOMED CT®, RxNorm, LOINC® etc.), that define clinical concepts,” that provide the foundation for clinical decision support (CDS) and quality measurement (1). The NLM Value Set Authority Center (VSAC) serves as the authoritative repository for value sets maintained by a variety of stewards, or organizations, institutions, and societies that develop and maintain value sets. Creating and maintaining value sets is challenging, and life-threatening errors in CDS or errors in eCQMs (electronic clinical quality measures) affecting payment can occur as a result of improper creation or maintenance (2). These errors are usually due to missing and/or extra codes contained in value sets.

Methods

The ONC (Office of the National Coordinator for Health Information Technology) maintains a Jira issue repository where users of value sets or systems and software that employ value sets (referred to as “reporters” here) can log, track, and discuss issues with subject matter experts (3). We queried the eCQM Issue Tracker Jira, pulling all the reported issues for which the “component” or “issue type” identified was “ValueSet” and also performed a search using the term “ValueSet” (n= 1033). We took a convenience sample of these issues (143) and then reviewed them to determine whether they were true value set errors. Of the 143 issues, 42 (29%) were true errors (non-value set errors included issues with authoring tools, browsers, or general support issues). The authors independently reviewed the reported issues and performed a preliminary content analysis using a deductive approach to determine the causes of value set errors. The individually determined error categories were discussed, adjusted, and agreed upon by all authors.

Results

Of the 42 value set errors, 32 were missing codes, 9 were additional codes and 1 was both. 18 errors pertained to SNOMED codes, 3 to ICD9, 8 to ICD10, 9 to CPT, 12 to RxNorm, 4 to LOINC, 1 to CVX, 2 to HCPCS, and 1 to CDCREC. 9 errors were associated with multiple terminologies. We identified the following causes of errors in the value sets and the number of occurrences of each:

- **Error by Steward in Value Set Creation**: The underlying guidelines and specifications were right, but someone made a simple mistake while creating the value set in the tool they were using [14 Issues].
- **Mismatch between coding systems**: A value set was written by the steward using one code system (e.g., SNOMED) but the reporter's data was coded using a different code system (e.g., ICD10) [11 issues].
- **Reporter misunderstood Steward's intent**: The reporter and value set creator simply disagree about whether a concept should be in the value set [9 Issues].
- **Clinical situation not contemplated**: A clinical situation arose that the value set creator had not contemplated, but likely would have included in the value set if he/she had [5 Issues].
- **Guideline issue**: Multiple guidelines, or multiple versions of one guideline conflict. The value set correctly reflects one of them, but the reporter expected a different one [3 Issues].

Conclusion

Categorizing errors in value sets can help us understand and tailor development of solutions to the specific problem.

Prediction Model for Detecting Asymptomatic Covid-19 Infection in Preoperative Patients

Amit K Saha, PhD¹, Scott Segal, MD, MHCM¹
¹Wake Forest School of Medicine, Winston Salem, NC, USA

Introduction
The COVID-19 epidemic has resulted in an ongoing worldwide epidemic with over 34 million cases in the USA and 180 million worldwide¹. Surgery on COVID-19 positive patients puts healthcare workers at risk during so-called aerosolizing procedures and also puts the patient at high risk for perioperative complications and death². At the present time, most large medical centers test all asymptomatic elective surgical patients for SARS-CoV2, and across the USA, 0.5%-2% of such patients test positive. We examined the prospect of implementing artificial intelligence to model combinations of available preoperative health records and demographic information in predicting the results of asymptomatic COVID-19 tests for patients undergoing elective surgery to derive a selective testing algorithm with low false negatives and sufficient accuracy to significantly reduce the burden of tests required. We sought to compare whether the use different sampling methods would improve predictive model performance.

Methods
With IRB approval, we conducted a retrospective observational analysis of a total of 42,377 asymptomatic patients scheduled for elective surgery at WFBMC who received a preoperative COVID-19 test from April 15, 2020 through January 14, 2021 (overall positive test rate 1.2%). No patient was tested because of suggestive symptoms or known close contact with an infected individual. Subjects were divided into a training set for model development (n= 37,128, data through December 15, 2020) and the test set (n= 5,249, data from December 15, 2020) for testing model performance. The intervals were chosen because both were prior to initiation of COVID vaccination and unchanged rules for testing. The training set was further split 80% for model building and 20% for validation. Variables included previous asymptomatic test results, demographics information, any previous hospital encounter during last year, socioeconomic characteristics, prevalence rate of COVID-19, community mobility index and comorbidities including hypertension, COPD, pulmonary disease, diabetes and cancer.

AUROC (the area under the receiver operating characteristic curve) was compared between logistic regression, random forest, and deep convolution neural network (CNN) models. The predictive model dataset consisted of 122 dimensions. Using feature reduction, we found 56 of the features were duplicative, constant or highly correlated with each other (r > 0.9). The final data set analyzed included 55 features which were standardized for predictive modelling. Because of extreme class imbalance (of all tests positive results were a very small), we used different sampling techniques (undersampling, oversampling, and cost sensitive learning) to improve model performance. Model performance validation was performed with tenfold cross validation.

Results
The preoperative asymptomatic COVID-19 positive rate for training set was 1.19% while for the testing set it was 1.2%. Based on available preoperative health records along with socioeconomic characteristics, the AUROC of the logistic regression model with cost sensitive learning (positive class weight 1:210) was 0.72, that for the CNN (positive class weight 1:270) was 0.66, and for random forest 0.71 (positive class weight 1:120). The highest sensitivity value of 98.31% with corresponding NPV of 99.86% for the logistic model with positive class weight 1:210 can be achieved with a classification cutoff at 0.33. However, to achieve this performance, 92% of all patients would still need to be tested.

Conclusion
Our single center retrospective study corroborates the concept that using machine learning algorithms, predictive models could potentially be used to predict positive COVID-19 test results for patients scheduled to have elective surgery with reasonable performance. Traditional logistic regression outperformed other machine learning algorithms. However, the best performing model still would require testing nearly the entire population, making selective testing with an acceptable false negative rate an elusive goal.

Introduction

Healthcare organizations commonly use dashboards to track and display key performance indicators (KPIs) and metrics related to patient safety. These dashboards support clinicians and administrators in viewing outcomes of care and to drive improvement initiatives. Due to their internal and often confidential nature, these dashboards have not been subject to much research. Consequently, there is little evidence of how they compare in design and functionality, even among affiliated institutions. We analyzed the characteristics of patient safety dashboards from several affiliated hospitals to ascertain their similarities and differences in terms of design, content, and target audience.

Methods

We collected electronic copies of patient safety dashboards from a sample of ten Harvard-affiliated hospitals as part of a larger project (the Safe Care study) aimed at studying the utility of nationally recognized safety metrics for various domains of healthcare. Four reviewers independently collected the following data about each dashboard: what information is being captured, how it is presented, what platform is it present on, the timeframe for which data is displayed, frequently of data refresh, who is the target audience of the dashboard, and whether and how performance status was conveyed for each metric. Our analysis was informed by prior work in evaluation of healthcare dashboards.1-3 We also compared the dashboards within and between hospitals to identify similarities and differences.

Results

The study hospitals included 3 large academic hospitals and 7 community hospitals (including 3 with < 400 beds) which were selected to be representative of the population of Massachusetts. Hospital type and size correlated with type and number of metrics shown on the dashboards, e.g., smaller hospitals may not have dashboards for certain conditions such as hospital-acquired pressure injury (HAPI) that have a low absolute frequency in their settings. Hospitals used different platforms to produce their dashboards (Tableau, Midas, Excel, and Google Sheets). All dashboards focused on either a 2-category or 3-category approach to identify the status of each metric—either above or below a threshold level, or above, below, or within a target level. Most institutions (80%) used color coding in their dashboards to accomplish this (e.g. red/green or blue/orange), but only some (67%) used a legend to explicitly describe the coding. Only 2 dashboards indicated who was responsible for monitoring each metric. All hospitals used a mix of targets, thresholds, benchmarks, and trendlines to indicate how they were performing for each metric, and there was no consistency in their choice of which one to use across different dashboards. Most dashboards included an aim to indicate the direction the metric needed to change to improve.

Conclusion

Even among affiliated hospitals, the variability in the design and function of safety dashboards was extensive. Some sites within the same hospital group used different platforms to produce their dashboards making comparisons for similar metric trends difficult to see. Future studies should assess whether standardizing the content and display of the dashboard or use of specific dashboard design can positively influence accountability and improvement initiatives.

User Centered Design of a Clinical Deterioration Response System for Outpatient Cancer Patients

Megan E. Salwei, PhD, Laurie L. Novak, PhD, MHSA, Shilo Anders, PhD, Kim M. Unertl, PhD, Carrie Reale, MSN, RN-BC, Joyce Harris, MA, Jason Slagle, PhD, Leigh Anne Tang, Michelle Gomez, Zhoujun Sun, Madhavi Mani, Reena Zhang, Akhil Choudhary, Paromita Nath, PhD, Matthew Weinger, MD, Dan France, PhD
Vanderbilt University Medical Center, Nashville, Tennessee, USA

Introduction

Cancer patients are at high risk for adverse events such as medical errors and unplanned hospitalization due to the complexity and toxicity of their treatment. A substantial amount of cancer care occurs in ambulatory settings, leading to vulnerability to undetected, avoidable clinical deterioration outside of healthcare settings. A recent study found that 31% of re-admissions in cancer patients were preventable. Identifying patients at risk for clinical deterioration is a challenge as clinicians are often unaware of patient complications between visits and thus are unable to intervene in a timely manner. With the growing use of health IT, there are opportunities to leverage these technologies to identify clinical deterioration before an adverse event occurs. In this study, we describe the user centered design (UCD) process used to develop a clinical deterioration risk prediction system for cancer patients.

Methods

We are developing a predictive model that generates a patient’s risk for clinical deterioration based on FitBit®, geolocation, EHR, and patient-reported data. The patient-specific risk information will be communicated to the patient’s clinical team if the risk of deterioration becomes high. Our system will then support the clinical team in contacting the patient to prevent an unplanned treatment event (e.g., hospitalization) due to the unanticipated clinical deterioration. Following the UCD process (Figure 1), we developed a prototype of the clinical deterioration risk prediction system. To understand the environment of use (step 1), we conducted 36 observations of clinicians, staff, patients, and their caregivers, across approximately 100 patient encounters. To define user needs (step 2), we conducted interviews with 17 clinicians from a variety of clinics and with differing roles (e.g., surgeon, nurse, pharmacist). We systematically analyzed the observation and interview data to develop a mock-up of the user interface in Sketch, which was iteratively refined (Figure 2).

Figure 1: User centered design process

Results and conclusion

The observations and interviews identified design requirements for the risk prediction system, including how to integrate the system in clinic workflow. We found that nurses would be the primary users of the system, which led us to conduct additional interviews with nurses to gather their specific design feedback. Clinicians reported that our system should include the caregiver’s phone number and support messaging the patient via the patient portal. Finally, we found that patient weight changes are a significant indicator of clinical deterioration. Based on this information, we added patient weight to our system and gave patients smart scales to collect their weight via FitBit®. Next, we will gather feedback on the prototype from various clinical roles. The design and implementation of a clinical deterioration risk prediction system may prevent adverse events for outpatient cancer patients. In the design of health IT, it is important to involve diverse perspectives so that the technology adequately supports users’ work.

Incorporation of American Hospital Association Annual Survey Data into a Health Services Research Data Warehouse

Nichole Samuy, MD, MSHI1, Bunyamin Ozaydin, PhD1, Ferhat Zengul, PhD1
1University of Alabama at Birmingham, Birmingham, AL, USA

Introduction
There are many challenges to developing data warehouses for health services research (1). A common obstacle is that raw datasets must undergo data preparation and integration comprising the extract, transform, and load (ETL) processes, which requires a technical proficiency that many researchers lack. The University of Alabama at Birmingham (UAB) maintains a research data warehouse (RDW) that serves as a resource for faculty and student health services researchers and includes such datasets as CMS Hospital Compare, Medicare Cost Reports, and HRSA Area Health Resources Files. Due to challenges with ETL automation, the RDW does not include American Hospital Association (AHA) Annual Survey data. To address this barrier, we developed a semi-automated process to incorporate AHA Annual Survey data and its yearly updates to the RDW. This poster will present the protocol design of data set incorporation including the process of using the incorporated data to design a multidimensional model and create data visualizations based on a hypothesis-generating research question.

Methods
The AHA Annual Survey of Hospitals is a serial cross-sectional survey that results in hospital- or system-level data involving >800 data fields from >6000 US hospitals (2). The major survey foci fall into 3 data categories and each yearly update is accompanied by an updated metadata file. After the most recent survey update data are extracted as raw CSV files from Wharton Research Data Services, a data portal with which UAB has a data use agreement, the overall incorporation/update procedures involve a four-step process (see Figure 1). Step I updates the metadata table and Steps II-IV update data category tables. Step II prepares a staging table upon which transformation occurs via the execution of a stored procedure and involves the creation of a view that is used in Step III for manual inspection of new columns. Step III also includes creating SQL statements used in Step IV to add new columns to the destination tables. Step IV finishes the process by transforming the new data to the correct data types, importing them to the destination tables, and dropping staging tables. Data quality issues such as missing values were identified by manual inspection after running verification queries, and SQL statements were added to the Step II SSIS package to address the presence of NULL values. After data incorporation, we created a multidimensional data mart including a star schema with measures representing physician and nurse staffing ratios and dimensions including year, geographic location, hospital type, hospital ownership, and bed size.

Results and Conclusion
In PowerBI, we created multiple visualizations including staffing ratios by state, over time, by bed size, and by primary service. To demonstrate the power of our designed process, we linked data from AHA Annual Survey to CMS Hospital Compare based on a common unique hospital identifier. Specifically, we evaluated Hospital Compare measures of stroke education and preventable venous thromboembolism by calculated AHA Annual Survey nurse staffing ratios and generated research hypotheses that could lend themselves to more rigorous study design and statistical analysis.

In conclusion, we successfully created a reproducible, semi-automated process to accommodate integration of AHA Annual Survey data to the RDW that could be applied to SQL server-based data warehouses at any institution with access to AHA Annual Survey data. Finally, we were able to demonstrate the value of this process by linking to other datasets in order to address research questions that could not be answered with a single data set alone.

Analyzing Associated Data Tracking via PubMed Secondary Source ID

Amanda R. Sawyer, MLIS, Vojtech Huser, MD PhD
National Library of Medicine, Bethesda, MD

Introduction
The semantic web promised a revolution in making web content machine readable. For healthcare research, semantic publishing offers opportunities to link literature with associated datasets with the goal of promoting increased transparency and reproducibility. Structured article metadata in PubMed represents partial fulfillment of this vision. For example, the Secondary Source ID (SI) field in PubMed tracks associated data found in life science databases (e.g., SWISSPROT) and clinical trial registries (e.g., ClinicalTrials.gov). Prior to 2016, publishers’ ability to edit databases in the SI field was limited. MEDLINE indexers reviewed each citation and added relevant databases from a controlled list of sources. Due to the ever-increasing volume of research, manual review became untenable and new policy increased journal involvement in article metadata management. Since 2016, publishers have been tasked with including external database sources in the SI field of the article XML submission, MEDLINE indexers manually review only a minority (around 45%) of citations. This study examines the content and past and future added value of SI article metadata.

Methods
The PubMed SI field currently tracks 42 databases, including 20 clinical trial registries and 22 biology databases such as molecular sequence databases or data sharing repositories. We examined the frequency these databases appeared in article SI metadata in a recent year (2019) and analyzed the trend over time by year (2000–2019). Given increased involvement of publishers in article metadata following 2016, we paid particular attention to how this change impacted the trends of individual databases by comparing SI metadata from 2016 to 2017. This analysis was motivated by another project that linked journal articles reporting results of observational research to healthcare real-world data (RWD) databases (e.g., Clinical Practice Research Datalink [CPRD] or PEDSNet) that were utilized in the article.

Results
In 2019, nearly 1.4 million citations were added to PubMed. Of those, 23,662 (1.7%) citations included a value in the SI field. ClinicalTrials.gov and GENBANK were among the most frequently cited databases. Some registries and databases included in the tracked list such as the Peruvian Clinical Trial Registry, BioProject, and the PubChem Compound Database were rarely or never cited. Trend over time analysis revealed some substantial changes to database frequency in SI metadata from 2016-2017. Several databases have declined in citations, likely due to the metadata authoring policy changes. For example, 12 of the 20 tracked clinical trial registries decreased in citations by at least 20%. 10 of the 22 tracked biology databases decreased in citations by at least 20%. Databases identified as priorities for MEDLINE indexers increased in frequency in the SI field, such as figshare (177.5% increase) and Dryad (6% increase). Complete trend data and additional results can be found online in the GitHub repository for this project.

Conclusion
The motivation for this study stemmed from an interest in evaluating RWD databases as candidates for SI metadata. However, given that publishers are the primary authors of metadata and citations including SI metadata have decreased for many databases in the last several years, determining an appropriate scope for the SI field presents an important semantic challenge.

Utilizing a Clinical Decision Support Alert to Increase Nasal MRSA PCR Ordering and Reduce Vancomycin Course Duration

Diana J. Schreier, PharmD, MBA, Patrick M. Wieruszewski, PharmD

1Mayo Clinic, Rochester, MN

**Background:** Despite widespread availability of nasal MRSA tests, a quality improvement project revealed a lack of knowledge amongst clinicians regarding the utility of the test in de-escalation practices. This resulted in low rates of test ordering and potential missed opportunities for vancomycin de-escalation, contributing to potentially prolonged antimicrobial exposure, increased opportunity for vancomycin-induced drug toxicity, and excess resource utilization.

**Methods:** The first iteration of the quality improvement project occurred from September 3, 2018 to September 2, 2019 and involved the provision of education on the utility of nasal MRSA PCR tests and authorized pharmacists to order the test if the prescriber did not order it when placing the vancomycin order. The second iteration of the quality improvement project occurred from September 3, 2019 to September 2, 2020 and included the implementation of a clinical decision support alert in the pharmacist verification queue when a prescriber placed a vancomycin order with a respiratory infection indication, but a nasal MRSA PCR had not been ordered or resulted in the past 7 days (Figure 1).

**Results:** Of 2,183 eligible patient encounters that occurred during the first iteration, MRSA nasal PCR tests were ordered 29.9% (n=652/2,183) of the time. This rate increased to 67.4% (n=1,573/2,331) after the implementation of the clinical decision support alert in the second iteration (Figure 2). The increase in nasal MRSA PCR testing was also correlated with a decrease in median empiric vancomycin course durations from 33.8 (12.0, 54.5) to 27.5 (12.0, 47.8) hours.

**Conclusion:** Clinical decision support tools can be used to reduce vancomycin overuse and improve adherence to antimicrobial stewardship initiatives.

![Figure 1. Clinical decision support alert display in the pharmacist verification queue when an order for vancomycin with a respiratory infection indication is placed.](image)

![Figure 2. Percent of unique patient encounters that met clinical decision support alert criteria and a MRSA nasal swab was ordered within 6 hours of vancomycin initiation.](image)
Using Mobile Integrated Health and Telehealth to Support Transitions of Care among Heart Failure Patients; MIGHTy Heart study protocol

Leah Shafran Topaz PT, MSc1, Brock Daniels MD, MPH1, Kevin Munjal MD, MPH, MSCR2, Meghan Reading Turchioe PhD, MPH, RN1, Rainu Kaushal MD, MPH1 Ruth Masterson Creber PhD, MSc, RN1

1 Weill Cornell Medicine, NewYork-Presbyterian, Department of Population Health Sciences, NYC, NY, 2Emergency Medicine / Population Health, Icahn School of Medicine at Mount Sinai, NYC, NY

Introduction Heart failure (HF) is a cardiac condition that results in a substantial burden on both health systems and patients because of preventable hospital admissions. The all-cause 30-day readmission rates for HF are 20-25% among Medicare patients, the highest for any single condition in the U.S. Outpatient follow up programs and telehealth interventions have been created to prevent readmission among this population, however, due to low appointment availability, challenges surrounding transportation and inability to administer therapeutic interventions at patients homes, these interventions have not consistently demonstrated improvement in clinical outcomes. Mobile integrated health (MIH) is a clinical informatics intervention including telemedicine and community paramedicine. The purpose of the, “Using Mobile Integrated Health and Telehealth to Support Transitions of Care among Heart Failure Patients” (MIGHTy Heart) study is to evaluate the effectiveness of an MIH intervention compared a transitions of care intervention on health utilization, patient reported outcomes and healthcare quality. We also aim to evaluate the factors that support the adoption and implementation of an MIH program from the perspective of multiple key stakeholders (e.g., nurses, paramedics, physicians, patients etc.).

Methods/Results The MIGHTy Heart study is a pragmatic randomized clinical trial (CT.gov # NCT0466254). The dual primary outcomes include hospital readmissions (measured using Medicare claims data at 30 days) and change in quality of life (measured using the Kansas City Cardiomyopathy Questionnaire). Secondary outcomes include preventable emergency department visits, unplanned hospital admissions from the emergency department at 30, 60 and 90 days (using a combination of Medicare claims, the electronic health record); and changes in PROMIS-29 outcome assessments at 30 days. Participants are prospectively enrolled during hospitalization across two health systems in NYC and randomized to either the MIH (intervention) or the transitions of care (comparator) intervention arms (Fig. 1). REDCap is used for all data collection. Follow-up surveys are sent to participants electronically and followed up by phone if not completed in time. The MIH group receives access to specially trained community paramedics who provide medical assessment and care at patients’ home under the guidance of remote emergency department physicians. During the MIH encounter, the medics use a standardized HF assessment, and an emergency medicine physician is contacted via telehealth. Physicians can access the patients’ chart via the institutional EHR to adjust to medications. Diagnostic testing, such as ECG and point-of-care labs, can be performed and treatments such as intravenous diuretics can be administered by paramedics. Participants in the comparator arm receive a follow-up phone call within 48-72 hours of discharge to evaluate their clinical and social status, identify unmet needs, reinforce patient education and confirm follow up appointments. In addition, we will conduct a multi-method study of the factors supporting the adoption, implementation, and maintenance of MIH within the two health systems, including qualitative interviews with key stakeholders and quantitative evaluation of specific implementation parameters, using the Reach Effectiveness Adoption Implementation and Maintenance (RE-AIM) framework. To date, 141 participants have been enrolled, 46.2% female (n=55), mean age 73.13 ± 14.63 years. Trial recruitment is ongoing.

Conclusion Overall, the MIGHTy Heart study will provide evidence regarding the comparative effectiveness of the MIH clinical informatics intervention for patients with heart failure after a hospitalization.
Impact of Social Determinants of Health on Predictive Models in 30-Day Hospital Readmission or Death for Patients with Severe Obesity

Marianne Sharko1, Yongkang Zhang1, Yiye Zhang1, Evan Sholle1, Sajjad Abedian1, Meghan Reading Turchhoe1, Jessica S Ancker2

1. Weill Cornell Medical College, New York, NY; 2. Vanderbilt University Medical Center, Nashville TN

Introduction: Predictive models identify patients at higher risk of readmission or death to provide information for targeted interventions. Existing models, such as the HOSPITAL score model,(1) usually do not incorporate social determinants of health (SDH) information, although this is important to health disparities. Our previous study found that the incorporation of SDH risk factors into the HOSPITAL score model resulted in a small improvement in risk prediction. This improvement was the largest for vulnerable patient groups, including those with obesity. In this study, we hypothesized that the impact of SDH on readmission risk prediction would increase with the severity of obesity.

Methods: We extracted EHR admission data between January 2015 and November 2017 in an academic medical center in New York City, including individual SDH (e.g., race/ethnicity, primary language) and patient residential zip-codes to link to census tract SDH (e.g., median income level, walkability score). We applied the simplified HOSPITAL score model to predict avoidable 30-day readmissions or death (model a). We augmented the model with three sets of predictors: individual SDH (b); census tract SDH (c); individual plus census tract SDH (d). We ran these models on patients with different classes of obesity and compared C-statistics for the performances.

Results: Our study included 14,439 admissions, 26.2% with obesity. The HOSPITAL score for non-obese patients produced a C-statistic of 0.652. Adding individual and census-tract SDH produced significant but small improvements for non-obese patients and those with class 1 obesity. However, there were greater improvements for those with class 2 and 3 obesity. The largest significant increase was found for those with class 3 obesity, with an increase from 0.679 to 0.761. Logistic regression identified significant risk factors for readmission and death based on level of obesity: class 1, dual insurance; class 2, non-English language, foreign born, lower walkability score, and class 3, single marital status, female sex, lower median house income, and lack of insurance.

Conclusions: Predictive modeling to identify patients with severe obesity who are at risk for readmission or death is augmented by the inclusion of individual and census tract SDH risk factors.

A multi-label classifier to screen different types of substance misuse in hospitalized patients

Brihat Sharma, MS1,2, Dmitrii Dligach, PhD2, Hale M. Thomson, PhD4, Matthew M Churpek, MD, MPH, PhD3, Niranjan S. Karnik, MD, PhD1, Majid Afshar, MD, MSCR3

1Department of Psychiatry and Behavioral Science, Rush University Medical Center, Chicago IL; 2Department of Computer Science, Loyola University Chicago, Chicago IL; 3Department of Medicine, University of Wisconsin-Madison, Madison WI

Introduction: Manual screening with self-report questionnaires is the predominant modality to identify substance misuse in hospitalized patients; however, these tools lead to poor adherence because they require additional time and staffing outside of usual care. Our group previously built discrete classifiers for detecting alcohol and opioid misuse to overcome the barriers to manual screening.1-2 We aim to further improve efficiency by building a single multi-label neural network-based classifier that can identify alcohol and opioid misuse using admission notes collected during the usual care from the electronic health record (EHR).

Methods: The training data (n=49530) and validation data (n=5504) were derived from adult hospitalized patients at Rush University Medical Center (RUMC) between October 2017 and December 2019. The Alcohol Use Disorder Identification Test questionnaire and the Drug Abuse Screening Test questionnaire served as the reference labels. The test data were composed of adult patients hospitalized at a separate health system, Loyola University Medical Center (LUMC). The separate health setting at LUMC for testing served as a more rigorous external validation. The reference labels at LUMC for alcohol misuse (n=999) and opioid misuse (n=992) were identified by expert annotation of the patient encounter in the EHR. We pre-processed the first 24 hours of EHR notes using the Clinical Text Analysis and Knowledge Extraction System (eTAKES) to map the text to concept unique identifiers (CUIs) from the UMLS metathesaurus. We used the CUIs as inputs to our machine learning model. A random search approach was applied to optimize the hyperparameters on the validation data tuned to the precision-recall area under the curve (PR AUC). Our final model was a convolutional neural network (CNN) with 1,024 filters of size 5 that consisted of an embedding layer followed by a convolution, fully-connected layers of 32 units, and three sigmoid outputs for alcohol misuse, opioid misuse, and other drug misuse (amphetamine, cocaine, and non-prescribed benzodiazepines). Results are reported on the LUMC test dataset for alcohol and opioid misuse with test characteristics and 95% Confidence Intervals (CI) for the optimal cutpoint derived from Youden’s J statistic.

Results: Our training data corpus at RUMC had 664,836 clinical notes and 37,317 unique CUIs. The case-rate for substance misuse was 4% (n=2,338) at RUMC. The PR AUC of the CNN classifier and the associated test characteristics on the test dataset at LUMC for alcohol and opioid misuse are listed in Table 1. The calibration slope and intercept for alcohol misuse were 0.81 (95% CI 0.71-0.92) and 0.29 (95% CI 0.12-0.46), respectively. For opioid misuse, they were 0.72 (95% CI 0.62-0.82) and 0.08 (95% CI -0.13-0.29), respectively.

</tr>
</tbody>
</table>

Note: Abbreviations (ROC AUC - Receiver Operating Characteristics Area Under the Curve, PPV - positive precision value, NPV- negative precision value)

Discussion: Our multilabel substance misuse classifier had good discrimination in our external validation dataset. An advantage of using a joint model includes information sharing across different types of substance misuse within the model, potential gains in efficiency, and the flexibility it provides to make individual substance misuse predictions. Our next steps include using multi-task learning and pre-training methods to further improve calibration. Our research is supported by the National Institute of Health (R01DA051464).

Introduction
Studies show inconsistent associations of diabetes mellitus (DM) with tuberculosis findings1, which could increase misdiagnosis2. Our objective was to pool published radiographic findings in tuberculosis with and without diabetes.

Methods
We systematically searched PubMed, EMBASE, Web of Science, and BIOSIS for studies of radiographic findings in tuberculosis patients with or without diabetes, and calculated the odds ratios of cavitary disease, lower-lung infiltrates, upper-lung infiltrates, consolidation, bilateral disease, and pleural effusion.

Results
Fifty-eight unique studies presented radiographic findings for 61,903 tuberculosis patients, of whom 12,655 had comorbid diabetes mellitus. Table 1 shows pooled sample sizes and the odds ratios of each finding in diabetic patients.

Table 1. Pooled odds ratios (OR) and confidence intervals (CI) of radiographic findings in tuberculosis patients

<td>1.33 (0.90, 1.98)</td>
</tr>
</tbody>
</table>

Conclusion
Meta-analysis found higher odds of cavitary, lower-lung infiltrates, lung consolidation, and bilateral disease in tuberculosis patients with diabetes, but no higher odds of pleural effusion or upper-lung infiltrates. Because diabetics have a higher risk of active tuberculosis3, this comorbidity may impact future tuberculosis control efforts.

Content in Context – Individualizing Knowledge Resources for Delivery at the Point of Care

Jane L. Shellum, M.H.A.¹, Robert R. Freimuth, Ph.D.¹, Davide Sottara, PhD¹, Aaron Nathan, MS¹, Adam Bartscher ¹
¹Mayo Clinic, Rochester, MN

Introduction
We have previously described the AskMayoExpert (AME) application (1), which was developed to provide answers to clinical questions at the point of care. AME is based on the concept of medical “gist” – concise, relevant, and clinically-applicable answers to clinical questions, written, vetted, and reviewed by Mayo Clinic faculty. The tool is infobutton-enabled and provides a pass-through search to complementary online knowledge resources, offering a single starting point for knowledge retrieval. While AME contains highly curated medical knowledge and is widely adopted by providers, it lacks the ability to situate knowledge within the context of a particular patient. In order to reduce the cognitive effort of clinicians using the application, we propose an approach based on the individualization of the knowledge content, using patient-specific and other contextual data collected at the point of decision-making.

Methodology
Knowledge content is authored using the Darwin Information Typing Architecture (DITA), an OASIS standard (2) for structured documents. DITA semantic markup facilitates the reuse of content and supports conditional formatting through attributes that allow applications to show, hide, and/or (de)emphasize fragments of content based on patient data, including lab values and observations, and keys that allow the application to insert patient-specific values into the content. The Patient data is retrieved using standard FHIR enterprise APIs; a production rule engine processes the data and generates the attributes and key values. A dedicated individualization engine applies the dynamic values to the static content and a rendering engine transforms the resulting DITA XML document into the HTML. The HTML is delivered via a standard SMART-on-FHIR application built on top of a ReSTful Service Oriented Architecture. The application is called using CDS hooks and runs inside of the EHR for a seamless user experience.

Figure 1. The Content Individualization Architecture

Results and Discussion
A usability study of 23 clinicians found that the individualized content was well received. Scalability is a concern; existing Word and HTML content could be migrated to DITA, but a non-trivial amount of editing was necessary to refactor the content and add metadata. To work in real time, efficient individualization and rendering engines had to be developed in house. The content was designed to revert gracefully to the original, static content when patient data required for individualization was not available. In this work, we have demonstrated one of many possible delivery mechanisms; there are many other possible integration patterns that could be explored.

Table 1. Static vs Individualized Content (Example)

<table>
<thead>
<tr>
<th>Static Content</th>
<th>Individualized Content</th>
</tr>
</thead>
<tbody>
<tr>
<td>Medications: A, B, C, D</td>
<td>Currently on 3 medications: A, B, D</td>
</tr>
<tr>
<td>If BP is not controlled on 1 medication, …</td>
<td>If BP is not controlled on 1 medication, …</td>
</tr>
<tr>
<td>If BP is not controlled on 2 medications, …</td>
<td>If BP is not controlled on 2 medications, …</td>
</tr>
<tr>
<td>If not at BP goal using 3 medications, consider …</td>
<td>BP of 138/94 is not at goal, consider Referral</td>
</tr>
</tbody>
</table>

Conclusion
While infobutton queries can leverage some context to find applicable knowledge resources, the context is not applied to the content itself. The conditional formatting capabilities of DITA can be used to individualize content to evolve a knowledge resource into a context-aware, cognitive support application. Future work will include evaluation of user experience and cognitive burden. We will also compare its effectiveness to more traditional forms of clinical decision support and consider options for integration with clinical workflows.

Digital Mental Health Priorities of People Affected by Mental Health Problems: A Pan-Canadian Survey

Nelson Shen, PhD1, Iman Kassam, MHI1, Navi Boparai, MHA1, Clement Ma, PhD1,2, Sheng Chen, PhD1,2, Wei Wang, PhD1,2, Damian Jankowicz, PhD1, Gillian Strudwick, PhD1,2
1Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2University of Toronto, Toronto, Ontario, Canada;

Introduction

The COVID-19 pandemic has accelerated the much-needed innovation and scaling of digital mental health (DMH). Engaging people affected by mental health problems to understand their experiences and perspectives is critical in ensuring that DMH initiatives provide care that is aligned with population needs.1 A pan-Canadian survey was conducted to understand the priority areas in which digital mental health tools can support people affected by mental health problems (i.e., people who are seeking care, currently receiving care, or care partners).

Methods

An online survey was administered in February 2021 by a research technology and data collection company to their national web-based patient pool. A proportional quota sampling based on age, gender, and geographical region was used to capture a sample proportional to the Canadian population. The survey consisted of discrete-choice questions on their digital mental health experiences and priorities. Open-ended questions were used to allow participants to expand on their responses. Descriptive statistics were calculated, and a qualitative content analysis was conducted.

Results

The online survey was completed by 1003 Canadians (410 seeking care, 271 currently receiving care, and 322 care partners) and had a response rate of 27%. Three-quarters of participants (n=766) have used one or more DMH tools to support their care. The top 5 uses were: information searching (n=524); wellness (n=388); virtual care (n=340); care coordination (n=335); and activity/symptom tracking (n=235). A minority of participants were satisfied with the availability of DMH tools (n=287). The remainder of users were either unsatisfied (n=117) or unsure (n=362). Privacy/security concerns (n=331), awareness of tools (n=327), costs of tools (n=221) and equipment (n=161), and aversion to using DMH tools (n=213) were the top barriers to access. The most common open-ended reasons (n=241) for aversion to DMH tools included: need for human interaction (n=83); lack of trustworthiness (n=59); not useful or irrelevant (n=31); questions about effectiveness (n=21); and lack of awareness of tools (n=9). Collectively, the top 5 priorities for digital mental health tools to support themselves or loved ones are: DMH tool curation resource (n=590); mental healthcare system patient navigation tool (n=541); DMH record passport (n=479); secure provider messaging (n=471); and DMH tool hub/library (n=389).

Conclusions

A majority of Canadians have used some form of DMH tool to support themselves or their care partners; however, many were unsatisfied with current offerings or were unsure about what was available to them. Most non-users did not want to replace the human element of care, while others questioned the trustworthiness, relevance/usefulness, and effectiveness of the tools. These factors may add additional burden to those who are navigating the complexities of the digital and physical mental healthcare landscapes1,2. As such, DMH tools that help navigate both spaces were identified as the top priorities. Understanding the perspectives of those affected by mental health problems will allow organizations to focus their efforts to address areas of need and develop supports to foster greater understanding, awareness, access, acceptance, and adoption of DMH tools.

Accessing Electronic Medical Record Data Through a Breast Cancer Prevention Decision Support Tool: Usability and Pilot Testing of a SMART on FHIR API

Thomas Silverman MPH¹, Jacquelyn Amenta², Jill Dimond PhD³, Cynthia Law MPH⁴, Tarsha Jones PhD⁵, Katherine D. Crew MD, MS⁵, Rita Kukafka DrPH, MA¹
1: Columbia University Department of Biomedical Informatics, New York, NY, USA 2: Columbia University Mailman School of Public Health, New York, NY, USA 3: Sassafras Tech Collective, Ann Arbor, MI, USA 4: Columbia University Department of Medicine, New York, NY, USA 5: Florida Atlantic University, Boca Raton, FL, USA

Abstract: We conducted three usability sessions on a decision support tool’s SMART on FHIR API. After modifying the tool based on the usability session findings, we pilot tested the tool at multiple clinics.

Introduction:
We developed a decision support tool called RealRisks that allows users to access their medical record data using a SMART (Substitutable Medical Applications, Reusable Technologies) on FHIR (Fast Healthcare Interoperability Resource) supported application programming interface (API). We conducted three usability studies on this functionality and pilot tested the tool at multiple healthcare organizations.

Methods:
We invited patients at Columbia University’s Irving Medical Center to participate in virtual usability sessions where they completed a prototype of the RealRisks module that uses the API. We recruited participants by email from a list of prior research participants who agreed to be contacted for future research. We conducted the usability sessions using Zoom. Participants shared their screens while navigating the module and expressing their thoughts aloud. We prompted participants with questions on their understanding of the process and aims of the module as well as the data the API returned to them. Sessions were recorded, and the recordings were reviewed and summarized by two researchers (TS and JA). After modifying the module based on the usability study findings, we piloted the module with patient advocates at clinical sites participating in a multisite trial aiming to evaluate RealRisks’ effectiveness in promoting informed choice for breast cancer chemoprevention.

Results:
Usability successes: All three participants understood the purpose of the API module and were able to easily navigate through it. All three participants were able to access their medical record data using RealRisks, confirmed that the data RealRisks pulled and presented was accurate, and were able to edit fields when necessary.

Usability issues: One participant did not realize she had been redirected to her patient portal and needed to log in using her patient portal credentials. All three participants were confused by the language in the consent form template provided by their patient portal (open.epic). For example, participants did not understand that the consent form was referring to RealRisks when using the phrase “app developer.” All three participants had trouble understanding the medical terminology of the data that was returned to them.

Response to usability issues: We created a “what to expect” section to help navigate the patient through the module and added more descriptive text to the data labels that are provided when a user is presented her medical record data. Where we could, we edited the text in the patient portal consent form to make it more descriptive.

Multisite pilot testing: Patient advocates at eight healthcare organizations across the US were able to access their EHR data using the API module. All of these organizations use Epic EHRs for their medical record/patient portal.

Conclusion:
The RealRisks SMART on FHIR API successfully allowed users to access their medical record data. Participants found the usability of this functionality to be acceptable, but they requested detailed descriptions of the process and data involved. After modifying the tool based on these requests, we successfully piloted RealRisks at multiple healthcare organizations that use Epic EHRs. More development is needed to support the API’s functionality with non-Epic products.
Integrative Analyses Identify Susceptibility Genes Underlying COVID-19 Hospitalization

Coronavirus disease 2019 (COVID-19) is caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) which rapidly progressed into a global pandemic. 10-20% of patients known to be infected with SARS-CoV-2 need hospitalization, and among them, a fraction face significant morbidity and mortality. The host’s genetic background is likely to contribute in explaining such diverse clinical outcomes. While previous efforts have demonstrated the role of ACE2 and TMPRSS2 in host defense against COVID-19, there remains limited understanding for the role of host genetics contributing to severe COVID-19 outcome variability. Our work integrates mRNA expression, splicing, and protein abundance data with GWAS of COVID-19 related hospitalization (n=7,885 cases, 961,804 controls; Freeze 4 COVID-19 HGI excluding 23andMe participants*1) to map genes and pathways involved in COVID-19 severity. We performed mRNA/splicing/protein transcriptome-wide association studies (TWAS/spTWAS/PWAS) to identify genes across different genomic regions whose genetically predicted activity is associated with COVID-19 related hospitalization. We investigated the functional role of these genes using phenotype-wide (PhesWAS) and laboratory-wide (LabWAS) association scans to map the functional consequences of these genes in European and African ancestry patients from the Vanderbilt University Medical Center biobank (BioVU; n=85,460). We replicated phenotypes identified from BioVU in various secondary cohorts of multi-ethnic individuals. Using the predicted expression of 22,207 genes across 49 tissues for association with COVID-19 related hospitalization, we identified 123 associations representing 21 genes across 45 tissues at 8 independent genomic regions (p < 2.3E-6). Next, we tested 131,376 splice sites of predicted alternative-splicing expression identified 420, associations representing 43 splice variants for 11 genes across 49 tissues and 5 genomic regions. Comparing genes identified from TWAS (13 genes) and spTWAS (11 genes), 9 genes were implicated by both approaches. Lastly, PWAS using 1,031 predictive models of plasma proteins fitted from population data in the INTERVAL study showed significant associations with the ABO and OAS1 genes. We observed that associated phenotypes and gene functions converged on cytokine-cytokine receptor signaling involved in inflammatory response and on JAK-STAT signaling pathways involved in antiviral host response (p < 0.05). We investigated the clinical influence of these genes by performing a PhesWAS and a LabWAS on their predicted expression values. For the PhesWAS, overall, 40 clinical phenotypes were significantly associated with genetically-predicted ABO, IFNAR2, and CCR1 expression levels; ABO accounted for the majority (30 out of 40) of the associations. Across the 17 phenotype categories, we found circulatory system-related phenotypes were enriched for association (7.23-fold enrichment, p = 8.62E-22). Next, we focused on laboratory results for N=85,460 individuals of European and African ancestry using the Vanderbilt Biobank, BioVU For the 323 laboratory traits tested, we found 32 labs significantly associated with four genes (ABO, IFNAR2, KEAP1, and SLC6A20; p < 1.55E-04). Of these, ABO captured 27/32 significant associations (mean OR = 1.33; p = 8.02E-14 < 1.40E-04). Across the 12 broad lab definitions in our data, our significant LabWAS findings were enriched for blood-related lab measurements (4.21-fold enrichment, p = 1.23E-11). Therefore, our work shows that genes implicated in COVID hospitalizations are associated coagulation-related clinical symptoms and blood-cell-related biomarkers at baseline.
Predictive Model for Inpatient Mortality

Joshua C. Smith, PhD, Allison B. McCoy, PhD, John A. Morris, Jr., MD, Ashi O. Weitkamp, PhD
Vanderbilt University Medical Center, Nashville, TN

Introduction
Over 700,000 Americans die in hospitals annually. The ability to forecast inpatient mortality soon after admission, particularly when death is not anticipated, could identify those who may benefit from additional clinical vigilance or consultation for advanced directives. A comprehensive mortality model must incorporate information from multiple domains: demographics, comorbidities, pharmacy, laboratory, and social determinants of health (SDOH). Previous models often focus on a single domain, are calculated at discharge, or only rarely include SDOH. Utilizing Electronic Health Record (EHR) data commonly available in the first 24-48 hours after admission, we are developing such a model. If successful, this project could reduce inpatient mortality, length of stay, hospital complications, and cost.

Methods
We developed a predictive model using random forests with both simple and engineered features as input. The simple features, those extracted directly from our data sources, included demographic and insurance information, counts of prior admissions and active medications, Braden score, mean arterial pressure, and common laboratory results, among others. The engineered features included Area Deprivation Index (ADI) and two popular comorbidity indices. The ADI is a measure ranking neighborhoods by socioeconomic disadvantage which has been linked with health outcomes. We calculated ADI using patients’ ZIP codes. The Elixhauser and Charlson Comorbidity Indices, morbidity/mortality predictors based on coded problems and past diagnoses, were calculated using the R package. The target output of our model was inpatient death. Our training and test sets consisted of approximately 84,000 and 44,000 historical patient admissions, respectively. As all features were not available for all patients, we developed a three-tiered system by creating slightly different models depending on available data, the major difference being the availability of certain lab results. We built our random forest models using the R package randomForest; individual models were created for each tier using a snapshot of patient data from 24-48 hours after each admission.

Results
Training and test sets contained 1832 and 1125 inpatient deaths, respectively. The AUC for tiers 1, 2, and 3 were 0.891, 0.895, and 0.893, respectively. In Table 1, we report sensitivity, specificity, and other metrics at a variety of decision thresholds. At the 0.10 threshold, for example, the model would have correctly flagged 913 inpatient deaths (81%) shortly after admission, representing 85% of expected and 80% of unexpected deaths (based on hospital mortality committee reviews) over the one-year period represented by the test set. The average time between prediction and death was just over eight days. We also analyzed retrospective alert performance in the one-year test set, as well as which features contribute most to the models.

Discussion
The model is potentially clinically impactful because it forecasts a high percentage of deaths soon after admission, but further development is required to address low precision to reduce false positives and prevent alert fatigue. Also, our use of 5-digit ZIP codes attenuated the impact of ADI for SDOH. Our next steps include calculating exact ADI from the full patient address, as well as experimenting with additional features and machine learning techniques.

Toward Privacy Implications in Developing and Deploying Chatbots in Informatics Research: Analysis of Chatbot Development Platforms

Diva Smriti, M.S.1, Rahil Rathod, B. Tech.1, Jina Huh-Yoo, MHCI, Ph.D.1
1Drexel University, Philadelphia, PA, USA

Introduction
Chatbots, a software application that allows for chat conversation via text or text-to-speech, are used for many purposes including information access, education, therapy, and customer service. Increasing number of researchers use chatbots for human subjects research. Research has showed consumers’ privacy concerns with chatbots1. This is because users interact with chatbots in a natural conversation form, and sensitive information can be unintentionally shared by the users as they converse with the chatbot. More work is required to examine how end-users or human subjects should be informed about how their data may be used in a complex integration of multiple third-party applications (TPAs) in enabling a chatbot. TPAs are those applications that are owned and operated by organizations external to the parent organization of the chatbot platform, that may collect end-users’ information through chatbots.

In this study, we investigated TPAs’ involvement in chatbots, and what information is presented to developers about end-user information being collected by TPAs to bring implications for human subject research with chatbots. We captured the process of creating chatbots from nine chatbot development platforms. We then conducted thematic analysis on chatbot developers’ access and control over end-user information and TPAs’ involvements.

Methods
We searched developer forums and search engines to retrieve a list of popular chatbot development platforms. From a total of thirteen platforms, we excluded the platforms that did not offer graphical user interfaces to focus on those that researchers could easily create chatbots with without in-depth programming knowledge. To standardize data collection, we also excluded voice-based only chatbots that did not offer a text-based and those that were only available to organizations not individual developers. This process resulted in nine chatbot platforms analyzed in this study: Google Dialogflow (P1), Amazon Lex (P2), ManyChat (P3), Chatfuel (P4), Wit.ai (P5), SAP Conversational AI (P6), IBM Watson (P7), Microsoft Bot Framework (P8), and QnA Maker (P9). We simulated a researcher navigating through the process of creating the chatbots, taking screenshots to document the process. We conducted inductive analysis of the screenshots in Nvivo 12 to generate themes on TPA’s involvement in chatbot development and use.

Results
Out of the 9 platforms, P3, P4, P5 required end-users to sign-in through a TPA (Facebook), but only P3, P4 explicitly state that the TPA collects end-users’ profile picture, language, and gender. Only P1 and P2 explicitly gave an option to the developers in enabling or disabling logging of end-user data. Only two platforms, P6 and P7, required developers to agree with their privacy policy, and five chatbot development platforms (P3, P4, P5, P6, P7) required developers to agree with their Terms of Service before moving ahead in the process of setting up a chatbot. These privacy policies and terms of conditions may include terms of TPAs for end-user data, the details of which were not mentioned in the set-up process of the chatbots. All nine chatbot development platforms had options for the developed chatbots to be deployed and/or exported on multiple TPAs to reach a wider audience. Developers had no control or given explicit explanation over the end-user information types being collected as part of chatbot deployment and export.

Conclusion
While for the developers the deployed platforms (e.g., Facebook) of chatbots are TPAs, for end-users, TPAs may be the chatbot development platform itself. Along with our findings, this shows the complexity of multiple TPAs being involved in chatbot development and use. The development platforms fail to explicitly state the information types collected from the end-users by TPAs. This shortcoming brings risks for conducting human subject research with chatbots, where the lack of control over human subject data pose challenges in applying key research ethics principles of data protection and privacy, such as informed consent, voluntariness, and coercion. Future work should examine how multi-parties are involved in end-users’ chatbot use and investigate end-user information types in terms of use and privacy statements across the multi-party applications. Researchers should be mindful of developing and using chatbots in human subjects research and ensure to inform IRB and human subjects on their pitfalls of end-user privacy.

Longitudinal Data of Cancer Patients with Prior Mental Health Diagnoses Show Differences in Demographics, Emergency Visits, and Suicidality Rates

Saira Somnay, William Chen, MD, Lauren Boreta, MD, Steve Braunstein, MD, PhD, Julian C. Hong, MD, MS

1University of California, San Francisco, San Francisco, CA, USA
2University of California, Berkeley, Berkeley, CA, USA

Purpose: Patients with pre-existing mental health conditions may be at greater risk of mental/emotional distress and need more frequent medical attention after a cancer diagnosis. The aim of this study was to compare demographics and disease characteristics/outcomes between cancer patients with pre-existing mental health conditions to those without. Further, longitudinal experience recording in a healthcare system may enable informatics-based approaches to identify patients with cancer, mental health diagnoses, and the outcomes of these comorbid conditions.

Methods: This was an electronic health record-based cohort study, utilizing an institutional Clinical Data Warehouse. A retrospective cohort study was conducted of patients with a new onset diagnosis of malignancy (ICD-10 codes C00-C97, with conversion of ICD-9 codes using the 2018 CMS general equivalence mappings) identified using an institutional de-identified electronic health data warehouse. Data collected included demographics, Charlson comorbidity index excluding cancer, and mental and behavioral health diagnosis (MHD, ICD-10 codes F00-F99), excluding substance use disorders, and emergency visits. ICD codes associated with episodes of suicidality were also extracted. Logistic and Cox regression was performed. Unless specified, models were adjusted for age, sex, cancer type, marital status, race/ethnicity, and Charlson comorbidity score.

Results: A total of 58,066 (46.6% female) patients (aged 18-90 years old) with 107,540 person-years of follow up were identified with a new diagnosis of cancer from January 2012. Of these patients, 2,683 (4.62%) had a prior MHD recorded. The most common prior MHD were depression (N= 939, 35.0%), stress related generalized anxiety (N=860, 32.1%), and Reactive and adjustment disorder (N=331, 12.3%). Based on logistic regression, patients with prior MHD were more likely to be female (OR 1.78, 95% confidence interval [CI] 1.64-1.92), have a higher Charlson comorbidity index (OR 1.61 per point, 1.58-1.65), to be unmarried (OR 1.95, 1.78-2.13) or widowed (OR 2.07, 1.87-2.40), to be a former smoker (OR 1.25, 1.15-1.35) or current heavy smoker (OR 1.42, 1.19-1.70), and were less likely to be Hispanic (OR 0.72, 0.61-0.81). After adjusting for cancer type and other covariates with Cox regression, patients with prior MHD experienced emergency visits at a slightly higher rate (HR 1.26, 1.16-1.36, P=2x10^-4). Patients with prior MHD were also substantially more likely to experience suicidality following a cancer diagnosis (N=32 of 2,683 [1.2%], OR 9.83, 5.82-16.36); overall, N=79 patients received ICD codes associated with suicidality after a cancer diagnosis, at a median of 210 days post-diagnosis (interquartile range 91.8-736.5 days). Patients receiving ICD codes associated with suicidality were less likely to be female (OR 0.58, 0.33-0.98), were younger (OR 0.97 per year, 0.95-0.99), and were significantly more likely to be unmarried (OR 3.75, 2.12-6.88) or divorced (OR 4.31, 1.94-9.17).

Conclusions: Patients with a mental health diagnosis preceding a cancer diagnosis showed increased emergency room visit rates and suicidality rates. The risk factors identified here may help identify patients needing increased medical support following a cancer diagnosis.

Natural Language Processing Algorithm to Detect Terms Representing Risk of Hospitalization or Emergency Department Visits during Home Health Care

Jiyoun Song1, PhD, RN; Marietta Ojo2, MPH; Margaret V McDonald2, MSW; Kenrick Cato1, PhD, RN; Sarah Collins Rossetti1,3, PhD, RN; Yolanda Barron2, MS; Sridevi Sridharan4, MSc; Sena Chae4, PhD, RN; Mollie Hobensack1, BS, RN; Kathryn H. Bowles2,5, PhD, RN; Maxim Topaz1,2, PhD, RN

1School of Nursing, Columbia University, New York, NY; 2Center for Home Care Policy & Research, Visiting Nurse Service of New York, New York, NY; 3Department of Biomedical Informatics, Columbia University, New York, NY; 4College of Nursing, University of Iowa, Iowa City, IA; 5School of Nursing, University of Pennsylvania, Philadelphia, PA

Introduction: More than 3.4 million adults receive home health care (HHC) every year in the United States, but about one in three HHC patients experience unplanned hospitalizations or emergency department (ED) visits during HHC service.1 One strategy for risk reduction is early identification of patients at risk to prevent negative clinical outcomes (e.g., deterioration, rehospitalizations).2 Given a significant portion of risk factors are documented in narrative notes,3 natural language processing (NLP) algorithms can be used for early identification. Thus, this study aimed to test an NLP algorithm to identify terms that represent risk factors associated with unplanned hospitalizations or ED visits documented in HHC clinical notes.

Method: In previous work,4 a list of potential risk factors for unplanned hospitalizations or ED visits were identified using the problems and their associated signs/symptoms from the Omaha System4 (a standardized interdisciplinary terminology). Specifically, 32 problems including 163 individual signs/symptoms were identified: e.g., problem “health care supervision” included signs/symptoms such as “fails to obtain routine/preventive care” or “inconsistent source of health care,” among others. This list of text terms was expanded by mapping to the Unified Medical Language System (UMLS) synonyms. Then, to identify synonyms for the risk terms present in HHC clinical notes, word-embedding model (Word2Vec) was built from a large body of HHC clinical notes that were approximately 1 million notes extracted from the largest HHC agency in the Northeast United States between 2015 and 2017. For validation purpose, gold standard testing set of 500 randomly extracted clinical notes was annotated by three clinical HHC experts for presence of the 32 problems. The observed interrater agreement was 0.89 and all discrepancies were resolved through discussion. Lastly, the NLP algorithm was tested on the gold standard testing set and precision, recall, and F-score for each problem category were calculated. To prevent the error caused by the small sample size, the performance was calculated only for the Omaha System problems documented 10 times or more.

Results: In the testing dataset, 298/500 notes (59.6%) included at least one Omaha System problem (total n = 327 problems). The most common problem documented in the clinical notes was “neuro-musculoskeletal function” (13%) which included signs/symptoms of “decreased balance” and “gait/ambulation disturbance,” “skin” and “mental health” problems followed as the next most common problems documented (8%). The overall NLP system’s performance of problem identification was good (average F-score =0.84), with best results for the “social contact” problem (F-score=1) and the poorest results for the “digestion-hydration” problem (F-score=0.69).

Discussion and Conclusion: This study is the first to test an NLP system to detect terms representing risk of hospitalization or ED visits in HHC. The NLP system achieved good performance on a subset of randomly selected HHC clinical notes. Our findings suggest that information regarding the risk of hospitalization or ED visits was frequently documented in narrative clinical notes and NLP can extract information from narrative clinical notes to improve our understanding of care needs in HHC. Further, these results can inform a development of an early warning scoring system to help reduce negative outcomes in HHC.

Acknowledgments: This study was funded by AHRQ #R01HS027742: Building risk models for preventable hospitalizations and emergency department visits in homecare (PI: Maxim Topaz).

Artificial intelligence identifies the progression of cancer patients with kidney disease

Qianqian Song¹,², Jing Su³
¹Center for Cancer Genomics and Precision Oncology, Wake Forest Baptist Comprehensive Cancer Center, Wake Forest Baptist Medical Center; ²Department of Cancer Biology, Wake Forest School of Medicine, Winston-Salem, NC, USA; ³Department of Biostatistics and Health Data Science, Indiana University School of Medicine, Indianapolis, IN, USA

Introduction As many cancer chemotherapeutic agents causes kidney dysfunction, acute and chronic kidney disease often manifests during different cancer stages. Given the potential link between kidney disease and cancer, investigating the landscape of the progression trajectories in the Cancer Patients with Kidney Disease (CPKD) allows us to better understand their specific progression patterns and heterogeneity among this risk population, as well as the underlying associated risk factors. Electronic medical records (EMRs) covering large CPKD cohorts with demographic, clinical, and socioeconomic features, provide unique and valuable opportunities to capture patients’ developmental status [1]. Through utilizing the graph-based artificial intelligence and a novel graph learning algorithm on EMRs data, we aim to learn the progression trajectory and the risk factors, which will contribute to the therapeutic improvement of patients with both cancer and renal impairment.

Methods and Results In this study, we collect the electronic medical records (EMRs) data at Wake Forest Baptist Medical Center (WFBMC), with 79,434 patients and 508,733 clinical encounters, to outline the progression trajectory roadmap of CPKD. Patients’ health status is described by 18 Essential Clinical Indices across clinical encounters. As the EMRs data are heterogeneous in comorbidities and clinical conditions, we first learn the deep latent representation of the heterogenous raw data through the graph-based artificial intelligence model, i.e., GraphSAGE [2](Figure 1A). Based on the deep represented EMR data, we then implement a novel graph learning algorithm, Discriminative Dimensionality Reduction Tree (DDRTree), to establish the progression trajectories of CPKD (Figure 1B). We also verify that this progression trajectory can be accurately predicted using the k-nearest neighbor model. Importantly, with the learned graph structure, we then annotate the trajectories with clinical, genomic features, and major risk indices of cancer and kidney function. Patients at the high-risk trajectory are associated with known modifiable risk factors such as hypertension, suggesting that the learned trajectories are clinically relevant. Meanwhile, novel and actionable knowledge about preventing the transition from low-risk to high-risk conditions are learned, including drugs with previously unknown nephrotoxicity.

Conclusion The progression trajectory roadmap reveals and highlights the disease progression patterns of CPKD patients. We identify the risk factors and prognostic clinical indicators associated with discovered trajectories. The CPKD progression trajectory roadmap reveals diverse kidney failure pathways associated with different clinical conditions. Specifically, we identify one high-risk trajectory and one low-risk trajectory. Patients who are associated with the high-risk trajectory demonstrate fundamentally different disease progression mechanisms from those at the low-risk trajectory.

Introduction
Nevada’s CARES Housing Assistance Program (CHAP) was implemented in Clark County, Nevada to address employment and financial challenges faced by residents as a result of the COVID-19 pandemic. To enhance access to resources and benefits, Clark County deployed a conversational agent, Watson Assistant (WA), to answer residents’ questions about the program, reduce web traffic to the application website, and screen for program eligibility.1 The conversational agent directs residents who may qualify for assistance to a website where citizens can apply for program benefits. Qualified beneficiaries include people residing in Clark County who have evidence of a pending eviction and who have less than $3,000 in a savings or checking account, with an annual household income below $118,000 or 120% of the median area income in the 2020 CARES Act program and below $79,200 or 80% in the 2021 Emergency Rent Assistance program.

Methods
We conducted a descriptive analysis of user interactions with the CHAP conversational agent and assessed utilization in the first three months of use (between 10/2020 and 12/2020). We also quantified the number of messages and conversations over the most recent 30-day time period. The WA platform can be used to build a conversational interface into a website or automated voice system. The platform can be trained to include customized information related to any specific use case, language preference, location or organizational content. There are four natural language capabilities of WA: (1) understanding content, (2) topic classification, (3) retrieving information from a knowledge base, and (4) generating responses in natural language. When a user enters questions about housing assistance, the conversational agent interprets the question to identify the intent (target of a user’s query) and match it to an internal list of topics that best answer the user’s question. This conversational agent is currently trained to support 29 core topics derived from policy documents including eviction, eligibility, benefit amounts, application status, application approvals, and appeals.

Results
The conversational agent created for the CHAP program was used by over 66,000 users to answer common questions regarding housing assistance in Clark County, Nevada over the three-month study period. In the month between December 13, 2020 and January 12, 2021, the system handled over 230,901 conversations (an average of 1.46 messages per conversation), and 348,521 messages. The most frequent topics of users’ queries over the study period included eligibility status (21,555), coverage (6,766), CARES program summary (5,241), and documentation (1,692).

Conclusion
This study describes successful deployment of a conversational agent designed to assist residents in navigating housing assistance programs in Clark County, Nevada during a public health emergency, demonstrating that WA can be customized to fulfill a variety of informational needs. Conversational agents have the potential to aid in screening a large number of applicants for program eligibility during periods of high need. The ability to answer user questions efficiently may facilitate enhanced delivery of information to a large number of individuals and may increase users’ access to benefits and services.

Automatic Stratification of Tabular Health Data

Skyler Speakman, PhD¹,* , Girmaw Tadesse, PhD¹, Victor Akinwande¹, William Ogallo, PhD¹, Claire Mershon, MPH², Nosa Orobaton, MD, PhD², Daniel B. Neill, PhD³

¹IBM Research, Nairobi, Kenya; ²Bill & Melinda Gates Foundation, Seattle, WA; ³New York University, NY

Stratifying an outcome of interest across a categorical feature is one of the most commonly-used methods of data visualization and exploration. This is because analyzing data through sub-groups is immediately intuitive to a broad range of audiences. Stratification has low barrier-to-entry data requirements and is applicable to almost any form of tabular data. The goal of stratification is to identify sub-groups where the outcome of interest (e.g., mortality, disease burden, access to care) is significantly higher or lower than the overall global average. Identifying these sub-groups is a key first step toward better understanding of complex data and formulating initial hypotheses as to the relevant trends and patterns. AutoStrat (Automatic Stratification) builds on the universal strengths and simplicity of manual stratification while adding high-dimensional scalability and disciplined, data-driven discovery. Manual stratification requires the investigator to presuppose the categorical feature to view the outcome of interest through. This may be repeated for multiple features separately in a manual process. In some cases, two features (e.g., age decile and gender) may be used together. However, going beyond two or three features introduces computational complexity from the exponentially-large search space of possible sub-groups to stratify across. AutoStrat efficiently stratifies over multiple features simultaneously and returns the strata (i.e. sub-group or sub-population) that has unexpectedly high (or low) outcomes as compared to the mean. AutoStrat builds on the subset scanning literature and Bias Scan in particular. We frame AutoStrat as a search problem with the goal of finding the “most anomalous” subset of the data by identifying which sub-population a naive predictive model is most biased against.

AutoStrat was applied to the Alliance for Maternal and Newborn Health Improvement (AMANHI) study data and focus on ~21,000 women/births in Ghana. 1.53% of these births resulted in a neonatal mortality. The identified strata was births at home where either a doctor or midwife was the delivery person. This group included 361 births with 153 deaths (42.4%). This group had a 28-fold increase in the proportion of neonatal mortality as compared to the overall proportion of 1.53%. This sub-population contained 46% of all neonatal deaths in the Ghana study. AutoStrat differs from explaining predictions made by machine learning models that have learned feature interactions. Rather, it discovers which sub-population shows the most evidence of higher outcomes than the global average without any predictive modeling assumptions in place. This pivot from fitting regression models (or interpreting black-box machine learning models) to understanding data through anomalous sub-populations represents an important direction in medical informatics and data science research. Code for AutoStrat is publicly available through the AI Fairness Toolkit. This work is funded by Bill & Melinda Gates Foundation, investment ID 52720.

Introduction
The World Health Organization (WHO) defines health as “a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.” Social Determinants of Health (SDoH) aim to address the external factors that impact health outcomes. As healthcare moves to address SDoH, data from Social Work (SW) should be incorporated. Social workers have been addressing disparities in our communities for over a century. They collect extensive and comprehensive information through assessment and evaluation during the provision of care. The SW record captures accurate and pertinent information that could contribute data to SDoH. This study aims to identify what information is currently available in SW records that can be collected and aggregated for SDoH.

Methods
SDoH categories and concepts were identified by subject matter experts (SMEs). To assess the contribution of SW documentation to SDoH information, we reviewed a sample set of SW psychosocial assessments that were available to the lead author and encoded the extracted SDoH concepts using SNOMED CT. Web-based searches were conducted to gather collateral information and validate team discussions. Findings were documented and reviewed by SMEs to reach consensus.

Results/Discussion
The following sections in a standard SW psychosocial assessment were identified: Demographics, Education, Employment, Family Support, Social History, Medical Conditions and Precipitating Events, Discharge Planning, Mental Health/Substance Abuse, Hospitalizations, Recommendations/Referrals, and Patient Strengths. Though these topics are occasionally mentioned in provider documentation, they are consistently documented in SW assessments. In the following table, we provided two examples encoded to SNOMED CT.

<table>
<thead>
<tr>
<th>SW section</th>
<th>Language in psychosocial assessment</th>
<th>Coding (SNOMED CT)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Condition precipitating admission</td>
<td>Pt was found in front of a 7-11 having uncontrollable seizures. The shelter clinic reported he had not filled his seizure medication for over a month. Pt reported that he was unable to afford his refill.</td>
<td>715036000</td>
</tr>
<tr>
<td>Discharge planning</td>
<td>Pt is chronically homeless and reports he does not have any family. He only receives $450 a month in Social Security Disability. SW also got pt on the waiting list for a Housing Choice Voucher (HCV).</td>
<td>329110000</td>
</tr>
</tbody>
</table>

On average, a SW assessment resulted in 12-20 unique SDoH concepts. Unfortunately, SW assessments are inconsistently formatted and stored in EHRs: Free text notes, MS Word documents, faxes, surveys, screening tools, etc. Even when an EHR SW assessment module is available, the data collected is most often not encoded, let alone standardized or interoperable. While EHR vendors are more frequently incorporating SW assessments into their platform and involving SW in the development, there is no standard for data collection and extraction. Industry efforts to develop a consensus list and organizational efforts to create terminology are a start to ensure that the necessary SDoH concepts are created. We need to look forward to how SDoH data will be captured from patients and how this aligns with SW practice. While the development effort is not trivial, it may still be more realistic than placing the burden of collecting SDoH on already overworked physicians. Further studies could be conducted on extracting and encoding SW assessments for SDoH compared to the data encoded from providers in EHRs.

Conclusions
Healthcare organizations that utilize social workers are frequently in possession of large amounts of SDoH data but are not extracting, analyzing, or drawing meaningful conclusions from it. There continues to be a need for alignment between the clinical workflow of social workers and EHR workflow while closing the gaps between social services and providers. It is critical to involve social workers in the development and design of standard terminologies and software systems while advocating for the SDoH movement.
Comparing Language Model Vocabulary Coverage on Clinical Documents

Bryan D. Steitz, PhD; Adam Wright, PhD
Dept. of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN

Introduction
Large bidirectional language models have transformed the field of natural language processing (NLP). These models utilize tokenized word sequences as inputs, and context-dependent word embeddings, which enables them to capture semantic meanings in text. The degree to which the language models can calculate accurate word embeddings depends on the extent to which their internal vocabulary matches text to be processed. A key example of a large bidirectional language model is BERT, which was trained on Wikipedia and a set of over 11,000 unpublished books. Many published models have retrained word embeddings on a domain-specific corpus (for example, biomedical text), but most of them have used the base BERT vocabulary, leading to many unknown input words. The goal of this study was to train a new vocabulary on a corpus of discharge summaries and compare coverage with popular language model vocabularies on corpora of clinical documents.

Methods
To develop our vocabulary, we extracted a random sample of 150,000 discharge summaries from January 2019 to February 2021 from Vanderbilt University Medical Center’s Epic electronic health record (EHR) system. We preprocessed the text to remove accent characters and split the text on whitespaces and punctuation. We trained cased and uncased 30,522-item wordpiece vocabulary with the preprocessed text using the HuggingFace Transformers library.1 We compared our vocabulary with the cased and uncased SciBERT2 and BERT Base3 vocabularies on random samples of 10,000 discharge summaries, progress notes, and patient instructions. We preprocessed each note by removing non alphanumeric characters. To test uncased vocabularies, we also converted all words to lowercase. For the purposes of comparing coverage, we tokenized each clinical document in its entirety, regardless of length.

Results
The average document length was 895.0, 527.9, and 493.3 tokens for discharge summaries, progress notes, and patient instructions, respectively. We present in Table 1 the percentage of unknown tokens encoded by each vocabulary. BERT and SciBERT had much lower success in matching clinical documents compared to our domain-specific vocabulary.

Table 1: Percentage of Unknown Tokens by Vocabulary and Document Type

<td>1.2%</td>
</tr>
</tbody>
</table>

Conclusion
Adequate vocabulary coverage is integral to obtain accurate contextual word embeddings. Previous work has found that applying a domain-specific vocabularies can improve NLP performance across multiple tasks.2 We hypothesize that training domain-specific and site-specific vocabularies and word embeddings can further improve state-of-the-art performance and transfer learning, which we will test in future work.

Use of the Electronic Health Record in Pediatric Medicine to Capture and Highlight Gender Identity in Order to Better Ensure Gender Affirming Care

Stacey T. Stokes, MD MPH1, Jessica Herstek, MD1

1Children’s National Hospital, Washington, DC

The number of gender diverse youth is growing in the United States, and with higher rates of negative health outcomes including depression and suicidality, at-risk behaviors, and bullying compared to their cis-gender peers, this cohort is a two-fold vulnerable population that is currently not having their needs met in the pediatric healthcare community. While documentation of gender identity (GI) is explicitly targeted within federal and academy initiatives, pediatric institutions and providers have been slow to respond. Many transgender patients are still educating their providers on GI language, and most pediatricians do not ask GI-specific questions during visits. This leads to a patient-provider relationship that extends the non-affirming environment and has impacts on patient well-being and interactions with healthcare professionals. Institutions can take several steps to ensure equity when considering gender affirming care (Table 1).

Table 1: Steps for Healthcare Institutions to Consider in Providing Gender Affirming Care

Gender Identity Documentation Implementation: A Proactive Model

The objective of our project was to uplift the universal demographic banner bar in our EHR to highlight GI-related content and allow providers and nursing staff the ability to quickly edit the information for real-time updates. Our clinical informatics team collaborated with our organization’s Diversity, Equity and Inclusion (DEI) taskforce and our EHR vendor (Cerner, Kansas City) to integrate both custom and standardized tools to capture sexual orientation, gender identity, affirmed name, and preferred pronouns, in addition to birth sex and assigned name, and have the information display face-up on the banner bar for clinical and administrative staff. The unique partnership in the spring of 2021 involving three stakeholder groups allowed for language integration and understanding that would not have been possible otherwise. Physician informaticists designed the banner bar layout, DEI subject matter experts (SMEs) reviewed content and education language, and EHR architects implemented the changes. Buy-in from DEI SMEs and hospital leadership was essential to this change success. Further refinement of the functionality and staff education are ongoing to ensure gender-affirming language is used and captured in an empathic and inclusive way to create a positive patient-provider relationship.

The data not only allows for better care which has several patient-centered benefits, but aims to improve individual and population health outcomes, aid in LGBTQ+ research, and improve information sharing for public health interventions to reduce disparities. Pediatric health care providers should prioritize GI understanding and documentation to ensure gender-affirming care, and therefore overall care, for all patients.

Introduction

The effective visualization of information is a key informatics process, yet methods to use visualizations for clinical communication is understudied. Well-designed infographics (graphics that convey information) have the potential to augment communication regarding Human Immunodeficiency Virus (HIV) by providing complex information in simple, visually appealing ways. This can be useful when patients and providers have different cultures/languages, as is the case for many Latino persons living with HIV (PLWH) who receive care in the United States. This disconnect between patient and provider is just one contributor to the HIV-related disparities experienced by Latino PLWH, and may be improved through infographic use. The purpose of this study was, therefore, to assess if using infographics to convey health information with Latino PLWH can improve communication and lead to better health outcomes.

Methods

We conducted a longitudinal pre-test post-test study at a clinic in Manhattan. We trained two bilingual researchers to use infographics (English/Spanish) that contain common HIV-related concepts and were previously designed by our team.1 Then, we enrolled 30 adult Latino PLWH. After three of their normal appointments, a researcher offered health information specific to their needs using infographics. At each session, we extracted CD4 count and viral load from medical records (primary outcomes) and participants completed questionnaires containing validated scales to measure HIV-related knowledge, satisfaction with provider, self-efficacy to manage HIV, adherence, and self-reported health status (secondary outcomes). Outcomes were selected using a theoretical model that identifies ways communication may influence health outcomes.2 We first summarized all variables with descriptive statistics. Then, we conducted chi-square tests for the categorical outcomes and Kruskal-Wallis nonparametric tests with the predictors: visit number (1-3), new patient status, and if visits were pre or post the COVID-19 research pause, for continuous outcomes.

Results

Participants (N=30) were mostly male (60%) and Spanish-speaking (60%), with a mean age of 52.4 years (SD±14.2). Changes in CD4 count and viral load were not significantly different. Knowledge scores improved between visits (p<.0001 for both time points). Health status also improved over time (p=.02). Knowledge scores (p=.04) and current health status (p=.01) also changed significantly from before to after the COVID-19 research pause.

Conclusion

This study provides preliminary evidence that infographics may improve communication and health outcomes among Latino PLWH. Observed changes are likely to be clinically significant, as participants demonstrated more understanding of self-management strategies and reported better health, but this must be further studied. The initial success of this intervention and questions it uncovered warrant robust exploration in a large, randomized trial.

Service Delivery Adaptations: Telehealth Creative Arts Therapy in the Veterans Health Administration

Kristin M Story¹, Sheri L Robb², Alaina Preddie ¹,³, Mindy Flanagan¹, Teresa M Damush¹,³,⁵

¹Department of Veterans Affairs (VA), Richard L. Roudebush VA Medical Center; Indianapolis, IN; ²Indiana University School of Nursing; ³VA Health Services Research and Development (HSR&D) Expanding Expertise through E-health Network Development (EXTEND) Quality Enhancement Research Initiative (QUERI); Indianapolis, IN; ⁴Department of Medicine, Indiana University School of Medicine; ⁵Regenstrief Institute, Inc

Introduction: In response to the COVID-19 pandemic, the Veterans Health Administration (VHA) instituted a Nation-wide shift to increase virtual care.¹,² However, there are unique technical challenges to telehealth delivery of Creative Arts Therapies (CAT) that include music and art. The aims of this study were to identify how telehealth CAT is being employed, clinician level barriers and facilitators, and how clinicians have adapted their practice for telehealth CAT delivery.

Methods: We deployed a survey, guided by the Consolidated Framework for Implementation Research (CFIR), to all VHA facilities.³ Of the 120 CAT therapists surveyed, 92 (77%) responded and a subset of 23 therapists were interviewed. Quantitative data from the surveys were analyzed. Open field responses were summarized and coded for thematic analysis. Interviews were video recorded and transcribed. De-identified transcripts were used for coding and thematic analysis by a minimum of two coders from the research team.

Results: Survey findings indicate that 76% of survey respondents have delivered a telehealth CAT session with 74% delivering more than 50 in the last year in response to the pandemic. More than 85% of CAT therapists have adapted or created new interventions in order to deliver services through telehealth. Most therapists (65%) encountered moderate technology issues that they were able to overcome and 55% of therapists indicated that technology issues were specific to their CAT discipline. Open field analysis from the surveys revealed challenges related to sound quality (for music therapists) and visual limitations (for art therapists). Administrative requirements to use specific platforms and software increased the need for CAT work arounds to deliver sessions successfully. But CAT therapists also identified increased creativity and clinician growth from telehealth delivery as well as the benefits of interacting virtually in the Veteran’s home environment. Organizational facilitators included new interventions/directives, and challenges related to specific platforms (e.g., sound/visual range).

Discussion – Identification of key facilitators and barriers to implementation and delivery has allowed us to create a foundational tool kit comprised of information and resources to help CAT therapists in their delivery of services. The relative advantage of CAT virtual delivery to reach patients across VHA is now being adopted by the healthcare organization as a hybrid delivery approach to improve its reach into its patient population.

A Machine Learning Approach for Identifying Emergent Phenotypes Associated with a Previous COVID Infection

Zachary H. Strasser, MD, MBI1,2, Hossein Estiri PhD1,2, Shawn Murphy MD, PhD1,2,3
1Massachusetts General Hospital, Boston, MA, 2Harvard Medical School, Boston, MA, 3Mass General Brigham, Boston, MA,

Introduction
The SARS-CoV-2 virus has long-lasting effects on a variety of organ systems.1,2 However many of the large cohort studies used for quantifying the symptoms and diseases that follow an acute COVID-19 infection, rely on large insurance databases or electronic health record systems that are at risk for inaccuracies, missingness, and incompleteness. Accurate identification of phenotypes will help the healthcare system focus its efforts and resources on adequately controlled age- and gender-specific sequelae of a COVID-19 infection.

Methods
We applied a computational framework for knowledge discovery from clinical data, called MLHO3 (Machine Learning for predicting Health Outcomes), to identify phenotypes that: 1) appeared for the first time in a patient’s electronic health records (EHRs) after the acute phase of the infection and 2) are positively associated with a past positive reverse transcription-polymerase chain reaction (RT-PCR) test for COVID-19. We evaluated the post-test phenotypes (based on International Classification of Disease codes) in two temporal windows after the test and in subpopulations based on age and gender. We then validated these new phenotypes with a physician’s chart review of the clinical notes to ensure that the diagnostic labels match the real-world experience of the patient.

Results
We analyzed 96,025 non-hospitalized patients who had a COVID-19 RT-PCR test, of which 22,475 (23.41%) had a positive COVID-19 result. We identified 33 phenotypes among different age/gender cohorts or time windows that were positively associated with past SARS-CoV-2 infection. All identified phenotypes were newly recorded in patients' medical records two months or longer after a COVID-19 RT-PCR test in non-hospitalized patients regardless of the test result. We then performed a chart review of samples of the selected phenotypes to ensure the clinical notes corresponded with the emergence of a new phenotype. Among these phenotypes, a new diagnosis record for anosmia and dysgeusia (OR: 2.60, 95% CI [1.94 - 3.46]), alopecia (OR: 3.09, 95% CI [2.53 - 3.76]), chest pain (OR: 1.27, 95% CI [1.09 - 1.48]), chronic fatigue syndrome (OR 2.60, 95% CI [1.22-2.10]), shortness of breath (OR 1.41, 95% CI [1.22 - 1.64]), pneumonia (OR 1.66, 95% CI [1.28 - 2.16]), and type 2 diabetes mellitus (OR 1.41, 95% CI [1.22 - 1.64]) were some of the most significant indicators of a past COVID-19 infection. Additionally, more new phenotypes were found with increased confidence among the cohorts who were younger than 65.

Discussion
Our approach avoids a flood of false positive discoveries while offering a more robust probabilistic approach compared to the standard linear phenome-wide association study (PheWAS). More than 63 percent of PASC phenotypes were observed in patients under 65 years of age, pointing out the importance of vaccination to minimize the risk of debilitating post-acute sequelae of COVID-19 among younger adults. As part of the NIH’s RECOVER Initiative, our team at Massachusetts General Hospital serves as part of the PASC Data Resource Core (DRC) to support and contribute to the collection, coordination, and analysis of data collected on PASC patients throughout the nation facilitating analysis of standardized data across different RECOVER cohort studies. The above approach will help to inform this ongoing initiative.

Measuring the correctness of All of Us physical measurement

Lina Sulieman, PhD¹, Karthik Natarajan, PhD², Qingxia (Cindy) Chen PhD³, Robert J Carroll, PhD¹, Kayla Marginean¹, Paul Harris, PhD¹, Andrea Ramirez, MD, MS⁴

¹ Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN, US; ² Department of Biomedical Informatics, Columbia University, New York, New York, US; ³ Department of Biostatistics, Vanderbilt University Medical Center, Nashville, TN, US; ⁴ Department of Medicine, Vanderbilt University Medical Center, Nashville, TN, US

Introduction

The quality of electronic health records (EHR) data can affect credibility, validity, and reproducibility of research,¹ therefore assessing the quality of the research data is essential. We assessed correctness, a data quality dimension, and identified possible incorrect values for six common physical measurements in the All of Us Research Program, a multi-site ongoing initiative to recruit one million or more diverse participants.

Methods

We investigated height, weight, body mass index (BMI), heart rate (HR), systolic blood pressure (SBP), and diastolic blood pressure (DBP), extracting measures taken at study enrollment (i.e., onsite measurement) or recorded at age 18 years or older and in an outpatient visit in the EHR. To identify erroneous measurements, we used three methods. We compared the enrollment values to the corresponding EHR value within one year before or after enrollment. For 2-SD method, the sample standard deviation (SD) was calculated using onsite values from all participants, and a value outside 2*SD was labeled as erroneous. The 3-SD-participant method calculated SD for all EHR values per participant and labeled as erroneous the values that were higher or lower than 3-SD from their mean. The moving average method compared a value to the moving average of previous values. It labeled the value as erroneous if the difference between the value and moving average was higher than a threshold. We performed a grid search to select the final set of parameters for moving average. To evaluate the concordance of values between the EHR and onsite, we calculated the Pearson and Spearman correlation between median of EHR values within a year and onsite values.

Results

The number of participants in fourth release who have EHR values outside the error or 2-SD bar were 4110, 1694, 1997, 266322, 231394, and 238420 for height, weight, BMI, heart rate, SBP, and DBP. Some weight and BMI values were clustered along the lines with slopes 0.45 and 2.2, as shown in Figure 1. Height, weight, and BMI had the highest correlation. The 3-SD-participant identified around 500,000 height and 6,000 weight values in the entire EHR that might be incorrect. The moving average labeled 220,435 EHR height values. Moving average labeled 400,000 weight values as erroneous. The correlation between onsite and EHR was above 0.96 for height, weight, and BMI, while it ranged between 0.55 to 0.62 for SBP, DBP, and heart rate. After removing values labeled as possible error, the correlation for most of the values increased; however, the improvement was not significant for all measurements and it ranged between 0.002 to 0.1.

Discussion

Our study is one of the few attempts to identify erroneous measurements recorded during adulthood for six common measurements. Removing some erroneous measurement improved correlation between onsite and EHR measurements recorded within a year. Moving average and 3-SD-participants can identify incorrect measurements that are not limited by their entry dates. For heart rate and blood pressure, at least one value per participant was flagged. The intra-variability in those measurements is high since they depend on rest and stress levels, and underlying conditions. Minimizing the error rate in clinical research dataset can lead to more accurate results. Our analysis can identify mapping errors and implemented as a processing step prior training models.

Introduction

Synthetic electronic health records (EHR) can facilitate effective use of clinical data in software development, medical education, and medical research without the concerns of data privacy. We propose a novel Generative Adversarial Network (GAN) approach, called Longitudinal GAN (LongGAN), that can generate high-quality longitudinal clinical data containing continuous laboratory and medication values for given diseases.

Methods

We randomly chose two facilities from the 10 highest volume inpatient facilities in Cerner Health Facts database and extracted inpatient encounters from 1/1/2016 to 12/31/2017 for the experimental evaluation of the proposed method. The architecture of LongGAN is illustrated in Figure 1. A recurrent autoencoder is trained with real longitudinal data and used to extract representations, the GAN model is trained with representations of real data and used to generate synthetic representations, which are then fed to the decoder part of autoencoder to get synthetic longitudinal data. Soft labels of diseases are used as conditional input of GAN model.

Results And Conclusions

We evaluated LongGAN with Train on Synthetic and Test on Real task, where we trained two classifiers for acute kidney disease, one using the real training dataset and the other using the synthetic dataset, and then evaluated both models on a real test dataset. The classifiers we chose include logistic regression, random forest, and LSTM network. The results are shown in Table 1. Our results demonstrate that the models trained on synthetic datasets generated by LongGAN have performances closer to those trained on real datasets than other synthetic datasets generated by RCGAN and TimeGAN, two most relevant methods for longitudinal data generation.

Extraction of Ambiguous Phrases Found Within Adverse Drug Event Mentions Using A Natural Language Processing-Based Annotation tool

Zhoujun Sun BS student¹, Rubina Rizvi MD, PhD², Shilo Anders, PhD¹, Brett South MS, PhD², Elisabeth L. Scheufele MD, MS², Karlis Draulis³, Henry J. Feldman MD, MS²

¹Department of Psychology, Vanderbilt University, Nashville, TN, USA; ²IBM, Watson Health, Cambridge, MA, USA

Introduction

About 80% of Electronic Medical Record (EMR) data are unstructured, rendering them relatively inaccessible to traditional analytics without manual review.¹ Natural Language Processing (NLP) offers a method to extract and classify unstructured text such as adverse drug events (ADE), drug names into structured codable concepts. ADE are defined as an injury resulting from medical intervention related to a drug.² Identifying true positive phrases with an accurate representation of a cause (drug) and effect (ADE) relations is a particularly challenging NLP problem. Ambiguity may arise from the fact that clinical notes are often written as telegraphic, short sentences, having acronyms and inconsistencies in punctuation and grammar. This could lead to uncertainty and variable interpretation, hampering communication and potentially resulting in undesirable clinical outcomes.³ We report on methods used to extract and identify a corpus of commonly observed, ambiguous phrases from clinical notes using The Watson™ Annotator Service for Clinical Data (ACD).

Methods

The MIMIC III v.1.4 database containing approximately 1.3 million full-text notes was utilized as our initial corpus. Our study focuses on ADE from admission notes for ICU patients (excluding in-hospital transfer), written by resident physicians. The MIMIC III database was loaded into MySQL, hosted on an Apple Macintosh server utilizing a 4-drive thunderbolt-3 RAID array. The notes were filtered on the NoteEvent.category for those containing “resident” and “admission”. The admission information linked to the note provided the source of the patient and excluded notes where originating service was not the emergency department. The ACD Medication Adverse Event engine processed the notes, excluding ADEs with a system probability of < 60%. Final system output included medication/agent ascribed to the ADE with surrounding text limit of +/- 100 characters and preceded by an “on” clause e.g., GI bleed on Coumadin. We removed any duplicate phrases. Using the output, we then conducted two rounds of manual, human review. In the first round, two co-authors, (ZS, RR) identified ambiguous phrases applying several heuristics (i.e., a complete, meaningful sentence with common drug mentions, removal of duplicate phrases). Next, two physicians (ELS, HF) reviewed and marked the phrases considered most concerning, and with potential critical outcomes, inter-rater agreement (IRR) was calculated. A frequency table was generated for categorical data, drug names (Table-1).

Results

The initial corpus selected from MIMIC- III database was comprised of N=11,500 admission notes from ICU admissions corresponding to an adverse drug event. The NLP algorithm identified N=9057 notes containing a possible ADE. After filtering on potential ADE phrase and applying a character limit (+/- 100 chars), the list consisted of N=597 phrases that was further reduced to the final selected N=155 after two rounds of manual review. The calculated IRR was of 89% with Kappa values (0.73 95% CI 0.8-0.87). The number of unique drug names (brand or generic) associated with an ambiguous phrases was N=102, with Coumadin having the most mentions N=112 (40%) out of 295 (Table 1).

Conclusion

In this study we demonstrate a method to identify ambiguous phrases found within ADE mentions from a collection of notes. In future efforts, these phrases will be utilized to study and model users’ (e.g., clinicians and non-clinicians) interpretation and deduction processes.

How Can Artificial Intelligence Tools Be Used to Manage Future Pandemics? A Scoping Review of Key Use Cases

Ania Syrowatka, PhD1,2, Masha Kuznetsova, MPH3, Ava Alsabai, MA1, Adam L. Beckman, BS2,3, Paul A. Bain, PhD2, Kelly J. Thomas Craig, PhD4, Jianying Hu, PhD5, Gretchen Purcell Jackson, MD, PhD4,6, Kyu Rhee, MD, MPP4,7, David W. Bates, MD, MSc1,2

1Brigham and Women’s Hospital, Boston, MA; 2Harvard Medical School, Boston, MA; 3Harvard Business School, Boston, MA; 4IBM Watson Health, Cambridge, MA; 5IBM Research, Yorktown Heights, NY; 6Vanderbilt University Medical Center, Nashville, TN; 7CVS Health, Wellesley Hills, MA

Introduction

Coronavirus disease 2019 (COVID-19) has had a profound impact on all aspects of society, and future pandemics are sure to follow. Seven months into COVID-19, it was estimated that 59-92% of U.S. deaths could have been avoided if the pandemic were managed differently and rates reflected those in counties with moderate COVID-19 mortality.1 Policymakers, clinicians, and other stakeholders need access to data and recommendations in near-real time to respond effectively as a pandemic evolves. Artificial intelligence (AI) could be widely used to inform clinical and public health decision making. The objective of this scoping review was to identify the key use cases for involving AI for pandemic preparedness and response from the peer-reviewed, preprint, and grey literature.

Methods

We identified studies by searching five databases (PubMed, Embase, Web of Science, IEEE Xplore, ACM) and two preprint servers (medRxiv, bioRxiv), and used a structured Google search to identify grey literature. This scoping review had two parts: an in-depth review on the use of machine learning (ML) for pandemic preparedness or response, and a limited review of traditional modeling approaches. ML applications from the in-depth review were categorized into use cases related to public health and clinical practice, and narratively synthesized. Data sources and types of ML well suited for each use case were summarized. The limited review of traditional approaches served to identify additional areas where ML could be leveraged for pandemic preparedness and response.

Results

One hundred and eighty-three articles met the inclusion criteria for the in-depth review and reported on the development of ML algorithms or tools in response to COVID-19, the 2009 H1N1 pandemic influenza, severe acute respiratory syndrome (SARS), or hypothetical pandemics. The in-depth review identified six key use cases (Box 1). Data sources and types of ML that were useful varied by use case. The limited review included 1,167 articles that reported on traditional modeling approaches and identified several additional areas where ML could be applied to improve the accuracy of estimations or projections.

Discussion and Conclusion

Important ML-based solutions have been developed in response to pandemics and particularly for COVID-19. However, most were still at the research or developmental stage and had not been widely used to inform clinical or public health decisions early in the COVID-19 pandemic. Most examples of ML tools that were rapidly implemented were identified through the grey literature and were developed by health systems or industry. This review highlighted that there was still a strong reliance on traditional approaches in response to COVID-19 and identified additional areas where ML could be leveraged for pandemic preparedness and response. These findings can support stakeholders in prioritizing research and development to operationalize AI to help effectively manage future pandemics.

Trauma Triage in an Information Rich Environment

Douglas A. Talbert, PhD¹, Steve Talbert, RN, PhD²
¹Tennessee Tech University, Cookeville, TN; ²University of Central Florida, Orlando, FL

Introduction

Trauma research has improved triage guideline accuracy while maintaining a simplicity that respects associated time and resource constraints, but accuracy goals have yet to be achieved¹. Presuming that our increasingly sensor-rich, connected society will enable rapid capture of prehospital data that allow the use of more complex models, we relax that simplicity constraint, which can hurt understandability and reduce trust. We make this accuracy/complexity trade-off explicit to inform future work to improve understandability while maintaining accuracy improvements.

Experiments and Results

We used trauma registry data from a Level 1 Trauma Center that included physiological parameters, anatomical criteria, mechanism of injury, and age with severe injury defined by an injury severity score > 15. We then created three feature sets and multiple patient subsets. The Baseline feature set (4 features) simulated human-friendly guidelines, the Full set included all 32 available prehospital features, and the CFS set included 8 features selected using correlation-based feature selection. We compared the accuracy of models using all combinations of feature sets and datasets, but the results presented here use the Full ED dataset, which includes all patients with complete initial ED physiological values (n=56,888). All models were built using Weka’s J48 decision tree algorithm with reduced error pruning to mitigate overfitting. Accuracy metrics were measured by averaging 10 runs of 10-fold cross-validation, and for consistent comparison, we tuned all models to 95% sensitivity.

We assessed model complexity using two complexity-based XAI metrics, complexity (the number of variables in the explanation or rule) and explainability², which is defined as \[ w_1 \frac{N_i}{N_a} + w_2 + w_3 (1 - I) \], where \( N_i \) is the number of variables input into the model, \( N_a \) is the number of variables used in the explanation, \( I \) is the strength of interaction among the variables on a 0 to 1 scale. We set, \( w_1 = w_2 = w_3 = \frac{1}{3} \).

The average Full feature set specificity (57.1%) is significantly higher than that of the Baseline feature set (29.8%), and the CFS feature set’s specificity (52.3%) maintained most of the accuracy gain using a much smaller feature set. Table 1 shows that the Full set resulted in higher complexity and lower explainability than the Baseline set. The CFS set, however, resulted in the lowest complexity and an explainability between the other two sets.

<table>
<thead>
<tr>
<th>Feature Set</th>
<th>Distinct Rules</th>
<th>Average Complexity</th>
<th>Average Explainability</th>
</tr>
</thead>
<tbody>
<tr>

<td>2.47</td>
<td>47</td>
</tr>
<tr>
<td>Full</td>
<td>401.33</td>
<td>7.27</td>
<td>34</td>
</tr>
</tbody>
</table>

Conclusion

We have demonstrated that a hypothetical system in a sensor-rich, connected environment can outperform other published trauma triage metrics, albeit with a corresponding increase in model complexity. Further research is needed to strengthen clinician confidence in complex models. Explanatory AI and uncertainty quantification are active areas of research that can potentially improve trust.

Supervised Machine Learning of Nursing Flowsheet Data to Identify a Signal of Racial Bias
Brittany N. Taylor, BS, RN1; Christopher Knaplund, MPhil2; Sarah Collins Rossetti, PhD, RN1,2; Kenrick D. Cato, PhD, RN1,3

1School of Nursing, Columbia University, New York, NY; 2Department of Biomedical Informatics, College of Physicians and Surgeons, Columbia University, New York, NY; 3Department of Emergency Medicine, New York Presbyterian Hospital, New York, NY

Introduction
Nursing documentation in electronic health records (EHR) contains information about patients’ clinical status and any changes in their condition1. The Communicating Narrative Concerns Entered by RNs (CONCERN) study linked increases in documentation frequency to increased concern for patients2. Previous studies have suggested that racial biases among nurses contribute to health care disparities3. This study represents a first analysis to determine if there is a signal for racial bias in nursing flowsheet data.

Methods
We collected nursing flowsheet annotations from the CONCERN study for the first 24 hours after admission to adult medical-surgical or intensive care units between June and July 2020. Each patient was classified as white or non-white, which included other. Using scikit-learn, we applied three supervised machine learning algorithms to train models, compare model performance, and identify important features.

Results
Of the total 4,840 visits, 1,741 were white patients, and 2,174 were non-white patients; the patients who declined to answer were excluded. CatBoost was the best performing machine learning algorithm (Table 1). Flowsheet items were highly predictive for the two different race classes; feature importance for white patients is shown on the right and non-white patients on the left. The y-axis shows flowsheet item numbers; for example, 3040109070.0 is interpreter provider service and 305610.0 is ambulation response.

<td>0.615000</td>
</tr>
</tbody>
</table>

Conclusion
We found a signal in the data, indicating the presence of a racial bias in nursing documentation. Analysis of these data is ongoing, and results based on comorbidity and discharge diagnosis have not been completed and will be presented in the poster at the annual meeting. Additional research is needed to analyze nursing documentation patterns by setting, since previous research by our study team has detected significant differences in intensive care versus medical/surgical inpatient wards1.

Telehealth Adoption and Healthcare Utilization During the COVID-19 Pandemic: Toward Understanding What Follows for Vulnerable Groups

Casey Overby Taylor, PhD; Ilia Rattsev, BS; Jeremy Epstein, MD; Jiawei Bai, PhD; Natalie Flaks Manov, PhD

1The Johns Hopkins University, Baltimore, Maryland, United States

Abstract: The COVID-19 pandemic provides a natural experiment to compare healthcare utilization among different demographic and community groups with the broad introduction of telehealth. Our findings suggest that individuals with high healthcare utilization pre-pandemic maintained a similar rate of visits during the pandemic, and that a large proportion of most groups compensated for declines in face-to-face visits with telehealth.

Objective: The objective of this study was to investigate the dynamics of telehealth adoption among Johns Hopkins patients with high healthcare utilization prior to the pandemic, by socio-economic and demographic characteristics.

Materials and Methods: This was a retrospective study leveraging electronic health record data of patients that had a Johns Hopkins Medicine (JHM) primary care provider visit at least twice within twelve months prior to the onset of the pandemic (Mar-Dec 2019). Encounter types included completed outpatient visits (face-to-face and telehealth), four demographic characteristics (age, gender, race, and ethnicity); and four socio-economic community factors (poverty, education, unemployment, and vehicle possession). The demographic factors were obtained for each patient from Epic, while the community characteristics were assigned to patients according to neighborhood-level US Census data. We analyzed the trends of outpatient visits by month for each encounter type. We also assessed rates of visits pre-pandemic and pandemic (i.e., total visits in a period over the total population visits during the same period.) To adjust for seasonal fluctuations in the dynamics of interaction with healthcare, the inclusion window timeframe for our analysis covered respective months pre-pandemic (Jun 1 to Dec 31, 2019) and pandemic (Jun 1 - Dec 31, 2020).

Results: The cohort included a total of 93,980 patients. 29,784 patients (32%) were 65 years old or older, the majority were White or Caucasian (55%, 51,745), with Black or African American being the second most represented race (31%, 29,229). There were 637,307 completed outpatient visits (both face-to-face and telehealth) and 336,529 portal messages in the pre-pandemic period. In the pandemic period, these numbers were 479,255 for outpatient visits. Findings from reviewing visit trends showed that telehealth visits were rarely used prior to the pandemic, and the rapid increase in telehealth use happened at the onset of the pandemic (Mar 2020, Figure 1). Face-to-face visits did not stop, but occurred to a lesser extent during the pandemic, while the total amount of visits has dropped (Mar 2020 to Dec 2020). The overall rate of visits was 4.9 pre-pandemic and 4.7 during the pandemic. For two groups, this drop approached 1 fewer visits on average per person: age 0-24 (3.5 to 2.7) and >= 40% in extreme poverty (7.7 to 7.0).

For groups maintaining a more similar rate of visits pre- to pandemic, over 50% of people had at least one telehealth visit (seven groups with 60% or more: Females, age 25-44, age 45-64, Black or African American, < 75% with high school diploma, >= 40% in extreme poverty, > 20% unemployed, >20% with no vehicle).

Discussion: Trends in healthcare utilization pre-pandemic and pandemic were similar to the findings of others. Most groups maintained a similar rate of visits during the pandemic as pre-pandemic. There was also a high proportion of people with at least one telehealth visit during the pandemic, including for some vulnerable groups.

Figure 1. Trends of outpatient patient-provider communications by month for two encounter types (face-to-face visits and telehealth visits [phone and video]).

Towards building a Recommender System: Analyzing Resource Sharing on an Online Ovarian Cancer Community

Khushboo Thaker\textsuperscript{a}, Susan Birkhoff\textsuperscript{b}, Vivian Hui\textsuperscript{c}, Young Ji Lee\textsuperscript{c}, Peter Brusilovsky\textsuperscript{a}, Daqing He\textsuperscript{a}

\textsuperscript{a}. Intelligent Systems Program, School of Computing and Information, University of Pittsburgh, USA
\textsuperscript{b}. Department of Acute & Tertiary Care, School of Nursing, University of Pittsburgh, USA
\textsuperscript{c}. Department of Health and Community Systems, School of Nursing, University of Pittsburgh, USA

Introduction: Ovarian cancer (OvCa) can be a deadly gynecological cancer affecting about 22k women per year in the United States with a high recurrence rate [1]. Women with OvCa and their caregivers often seek support from online health communities (OHCs) [2]. These OHCs allow for the exchange of information and resources with other individuals who have had similar experiences. Prior research studied OvCa patients’ informational needs using OHCs [2], yet there is a paucity of research investigating the types of resources shared among users, such as articles or websites. The overarching goal of our project (R01LM013038) will be to develop a recommender system that personalizes online health-related materials to patients with OvCa and their caregivers. As a part of this project, we studied the types of resources shared by users on an online OvCa OHC to recognize health materials sought after by patients with OvCa and their caregivers.

Data and Methodology: Data extracted from the National Ovarian Cancer Coalition online forum contained 909 threads. Each thread included anonymized user details, thread title, initial post, and reply comments. We selected 105 initial threads based on users asking for explicit information need from other users. Within these initial threads, users shared Uniform Resource Locators (URLs) in their reply comments. These URLs were extracted for analysis utilizing regular expression [3]. Manual content analysis was performed for each URL and these URLs were classified based on their content (health blog, health news, research articles, patient guidelines and factsheets).

Results: Of the 176 URLs shared among users, 112 were direct links to reading materials. The 64 other URLs belonged to events, organization websites, doctor listings, videos, and shopping sites. Users primarily exchanged commercial, government, health organization and academic sites (.com, .gov, .edu and .org) (Figure 1). The most shared domains were news.cancerconnect.com, cancerconnect.com, nccn.org and harvard.edu. Classification of 112 URLs, as shown in Figure 2 revealed, OvCa OHC users predominately exchanged health news and health blogs, which summarized research and clinical trial findings rather than sharing original research articles. Infrequently, research articles were shared eleven times within reply to threads.

Conclusion: Analyzing these exchanges of information among users on an OvCa online forum builds the preliminary evidence demonstrating OvCa OHC users primarily rely on articles which summarizes the medical findings in layman terms. This insight informs our HELPeR recommender system to prioritize these shared resources over research articles.

Assessment of Fast Healthcare Interoperability Resources Response Times in a Production Electronic Health Record Embedded Visualization

Jeritt G. Thayer1, Megan O. Lewis MSN CRNP1, Jonathan Spergel MD PHD1,2, Robert W. Grundmeier MD1,2
1Children’s Hospital of Philadelphia, Philadelphia, PA; 2Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Introduction
Clinical decision support (CDS) has demonstrated the ability to improve patient safety and the quality of patient care. These systems are often developed using internal electronic health record (EHR) rules engines that collect patient information directly from the chart and provide alerts (e.g. drug allergies) or reminders (e.g. preventive healthcare interventions such as vaccine administration) to the care provider. With recent advancements in health information exchange, such as the introduction of Fast Healthcare Interoperability Resources (FHIR),1 health organizations are now able to more easily take advantage of external CDS services, which often help to provide more robust visualization of patient information or computation of complex decision logic. Unfortunately, the use of FHIR for CDS applications has traditionally been limited to small timeframes (e.g. within the same encounter) or for retrieving specific values from the patient’s chart (e.g. current medications). Limited information exists about the effectiveness of FHIR application programming interfaces (API) for aggregating data across a larger time frame in the context of clinical care. At the Children’s Hospital of Philadelphia (CHOP), we sought to assess the capabilities of FHIR APIs in the context of an EHR-integrated production information visualization.

Methods
We utilized application performance monitoring logs captured between October 26, 2020 and December 10, 2020 from a single EHR-integrated production application used by CHOP’s Division of Allergy and Immunology outpatient clinics. The application is an information visualization of a patient’s asthma history, which presents two years of relevant asthma data. The application utilizes four Release 4 (R4) FHIR application programming interfaces (API) – Patient, Encounter, Procedure, and Condition. Details of each API request, which includes how long the EHR web server took to respond, was logged by the application to our hospital logging infrastructure. We also logged the total amount of time it took to load the application, which, in addition to requesting data, includes activities such as executing clinical logic and building the visualization. We evaluated each FHIR resource and the total application load time based on four response time percentiles (50th, 75th, 90th, and 95th), which are common thresholds for monitoring application response times.

Results
During our analysis period, the application was used by 124 users for 2,396 patients in 3,790 encounters. Average application response time across all patients was 1.052 seconds. Average FHIR API response time was: Patient – 0.187 seconds; Encounter – 0.635 seconds; Procedure – 0.204 seconds; and Condition – 0.169 seconds. Our analysis showed that, across all percentiles, the FHIR Encounter resource was the slowest service to respond (Table 1). This was especially pronounced for patients deemed “high utilizers” by the application, where 5% of requests took more than 5 seconds to respond.

</table>

Table 1 Response time percentiles measured in seconds partitioned by healthcare utilization for asthma
* Utilization level was determined by the application.

Discussion
We explored the real-world use of FHIR in the context of a production clinical application. Our work demonstrates that requests for data using the FHIR standard, as implemented by one commercial EHR, may be unacceptably slow to be useful in typical clinical workflows. Previous research has suggested that users’ thought processes can be interrupted for response times greater than 1 second.[2] Our study was limited to a single institution and the analysis does not account for potential variation in the underlying information architecture (e.g. server load, network latency, EHR database). Future work should focus on assessing the impact of long application load times as well as developing methods to reduce such impacts.

Vancomycin Dosing in Critically Ill Patients: A Machine Learning Approach

Mohammad Samie Tootooni, Ph.D.\textsuperscript{1}, Erin F. Barreto, Phram.D., M.Sc.\textsuperscript{2}, Kalyan S. Pasupathy, Ph.D.\textsuperscript{2}, Kianoush B. Kashani, M.D., M.Sc.\textsuperscript{2}

\textsuperscript{1}Loyola University Chicago, Maywood, IL, USA; \textsuperscript{2}Mayo Clinic, Rochester, MN, USA

As a renally-eliminated and nephrotoxic medication, both sub- and supra-therapeutic vancomycin trough concentrations have consequences. A high vancomycin level can lead to drug-associated nephrotoxicity, whereas low levels could result in therapeutic failure and antimicrobial resistance. Selecting the right drug dose and frequency remains challenging, particularly for complex patients such as those in the intensive care unit (ICU) \cite{1}. Despite several efforts to optimize dosing methods, it is recently demonstrated that the majority of critically ill patients do not reach the targeted trough concentration until at least three days into their course \cite{2}. We aimed to identify the key predictive factors for the vancomycin steady-state trough level and their relative contribution, estimate the risk of a steady-state trough outside the goal range, and recommend the optimal individualized dosing recommendations.

A theoretical timeline for vancomycin concentration in a patient's serum is shown by Figure 1. At each decision point (DP), we aimed to have two classification models to accurately predict the class within which the steady-state trough concentration would fall (i.e., sub-therapeutic, therapeutic, and supra-therapeutic). Five-fold cross-validation was used for training and validation. We trained and tested six models selected partially based on maximum dissimilarity between model structures. The prediction models with highest performance are used to develop our recommendation engine. To find the optimum recommendation, a discrete optimization problem was formulated where the decision variables are: Loading Dose ($LD$), Maintenance Dose ($MD$), and Interval ($T$).

Our cohort consists of adult patients admitted to the ICUs at Mayo Clinic, Rochester, MN. All ICU patients from 2007 to 2017, who had a vancomycin concentration measured were included. The final cohort consisted of 5,337 patients, 80% used for training and cross-validation purposes, and 20% were hold-out (test set) for performance measurement. The xgbTree ensemble models were finally chosen to be tested via the left-out set in predicting sub-therapeutic (ROC: 0.85, Specificity: 0.53, and Sensitivity: 0.94) and supra-therapeutic (ROC: 0.83, Specificity: 0.47, and Sensitivity: 0.94) categories, respectively. Also, the Hosmer and Lemeshow calibration tests were performed, which suggested that the output probabilities from the xgbTree models embodied the actual risk of the defined therapeutic categories without additional calibration steps. The serum creatinine related measurements, prior dosages and frequencies, comorbidities, BMI, age, gender, and Mean Arterial Pressure were among the most contributing variables.

The optimal recommendations were calculated and compared with historical dosing decisions to measure the potential improvement in practice in a retrospective setting. McNemar’s tests were performed to measure the potential effectiveness from using the recommendations and shown in Table 1. The $P$ values ($<0.0001$) showed the outcome improvement by following the recommendations were statistically significant. Details showed the recommendations are more accurate for detecting/preventing supra-therapeutics compared to sub-therapeutic. The next steps include additional efforts for improving the recommendations and retrospective and prospective validations.

Extracting Daily Dosage from Medication Instructions in EHRs: An Automated Approach and Lessons Learned

Ching-Huei Tsou, PhD, Diwakar Mahajan, MS, Jennifer J. Liang, MD
IBM TJ Watson Research Center, Yorktown Heights, NY

Introduction
Medication timelines have been shown to be effective in helping physicians visualize complex patient medication information. A key feature in such designs is a longitudinal representation of a medication’s daily dosage and its changes over time. However, daily dosage as a discrete value is generally not provided and needs to be derived from free text instructions (Sig). Existing works in daily dosage extraction are narrow in scope, targeting dosage extraction for a single drug from clinical notes. Here, we present an automated approach to calculate daily dosage for all medications, combining deep learning-based named entity extractor with lexicon dictionaries and regular expressions.

Methods
We define the task as a 2-step process. First, we employed ClinicalBERT to train a model to extract two entities of interest from the Sig: DosagePerAdministration and AdministrationFrequency. To overcome lack of data, we adapted annotations from the publicly available n2c2 2018 Adverse Drug Events and Medication Extraction in EHRs dataset to form our entities of interest. Second, we normalized extracted spans to corresponding numerical values using a pre-built lexicon, and then applied a set of rules on the normalized values to calculate the daily dosage. Figure 1 presents an overview of our system. For evaluation, we sampled 1000 medication orders from 427 patients within a large multidisciplinary medical center for ground truth generation. Annotators were provided with the Sig text (“1-2 tabs qd”) and medication strength (“7.5mg”) to calculate the minimum (“7.5mg”) and maximum (“15mg”) daily dosage.

Results and Discussion
Out of 1000 Sigs, human experts were able to provide a daily dosage in 83% of the data. The remaining 17% consists of cases with missing or contradicting instructions, variable dosing over different days, cases where daily dosage is not meaningful (e.g. non-routine dose, single administration), and cases where dosage is not easily quantifiable (e.g. topical creams, eye drops). When evaluated on this dataset, our system achieved 0.98 precision, 0.95 recall, 0.96 F-score and 96.2% accuracy. Another way to understand these results is by comparison to human experts. In our evaluation dataset, human experts provided a daily dosage in 83% of the data and is 100% correct when a daily dosage value is returned, whereas our system returned a daily dosage in 81.6% of the data and is 98.2% correct when returned. Error analysis of our system revealed 4 main categories of errors: multiple dosage expressions, new expressions not understood by system, extra information in Sig not understood by system, and typos/misspellings.

Conclusion
To the best of our knowledge, this work is the first to generalize the task of daily dosage extraction on all medications. We hope this research will help realize many medication timeline designs and ultimately reduce the cognitive burden on healthcare providers. In future, we plan to improve our system by developing a generalizable end-to-end seq2seq model to calculate daily dosage and thereby removing the reliance on the manually curated lexicon.

Inconsistencies in handling missing data across stages of prediction modelling: a review of methods used

Antonia Tsvetanova, BSc MRes, PhD¹, Matthew Sperrin, PhD¹, Niels Peek, PhD², Iain Buchan³, MD, FFPH, FACMI, Stephanie Hyland⁴, PhD, Glen Martin, PhD¹
¹Centre for Health Informatics, Faculty of Biology, Medicine and Health, University of Manchester, UK; ²NIHR Manchester Biomedical Research Centre, Faculty of Biology, Medicine and Health, University of Manchester, Manchester Academic Health Science Centre, Manchester, UK; ³Microsoft Research Cambridge, UK; ⁴Institute of Population Health, The University of Liverpool

Introduction

Missing data need to be addressed at each stage of developing, validating and implementing a clinical prediction model (CPM). No clear guidance exists on handling missing data across this pipeline and it is unknown which methods are used in practice. We aimed to review the approaches to handling missing data that underly the CPMs currently recommended for use in UK healthcare.

Methods

We identified eligible CPMs through discussions with National Institute for Health and Care Excellence (NICE), a call on Twitter, and contacting other research groups. We identified the paper corresponding to each model’s development and identified the ten most cited external validation papers. We extracted information on methods used for handling missing data, as well as reported strengths and limitations, and any stated assumptions. We preferred to get information on the implementation stage for each CPM from documentation provided by the CPMs’ developers. If this was not available, we utilised online calculators to infer how missing data were handled during the implementation stage.

Results

23 CPMs were included. Six missing data strategies were identified: complete case analysis (CCA), multiple imputation, imputation of mean values, k-nearest neighbours imputation, using an additional category for missingness, considering missing values as risk-factor-absent, as shown on Figure 1. 52% of the development articles and 48% of the validation articles did not report how missing data were handled.

Conclusion

Missing data handling strategies were generally inconsistent. Our future work will involve a simulation study to explore whether these inconsistencies have an effect on the predictive performance of CPMs.
Comparison of Three Phrase Chunking Approaches on Medical Concept Coverage in Clinical Text

Grace K. Turner, BSE. and Meliha Yetisgen, PhD.
Biomedical Informatics and Medical Education, University of Washington, Seattle, WA

Abstract

Medical concept extraction pipelines commonly first chunk text into phrases (sets of words and punctuation such as “M.I.” or “myocardial infarction”) and then map those phrases to controlled vocabularies. In this work, we explored the effect of different phrase chunking approaches on medical concept coverage by using a subset of the i2b2 2010 medical concept dataset\(^1\) as the gold standard. By selecting the best chunking mechanism, we can potentially improve the entire pipeline performance and better facilitate access to the information stored in clinical notes.

Methods and Discussion

In our experiments, we used the official test subset of the i2b2 2010 dataset, with 45004 unique annotations over 477 reports. Including stop words, the number of tokens or words per annotation ranges between 1 and 26 with an average of 2.16. We evaluated the following three types of chunking approaches. (1) N-grams: We chunked text into basic n-grams (1,2,3-gram). (2) Stanza: We used Stanford’s Stanza CoreNLP package\(^2\) to generate all possible noun phrases (NP) and verb phrases (VP) based on part of speech tags. (3) Wildgram: We developed a heuristic approach called Wildgram that chunks text based on at least two instances of white spaces, punctuation marks, and stop words. A sentence such as “the patient had a myocardial infarction” would therefore be split into two tokens: “patient” and “myocardial infarction”. We also evaluated two combinatorial methods. The first combined the phrases created from Wildgram and 1-gram. The second combined the phrases from 1-gram, 2-gram, and 3-gram. We measured the quality of the chunking methods through precision, recall, and the F-1 score of perfect span overlap. Additionally, we measured the speed and the total number of chunks that partially match the true annotations.

Table 1: Concept coverage performance of different chunking methods on the 2010 i2b2 dataset

<tr>
<td>1,2,3-gram</td>
<td>380055</td>
<td>0.09</td>
<td><strong>0.758</strong></td>
<td>0.161</td>
<td>0.0042</td>
</tr>
</tbody>
</table>

Table 1 presents the concept coverage performance on the 2010 i2b2 test subset. Wildgram had the highest precision and F-1 score overall. Combinatorial methods resulted in higher recall with a consequent reduction in precision due to the significant increase in the total number of generated spans. Wildgram and n-gram methods ran at around the same speed, while Stanza is significantly slower. N-gram methods typically failed on phrases of a different size. For example, the 1-gram method failed on two word phrases. Wildgram typically failed most with sentences that had fewer stop words or other natural breakpoints. Wildgram can be downloaded as a python package.

Advance Care Planning Documents Should be ‘FAIR’: Towards Findable, Accessible, Interoperable, and Reusable Advance Care Planning Documentation

Elizabeth Umberfield, PhD, RN\textsuperscript{1,2}, Susan E. Hickman, PhD\textsuperscript{1,3,4}, Titus K. Schleyer, DMD, PhD, FACMI, FAMIA\textsuperscript{1,4}

\textsuperscript{1}Regenstrief Institute, Indianapolis, IN; \textsuperscript{2}Fairbanks School of Public Health, Indiana University, Indianapolis, IN; \textsuperscript{3}School of Nursing, Indiana University, Indianapolis, IN; \textsuperscript{4}School of Medicine, Indiana University, Indianapolis, IN

Introduction

It is ethically imperative that providers honor patients’ end of life treatment preferences. However, advance care planning (ACP) documentation often exists solely on paper or is buried in the electronic health record (EHR).\textsuperscript{1} A lack of standardized and interoperable strategies for storing ACP documents make it challenging to find ACP documents to guide treatment decisions; this increases the likelihood preferences will not be honored. This review examines challenges for exchanging ACP documentation and proposes generalizable solutions derived from the framework of the FAIR Guiding Principles (i.e., Findable, Accessible, Interoperable, and Reusable), which was originally proposed for management of scientific data rather than clinical documents.\textsuperscript{2}

Methods

This derivation of the FAIR Principles follows review of the literature and semi-structured qualitative interviews with clinicians to understand current approaches for and challenges when accessing advance care plans through the electronic health record. We comprehensively examine challenges for ACP document exchange across a range of settings and perspectives, including: end users; health information management departments; and a regional health information organization (RHIO). We derive and adapt each of the FAIR Principles,\textsuperscript{3} translating them for ACP document exchange rather than research data management.

Results

ACP document interoperability remains underdeveloped. Despite multiple bespoke and proprietary tools to facilitate ACP documentation in electronic workflows, few enable exchange across information systems. Applied to ACP, the FAIR principles could be initially adapted as follows:

- **F** ACP documents must be indexed in a searchable resource.
- **A** ACP document access must be open to providers, contingent upon robust authorization and authentication.
- **I** ACP common data elements and their value sets must be based on broadly accepted knowledge representation languages and standardized vocabularies.
- **R** ACP documents must be linked with detailed provenance records, demonstrating document revision and approval over time.

Conclusion

The FAIR Principles provide a solid framework for HIT infrastructure which may support ACP document exchange and discovery. The vision for seamless health information exchange has the greatest likelihood of being realized when it is supported by rich data and metadata annotation. This will ensure information is discoverable and actionable by its intended users and contribute to the provision of dignifying care for patients towards end of life.

DEVELOPING CLINICAL PREDICTION MODELS USING PRIMARY CARE ELECTRONIC HEALTH RECORD DATA – THE IMPACT OF METHODOLOGICAL CHOICES ON MODEL PERFORMANCE

Hendrikus J. A. van Os, MD*1,2,3; Jos P. Kanning, MSc*4; Marieke J. H. Wermer, MD, PhD2; Niels H. Chavannes, MD, PhD1,2; Mattijs E. Numans, MD, PhD3; Ynte M. Ruigrok, MD, PhD4; Erik van Zwet, PhD5; Hein Putter, PhD2; Ewout W. Steyerberg, PhD2; Rolf H. H. Groenwold, MD, PhD5,6 *Shared first authors

Problem description: Earlier research already identified several methodological challenges when developing clinical risk prediction models using electronic health record (EHR) data.1 This study quantifies the impact of these challenging methodological choices on model performance.

Study Design and Setting: Cox proportional hazards models were developed predicting cardiovascular events using Dutch primary care EHR data. The reference model was based on a one-year run-in period, cardiovascular events were defined based on both EHR diagnosis and medication codes, and missing values were multiply imputed. We compared methodological choices regarding i) length of the run-in period (more years); ii) outcome definition (EHR diagnosis codes or medication codes only); and iii) methods addressing missing values (mean imputation and complete case analysis) by making variations on the derivation set and testing their impact in a validation set.

Results: We included 89,491 patients in whom 6,736 cardiovascular events occurred during a median follow-up of 8 years. Outcome definition based only on diagnosis codes led to systematic underestimation of risk (intercept:0.835;95%CI:0.827–0.843), while complete case analysis led to overestimation (intercept:0.519;95%CI:0.509–0.529). Differences in length of run-in period showed no relevant impact on calibration and discrimination.

Conclusion: Methodological choices regarding outcome definition or methods addressing missing values can have a substantial impact on the calibration of predictions, hampering reliable clinical decision support. Transparent reporting of modelling choices is hence essential.

Quantifying Uncertainty in Patient Count Metrics Derived from Imperfect EHR-Based Phenotypes
Jack Vanschaik1, Sunandan Chakraborty1
1Indiana University Purdue University of Indianapolis, School of Informatics and Computing

Cohort identification via electronic health record (EHR) data has played an increasingly important role in retrospective clinical studies1 and public health reporting. Patient cohorts are identified via EHR-based phenotypes, a broad class of algorithms that attempt to classify patient inclusion using their medical records. While EHR-based phenotypes span various levels of sophistication, from rule-based methods to deep learning algorithms, a universal issue is their imperfect accuracy2. Phenotypes are subject to classification error, which is commonly measured by sensitivity and specificity. Due to the extensive time and expert knowledge required for phenotype validation, such measures are usually unknown3. Furthermore, EHR data quality issues may lead to irreducible error in cohort validation.

Problem
Retrospective analysis of EHR data and the need for public health reporting may necessitate the use of EHR-based phenotypes, even if those phenotypes have not undergone complete validation. Desired cohort metrics, such as population sizes and relative risk ratios, are associated with uncertainty due to phenotype error. These metrics are often reported as single values or reported with confidence intervals that do not account for the unavoidable issue of phenotype accuracy.

Solution
We introduce a Bayesian model for quantifying uncertainty in patient count metrics derived from one or two imperfect EHR-based phenotypes. We account for phenotype uncertainty by placing Beta priors over phenotype sensitivity and specificity. Hyperparameters can be determined from the best-known information about phenotype performance. For example, a phenotype estimated to have sensitivity 90% +/- 5% could be modeled as a Beta distribution with α = 36 and β = 4 which has mean 0.9 and standard deviation ~0.05. Combining prior information with collected EHR data allows for sampling of a posterior distribution. This distribution can be used to create posterior estimates and confidence intervals for EHR derived cohort metrics. The model was tested using a cohort of 124,150 COVID-19 positive patients from the synthetic EHR dataset SyntheticMass4. We used the model to estimate uncertainty in the relative risk of death for Black and Hispanic patients with COVID-19. Hyperparameter selection and the resulting posterior intervals are detailed in Figure 1.

Conclusion
The model produces confidence intervals for population counts that are scaled and shifted in accordance information about phenotype uncertainty. Accuracy priors modeling perfect phenotypes (e.g. α > 1000, β = 1 for sensitivity and specificity) yield nearly identical results to frequentists estimates. Tests with synthetic data showed substantial adjustment in confidence intervals when the model accounted for phenotype imperfections. Such differences could be significant for public health reporting and research. This model can save expert reviewer hours by enabling the use of EHR-based phenotypes when they have not undergone complete gold-standard validation, or the EHR in question has data quality issues. Code for implementation of the model in the R programming language is open sourced and freely available via GitHub.

Integrating Hospital Compare Data into the Health Services Research Data Warehouse

Madison Vinson, MSHI, Bunyamin Ozaydin, MSEE, PhD, Ferhat Zengul, PhD
University of Alabama at Birmingham, Birmingham, AL, USA

Introduction
As performance and quality improvement healthcare initiatives are increasing, data from Hospital Compare are being extensively utilized by health services researchers. These publicly available data are gathered through the voluntary Hospital Inpatient Quality Reporting Program (IQR) and Hospital Outpatient Quality Reporting (OQR) Program and reported by The Centers for Medicare and Medicaid (CMS) (1). Hospital Compare ratings have been shown to impact financial value, influence perception, and highlight areas of improvement within hospitals (2). The current extract-transform-load (ETL) process for retrieving Hospital Compare data from the website is tedious, repetitive, and leaves room for human error.

By creating an automated ETL process using SQL Server Integration Services to incorporate and update Hospital Compare data to a health services research data warehouse that includes data from other sources as well, researchers can eliminate separate manual ETL processes for each research project. This poster will present a process to allow researchers to access previous and current Hospital Compare data without having to spend their time on data management tasks each time an analysis needs to be performed.

Methods
The process for this project is a five-step ETL process as seen in figure 1. Phase one involves separating the raw data from the Hospital Compare websites into folders based on reported date and relevant measures. Every time there is a change in the structure of a data table (column was renamed, removed, added, or added files, etc.) we consider a new version of that table. The second phase is an SSIS package consisting of one large sequence container broken into hospital, national, and state sequence containers that are then further broken into foreach loops that will hold one version of a file. The foreach loops are used to run multiple Hospital Compare files in one data flow task. Stage three is an SSIS package that works dynamically to sort through Access files, pull relevant tables, and insert them into raw tables in SQL Server. This step is done to all Hospital Compare data prior to 2013. The fourth phase of this project involved creating SQL scripts to move the data from the raw tables into relational database tables. The scripts created in this phase remove data replication and convert data into a usable format for data visualization purposes (ex. dates). The final phase of this project handles updates to Hospital Compare data. This package does not contain foreach loops like the previous archive load package because it was created to only process one release and requires little to no technical knowledge to maintain.

Results and Conclusion
The measure of this study’s effectiveness was how well the framework integrated within The University of Alabama at Birmingham’s health services research data warehouse. Numerous visualizations were made in Power BI and Tableau to sort specific measures by date, performance scores, states, cities, or hospital using the tables in the health research database. The result of this project will lessen the burden on researchers by utilizing a data warehouse and SQL server business intelligence tools to streamline the data management stage of research. The final product provides researchers with the tools to automatically process all archived files and new releases with a set of SSIS packages and SQL scripts.

1860
INTRODUCTION. Much like other facets of healthcare, data interoperability and data exchange are a major concern in clinical research informatics (CRI). REDCap is one of the leading CRI data collection tools and is integral to the success of many observational studies. The Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) serves as a solution for organizations across the globe to conduct systematic analysis of disparate databases. Health Level Seven (HL7) Fast Healthcare Interoperability Resources (FHIR) is a well-trusted standard for facilitating data-exchange at the electronic health record (EHR) level. There have been recent efforts to combine each of these resources: REDCap and OMOP; REDCap and FHIR; and OMOPonFHIR and more recently, an official partnership between HL7 and the Observational Health Data Sciences and Informatics (OHDSI) network who maintains OMOP. To our knowledge, no prior work offers a direct pipeline for exchanging OMOP and FHIR compliant REDCap data. As such, we are developing REDHot OMOP.

METHODOLOGY. REDHot OMOP is a SMART on FHIR application and conduit in a system that will leverage FHIR and OMOP to exchange REDCap data standardized in a format tailored toward improving translational and observational research endeavors.

The pipeline works as follows: (1) users enter information into a REDCap form with any free-text input being (1a) captured in a specialized field to a local FHIR Terminology Service that (1b) returns a list of potential codes for the user based on a pre-defined list of values (FHIR ValueSet Resource) from a local code system selected by the form designer in advance. Once completed, the form report is (2) exported into Redmatch, which (3) converts the REDCap data into FHIR Resources and sends them to REDHot OMOP. The FHIR Resources are stored in REDHot OMOP and the local codes within the Resources are (4a) sent to OMOPonFHIR, which maps the codes in the FHIR Resources to OMOP and returns all viable mappings to REDHot OMOP. REDHot OMOP then (5a) provides the user with a representation of the transformed REDCap data for uses such as visualization or covariate analysis. REDHot OMOP can (5b) connect with an EHR or external application to assist in clinical decision support or be integrated into a mobile app. Information can also be (6) extracted from the EHR and associated with a participant in future research.

DISCUSSION & CONCLUSION. REDHot OMOP will support interoperable data exchange between observational research and clinical practice and has the potential to foster robust learning health systems. Some key limitations to implementing REDHot OMOP include relying on open-source software and requiring that institutions have a local OMOP instance and FHIR terminology server for concept mapping. This work could have lasting implications on CRI, observational and translational research.

**DS-DETERMINED: Using PCORnet and Referral Code Linkage to Expand the NIH DS-Connect® Registry and Assess Down Syndrome Participants’ Self-Determination**

Lemuel R. Waitman, Ph.D\(^1\), Sravani Chandaka MS\(^2\), Daniel W. Connolly BS\(^2\), Jud Rhode BS\(^3\), Debbie Jae MS\(^3\), Evan Dean, Ph.D\(^4\).

\(^1\)Department of Health Management and Informatics, University of Missouri, Columbia, MO; \(^2\)Division of Medical Informatics, Department of Internal Medicine, University of Kansas Medical Center, Kansas City, KS; \(^3\)Invate Corporation, San Francisco, CA; \(^4\)Kansas University Center on Developmental Disabilities, University of Kansas, Lawrence, KS.

**Introduction**

Online cohort studies may seek to build upon national registries but are challenged when studies also collect patient reported data via validated survey websites or use existing EHR data repositories. The DS-DETERMINED study supports and enhances Down Syndrome research and the DS-Connect\(^®\) registry by leveraging PCORnet\(^1\), the National Patient-Centered Clinical Research Network (www.pcornet.org). This study links PCORnet to the DS-Connect\(^®\) (dsconnect.nih.gov) and tests capability to: 1) increase DS-Connect\(^®\) enrollment, 2) extract of clinical observations, treatments, and outcomes from PCORnet patients, and 3) conducting cognitive assessment of self-determination in the PCORnet Down Syndrome population.

**Methods**

DS-DETERMINED builds upon the PCORnet ADAPTABLE\(^2\) study’s use of a trial invitation identifier to link the de-identified pat_id identifiers used in the PCORnet Common Data Model (CDM) to the invited patient’s specific enrollment in DS-Connect\(^®\). REDCap is used to generate random identifiers centrally for each recruiting site who will track their relationship to the random identifiers used to uniquely identify patients in their site PCORnet CDM (e.g. pat_id). Site personnel then distribute these trial_invite_codes to the subject via REDCap. Upon enrollment to the DS-DETERMINED study, the subject is sent into DS-Connect\(^®\) directly using a specific study_id referral code. After enrolling and consenting to DS-Connect\(^®\), participants enter additional patient reported outcomes and upon completion, the participant is directly sent to a third website hosting the Self-Determination Inventory (SDI https://selfdetermination.ku.edu/homepage/assessments/) passing the referral code from DS-Connect\(^®\). The definitions for this specific study are logged in the PCORNET_TRIAL table. Information about completion status of DS-Connect\(^®\) surveys and SDI are sent back to the DS-DETERMINED study to ascertain how subjects are progressing so that coordinators can provide support and generate an electronic gift card upon completion.

**Results:** This linkage methodology and study framework is implemented (creating new APIs for DS-Connect and he Self-Determination Inventory) and is recruiting participants to the study.

“The study was supported by the KIDDRC NIH U54 HD 090216 and the authors acknowledge the contribution of DS-Connect\(^®\) (The Down Syndrome Registry) which is supported by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), NIH for the study. used in this presentation.”

A Responsive Data Curation and Integration Pipeline for Rare Disease Data

Walls, Ramona L, Ph.D.1,2, Jeffery S. Barrett, Ph.D., F.C.P.1, Alexandre Betoune, Ph.D. 1, Emily Hartley, B.S.1, Jane Larkindale, D.Phil. 1, William T. Roddy, B.S.1, Amanda Borens, M.S. 1

1Critical Path Institute, Tucson, AZ, USA; 2University of Arizona, Tucson, AZ, USA

Introduction: Rare diseases are defined in the United States as conditions or disorders that affect fewer than 200,000 people. There are over 7,000 known rare diseases, with an estimated 350 million people affected worldwide. Development of therapies for rare diseases is slow, due to limited biological understanding, challenges in running clinical trials in small, heterogenous, dispersed populations, and limited data sharing. Existing rare disease data are fragmented and often siloed. Making them interoperable is crucial but remains challenging due to lack of standardization. Recognizing these challenges, the Food and Drug Administration (FDA) initiated the Rare Disease Cures Accelerator (RDCA) that includes the development of a data and analytics platform (DAP). RDCA-DAP is a partnership between Critical Path Institute, National Organization for Rare Disorders, and others to improve the quality and the accessibility of existing rare disease data by using FAIR (findable, accessible, interoperable, and reusable) best practices, including ontologies. The platform includes sophisticated analytics (e.g., cohort building, statistical analysis, R, virtual machines) in support of development efforts and regulatory approval. Our unique approach to responsive curation bridges the gap between generalist and specialist data repositories by providing detailed curation for specific use cases with rapid discoverability of diverse datasets and disease presentations.

Data, Governance, and Privacy: RDCA-DAP currently houses over 50 rare disease datasets, including clinical trials, natural history studies, patient-reported registries, and electronic health records. All data are shared through a data contribution agreement (DCA) specifying re-use requirements and ensuring that data were gathered in an ethical manner and that individuals have provided appropriate consent. Custodians agree to share summary level data with the community, so that users may explore what data are available through the platform. Only de-identified data are included, and all data are encrypted in transfer and at rest. Users must sign a data use agreement that legally binds them to maintain the data as secure as the platform and prevents further sharing without permission.

Data Curation and Processing Pipeline: All data processing takes place on a secure cloud platform built on the Aridhi Digital Research Environment. Once a DCA is in place, the custodian shares a copy of the de-identified dataset (including metadata, data dictionaries, and supplemental documents) with the platform through a secure mechanism. A data receipt is automatically sent to the contributor to ensure correct content, including a report with feedback related to data quality improvement. A read-only copy of the data is moved to a secure data warehouse, and another copy is moved to an internal workspace for curation. All data receive a minimal level of curation that includes semi-automated generation of data dictionaries and structured metadata, and data are immediately searchable by disease and study type, variables included, and number of patients. As users discover datasets they want to analyze, a responsive curation process triggers full curation of needed variables. High priority data needed for near-term analysis are curated at the variable level by standardizing to the OMOP Common Data Model, cleaning data values (e.g., tagging outliers), and mapping to ontologies. Fully curated data are stored in both relational and graph databases in a data lake along with minimally curated data as files. Data at all levels are discoverable through a search index.

Innovation and next steps: RDCA-DAP is a neutral platform available to the rare disease community (pharma and biotechnology companies, academics, nonprofit groups, others) that provides integrated patient-level data and facilitates their analysis. The data pipeline builds off existing technologies but combines them in a novel way. It allows for scalable, standards- and ontology-based integration of diverse data sources and automated data status tracking in a responsive workflow that prioritizes curation based on need. Because fully curated data are mapped to a format-agnostic semantic knowledge graph, multiple datasets can be integrated and used together, both within a single disease area and across diseases. Future development will allow users able to export the data in multiple formats, including tabular data for analysis and CDISC-SDTM (Standard Data Tabulation Model) for regulatory uses. The platform launches in September 2021 with data from at least 20 disease areas and basic analytic features, with more to be added over time. Critical Path’s quantitative medicine and regulatory science experts can partner with groups working on common problems in the precompetitive space to develop tools and quantitative solutions.

The Representativeness of “People Also Ask” of Google Web Search on the Information Needs Concerning Alzheimer’s Disease and Related Dementias

Lu Wang, M.S.1, Jina Huh-Yoo, MHCI, Ph.D.1
1Drexel University, Philadelphia, PA, USA

Introduction
While caring for patients with Alzheimer’s disease and related dementias (ADRD) requires specialized knowledge and skills, the training and education caregivers receive are often not systematic or organized. To better support millions of people with ADRD and their caregivers, their information needs have been investigated by many researchers to guide the assistive technology design. Researchers applied multiple research methods including interviews, diary studies, focus groups, and questionnaires. However, several problems make it challenging to gain a whole picture of the information needs: (1) The results are generally limited to small samples due to the high resources required in recruiting participants and analyzing qualitative data; (2) It is challenging to relate the results of different studies based on the incommensurable data derived through different methodologies; (3) The results might carry bias and errors for the retrospective, self-reported studies. Systematic reviews of consolidating existing studies can be helpful, but they are costly in terms of time and effort. A more economical solution could be to collect the information needs using behavior statistics. Google Web Search, as the most widely used search engine in the United States, introduced the “People also ask” (PAA) section, which applied machine learning models, RankBrain and BERT, to identify search patterns, predict individual searches, and offer suggestions according to a search query. We compare the results of systematic reviews and that of PAA to investigate how much PAA represents the review results.

Method
Information needs summarized in systematic review and scoring review in the past three years introduce four themes with thirty-eight specific information needs from 50 original studies in total1-3. We collected the data by entering the terms “dementia” and “alzheimer’s” into Google Web Search (www.google.com) and generating the list of frequently associated questions from PAA on the search result page. Clicking on each question on PAA will populate 1-2 more questions. For each search term result, we clicked 100 questions in its ranked order. As a result, we collected 574 questions in total (282 for “dementia” and 292 for “alzheimer’s”) and classified the questions according to the references. A clean-installed Chrome browser was applied to avoid the influence of personalized recommendations. We used the Scrapper (v.1.7) tool to download the questions. The date for this collection was January 4th, 2021.

Results
Results showed that, for the theme of “disease-specific information,” questions generated from PAA covered 91.67% of the 12 information needs identified in1-2, but missed the information need of “current research on ADRD.” For the theme of “patient care provision information”, questions generated from PAA covered 73.33% of the 15 information needs, but missed “safety issues like how to improve safety of environment, how to keep patient safe, how to recognize fall risks and poor mobility”, “emergency situations”, “helpful experiences of other caregivers” and “how to deal with family and friends.” For the theme of “healthcare service-related information”, only 14.29% of the 7 information needs were covered, missing “where and how to use services/help available”, “legal issues”, “how to apply for care programs eg. daycare, long term care”, “insurance”, “home help” and “transportation options.” For the theme of “caregiver self-care,” none of the 4 information needs was covered, including “stress management”, “caregiver’s entitlements (pension)”, “managing emotions” and “general caregiver self-care activities”.

Conclusion
The representativeness of PAA varied among the themes of information needs, possibly resulting from different usage habits on different platforms. PAA can be an efficient tool to identify specific areas of information needs. Future work should investigate the patterns of which information needs PAA represents better than others. Furthermore, we can explore combining behavior statistics from multiple aggregate search behavior tools (e.g., Google Trends, Alexa).

Factors Affecting Telemedicine Utilization among Cardiovascular Disease Patients During the COVID-19 Pandemic
Suwei Wang, PhD1, Hu Huang, PhD1, Elisabeth Lee Scheufele, MD, MS1, Gretchen P. Jackson, MD, PhD1,2, Irene Dankwa-Mullan, MD, MPH1
1IBM Watson Health, Cambridge, MA; 2Vanderbilt University Medical Center, Nashville, TN

Introduction
The COVID-19 global pandemic severely disrupted patterns of in-person outpatient visits and contributed to delayed or limited care of patients with chronic diseases. Telemedicine expanded rapidly as a safe and viable means to extend access to routine care while reducing COVID-19 exposure risk for vulnerable patients and health professionals. Early evidence pointed to higher risk of disease and poorer outcomes for patients with cardiovascular disease (CVD). In this cohort of commercially insured individuals, we sought to examine demographic and patient-level factors associated with patients with CVD who attended telemedicine visit vs who didn’t (“no-shows”).

Methods
This retrospective study examined adult patients (age ≥18 years) with CVD and telemedicine appointments using the IBM® Explorys® Database, a data set of United States (US)-based electronic medical records, using Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) codes for CVD and internally developed code-sets, in the timeframe of 03/01/2020 to 09/30/2020. Telemedicine encounters were identified through eligible Current Procedural Terminology (CPT®) codes. Patient demographic (e.g., sex, race, ethnicity, insurance) and clinical characteristics (e.g., liver disease, renal disease) were identified and analyzed. Univariate and multivariate logistic regression were performed to identify patient-specific factors associated with a completed telemedicine visit.

Results
A total of 744,485 patients with CVD were identified with 1,548,368 scheduled telemedicine appointments, of which 376,118 patients (50.5%) attended their appointment. There were 714,965 completed telemedicine encounters (some patients had more than one completed telemedicine visit). Mean age of patients who attended at least one telemedicine visit was 59 years (range 18-90 years), with demographic distributions: 60.5% female, 74.0% Caucasian, 14.5% African American, 1.2% Asian, 5.3% Hispanic, 1.5% Other, 98.0% English-speaking, 10.3% self-pay, 50.4% commercial insurance (private), and 29.0% on Medicare. Multivariate analysis identified the factors associated with lower odds of attending telemedicine appointment including male sex (OR=0.75, 95%; CI:0.75-0.79), African American race (OR=0.81, 95%; CI:0.76-0.87), speaks languages other than English or Spanish (OR=0.43, 95%; CI:0.36-0.54) and self-pay (OR=0.78, 95%; CI:0.73-0.85). Patients with comorbid chronic liver disease (OR=1.32, 95%; CI:1.19-1.47), kidney disease (OR=1.27, 95%; CI:1.16-1.40), hyperlipidemia (OR=1.12, 95%; CI:1.20-1.35), cancer (OR=1.25, 95%; CI:1.18-1.31) and with Medicare (OR=1.11, 95%; CI:1.03-1.19) had higher likelihood of completing telemedicine appointment.

Discussion
In this study during the early COVID-19 pandemic, only half of patients with scheduled telemedicine appointments showed up to their visit. Factors associated with telemedicine no-shows were similar to characteristics associated with barriers to in-person care. However, medical complexity and having insurance coverage were associated with telemedicine visit completion. As such, individuals who are male, African American, speak languages other than English or Spanish, or are self-pay may require additional efforts to ensure that barriers to attending telemedicine are anticipated and addressed.

Conclusion
Telemedicine has rapidly become an essential resource for patient care during the COVID-19 pandemic. In this study, patients with comorbidities and Medicare were more likely to attend telemedicine appointments, and those patients who were male, African American, speaking languages other than English or Spanish, or self-pay were less likely to complete telemedicine encounters. This study has identified gaps in equitable telemedicine access. Additional research is needed to determine whether these trends continue as telemedicine adoption increases and to understand the causes of these association to develop effective mitigation strategies.
Introduction

Chest X-ray images have proven useful for monitoring various types of the disease, including COVID-19 and related disease diagnosis. The rapid spread of COVID-19 has caused a global pandemic with variants Delta and Beta spreading fast. Deep learning based models for COVID-19 detection has shown high performance. However, there is a gap between the current deep learning-based classification and the clinical needs: detecting subtle differences in the medical images. In addition, current supervised training of deep neural networks on medical image diagnosis relies on large pools of labeled data, which is scarce, inflexible, and limited by types of annotations. A flexible approach that can reflect user-defined criteria without a large amount of annotation is needed. Further, the approach needs to enable collaborated real-time labeling from radiologists distributed across different geographic locations. In this study, a 5G-based active learning framework is proposed for selective annotation to magnify the labeling effect, precisely connecting the medical images to corresponding patients’ history records, support secure distributed annotation across multiple locations and enables low latency near-real-time decision support.

Methods

Existing CNN-based supervised deep learning CheXNet shows high accuracy in 14 common diagnoses in Chest X-rays. Grad-CAM\textsuperscript{1} introduced for ‘visual explanations’ for decisions. Based on the two models used the last layer of Full connection and the last layer of deployed CheXNet models as Feature construction for active learning and initial domain knowledge injection. Instead of identifying pre-defined diagnoses, the proposed system enables a user-defined target through the labeling of images. Such labeling has multiple sources: radiologist and medical experts, cross-sourcing patients’ history, EHR records or referencing other models, etc.

An end-to-end 5G network slice with Multi-access Edge Computing (MEC) is being built to enable a low latency, secure communication of medical images, and cross-platform patients’ medical records, distributed annotation, and near-real-time decision support. Through active learning, labeling is not a prerequisite but an ongoing process with utilizing the model. The key for active learning is selecting the right sample for interactive labeling. The specified domain knowledge is introduced through label propagation, enables user-defined target, maximizes the value of labeling through active learning by introducing the concept of records resolution. The labeled image improves model performance by guiding the direction of the model.

Results and Future Work

The proof of concept model accuracy was evaluated by the average value of F1 scores at different sample percentages. As the percentage of the labeled sample increased, the F1 score also increased. At the percentage of 40\%, F1 score ranged from 0.86 to 0.96 in between different diagnoses\textsuperscript{2}. Further evaluation of the model is still in progress. The Future work includes: incorporating unlabeled samples into training through Generative Adversarial Networks (GAN), Cross-referencing can directionally search the patient’s historical records related to the target definition and incorporate policy, regulation, and labeling costs into the system.

References

Introduction

As the world searches for effective treatments and potential cures for the COVID-19 pandemic, the ability to consolidate data, insights, and expertise from many disparate sources will be key to fully understanding the patient outcomes of the infection. At Mass General Brigham, we have developed a cohesive research data portal called the COVID Biobank Portal that enables clinicians, researchers, data scientists, and technologists to work together with a common goal of better understanding COVID-19 symptoms, associated risk factors, and successful therapies. The novel data portal brings data, analytics, and applications together in a way that provides immediate value for the current COVID-19 crisis while also unlocking the bench-to-bedside capabilities that researchers currently need to advance research.

Methods & Discussion

At Mass General Brigham, the COVID Biobank Portal is an Integrating Informatics Bench to Bedside (i2b2) instance that contains Electronic Health Record (EHR) data for over 33,000 COVID-tested patients already consented within the Mass General Brigham Biobank. Genomic array and exome sequence data is also available for a subset of these patients. Within the data portal, EHR data types are classified into an ontology system that groups medical terms and links directly to the underlying data—these groupings include encounter variables, demographics, vital signs, personal health and family history survey data, diagnoses, procedures, medications, laboratory results, blood-sample availability, and, where available, genomic data.

The COVID Biobank Portal is not only used to query for patients, but also provides the ability for users to download data files of limited data sets (LDS) for further cohort analysis. The downloaded file format includes de-identified patients in a customizable single-patient-per-row file with curated data in the columns. The novel approach to customizing the patient-level data file is key to producing a file with temporal constraints related to COVID-19. For instance, we have provided the ability for the user to designate one column as the index date. You can define an offset-in-days around that index date, for example, whether a patient was on a medication within one year to one week before they were tested and found COVID positive.

Results & Conclusion

The COVID Biobank Portal has been implemented and released to a group of beta testers made up of members from the ‘Using EHR data for COVID-19 research’ Working Group, an initiative of the Mass General Brigham Center for COVID Innovation. The operation and maintenance of the novel data portal is considered ‘production-ready’ in which data is refreshed and new COVID-tested consented patients are added on a weekly basis. The initial response from the beta testers has been overwhelmingly positive and the utility of the data portal has been demonstrated.

Building a focused data portal for COVID-19 can help facilitate analytics and knowledge management of the COVID-19 pandemic. The development of novel tools that work with the i2b2 platform allowed for the creation of the COVID Biobank Portal to be flexible to disparate data sources and highly scalable in producing useful data files for further COVID-19 research.

DeBakey VA Medical Center, Houston, TX; 8VA Bedford Healthcare System, Bedford, MA; U.S.A.

Introduction

The world’s largest transition between electronic health record (EHR) systems is occurring in a $16 billion implementation in the U.S. Department of Veterans Affairs (VA). Research is needed in clinical outcomes, human factors, decision support, visualization, methodology, data access, training, satisfaction, costs, and the advancement of quality, safety, and value. To foster research in these areas, the VA Health Services Research and Development Service has funded a Coordinating Hub to Promote Research Optimizing Veteran-Centric EHR Networks (PROVEN).

Aims of the Coordinating Hub

PROVEN’s aims are to support, promote, & enhance health services research related to EHR modernization; provide methodological training, methodological and informatics expertise, and support to investigators; serve as a liaison between EHR modernization researchers and VA operational partners and implementation sites; communicate research findings to VA decision makers and the research community; and oversee the conduct of pilots investigating EHR implementation.

Organizational Overview

PROVEN has four cores: administrative; health informatics; data and methods; and implementation & training. PROVEN regularly interacts with stakeholders including the VA Office of EHR Modernization. An initial set of core pilot projects have been developed, covering areas of governance, clinical care, and Veteran engagement.

Progress to date

The PROVEN Hub has held online seminars, established an investigative network, and developed and disseminated a research agenda for EHR modernization. Projects in data quality and data training are in development. Discussions with partners led to expanded involvement of researchers in EHR Councils and site-level planning for implementation. Enhancing enterprise-wide access to EHR data for research remains a priority. Published articles on EHR transitions have been identified. Findings are being methodically mapped and analyzed, to synthesize lessons that may guide the implementation efforts.

Conclusion

The PROVEN Hub has created necessary research infrastructure to support and foster research about EHR modernization in VA. Pilots have been initiated, but the bulk of the critical work lies ahead and includes not only research and implementation science but also attention to workforce capacity in informatics research.

Nursing Data in a CoVID-19 Vaccination Clinic

Luann Whittenburg, PhD, RN BC, FNP BC, FHIMSS, FAAN, FAMIA1
Virginia K. Saba, EdD, RN, FACMI, FAAN LL2
1Health Informatics Consultant, Fairfax, VA
2President and CEO, SabaCare, Inc. Arlington, VA

Keywords: Data Sharing, Interoperability, Knowledge Representation, Nursing Informatics, Clinical Care Classification System, CCC

Overview: The Coronavirus 2019 (CoVID 19) pandemic is a global health crisis. Frontline nurses have suffered psychological stress and prior studies have focused on knowledge of the disease and information sources for the public.1-2 In January 2021, CoVID-19 vaccination clinics opened, and a literature review identified a data gap. No standard, coded nursing data was associated with the CoVID-19 vaccination process. For example: nursing services required to discuss potential vaccine side effects, post-vaccine care, injection administration or nursing services for infection control. This project identifies the relationship between nursing concepts in a recognized nursing informatics standard and the nursing services provided in a CoVID-19 vaccination clinic to evaluate if nursing services data from CoVID-19 vaccination clinics could be coded and if so, can standardized, coded nursing data enhance the granularity of nursing data pertaining in CoVID-19 vaccine administration predictive workload models. The recognized nursing terminology of choice for documenting the essence of patient care in electronic health record systems is the Clinical Care Classification System (CCC) classified by 21 care components to form a single interrelated system that provides a framework linking nursing diagnoses to interventions, and outcomes as well as linking to other health-related terminologies.3-4 The CCC four level framework allows aggregation of coded data upward for big data analytics and downward to granular data. The CCC has a five-character alpha-numeric structure for data interoperability based on the ICD-10.5

2. Objective: The objective was to code the nursing services performed during a CoVID-19 vaccination clinic and identify the actual nursing services involved in the vaccination process in a CoVID-19 vaccination clinic.

3. Methodology: The design was a deductive content analysis based on degrees of equivalence often used to match concepts between defined process documentation and coding systems. Of the available 201 CCC Nursing Interventions and four CCC action types the CCC nursing intervention concepts total of 804 concepts. The CCC concepts were input into an Excel worksheet matched to CoVID vaccine documentation based on degrees of equivalence. Matches were reviewed by CCC content experts with differences discussed until 100% consensus agreement was reached. With agreement reached, the match outcome was entered on the Excel abstraction form.

4. Result: All 10 of the unique nursing services in the CoVID-19 vaccination documentation matched a CCC concepts. The CCC demonstrated an ability to code nursing services at the smallest data level and the content analysis process data enhanced CoVID vaccination documentation. The CoVID nursing services data matched to CCC concepts provided a cohesive, objective view of the CoVID vaccination process and realistic assessment of the nursing services provided in a CoVID-19 vaccination clinic.

5. Discussion: The CCC System is designed for computer processing, free for use with copyright permission, approved by the ANA, HHS, and conforms to Cimino criteria6. The CCC increased the descriptive validity of the CoVID-19 vaccination documentation and data consistency between CoVID vaccine documentation and CCC nursing concepts. Future studies may access the CCC Workload Actions Measures Method6 (WAMM)7 to generate valid, reliable measurement of nursing workload through weighted CCC ‘care value’ (intervention/action types) coupled with CCC ‘base values’ (health conditions acuity).

6. Conclusion: Nursing documentation in a public health system using coded nursing concepts in the CCC System is important to understanding the actual workload of nursing practice in a CoVID-19 vaccination clinic. This CCC application demonstrates nursing services data from clinic vaccination processes can be coded in a recognized nursing informatics standard and nursing data increases the granularity of available nursing data.

Complementing Automated Risk Prediction with Face-to-face Screening Improves Suicide Risk Prediction

Drew Wilimitsis1, Robert W. Turer, MD1, Michael Ripperger1, Allison B. McCoy, PhD1, Sarah H. Sperry, PhD1, Colin G. Walsh, MD, MA1; 1Vanderbilt University Medical Center (Nashville, TN, United States)

Background
In a systematic review, the U.S. Preventive Services Task Force found insufficient evidence to support the accuracy and effectiveness of suicide risk screening in primary care settings. Although machine learning can leverage electronic health record (EHR) data for scalable risk detection, suicide prediction models have high false-positive rates that limit their clinical utility. Our team at Vanderbilt University Medical Center (VUMC) has developed and implemented a real-time suicide risk prediction model across the enterprise. To investigate the respective and combined predictive abilities of in-person screening and an automated prediction model, we evaluated (1) the ability of the Columbia-Suicide Severity Rating Scale (C-SSRS) to predict suicide attempt and ideation, (2) compared the performance of the C-SSRS to our risk model, and (3) analyzed the performance of our risk model combined with the C-SSRS to evaluate synergistic effects.

Methods
We studied an observational cohort of all adult patients from June 2019 to September 2020 that received both in-person screening and real-time risk predictions. This cohort included visits in the inpatient outpatient, and emergency department (ED) settings. At each index visit, we extracted C-SSRS responses and VSAIL (Vanderbilt Suicide Attempt & Ideation Likelihood) scores generated by our prediction model. To assess the predictive validity of the C-SSRS, we trained a logistic regression model using binary features that represented patient screening responses. Then, we compared the performance of the C-SSRS, VSAIL, and ensemble models (Lasso regression, unweighted average, and a weighted average based on screening risk) that combined both predictions.

Results
After applying inclusion criteria, 120,398 unique patient encounters were included in the dataset. Logistic regression odds ratios for significant C-SSRS predictors were Q1 (SA: 8.8, SI: 10.59), Q2 (SI: 2.04), Q5 (SA: 2.35), and Q6 (SA: 2.46, SI: 1.56). Within thirty days of an index visit, combined models had higher AUC (SA: 0.874 - 0.887, SI: 0.869-0.879) than both the VSAIL (SA: 0.729, SI: 0.773) and C-SSRS (SA: 0.823, SI: 0.777). In the top 5% of risk scores, ensemble methods had PPV (SA: 2.6%, SI: 15.2%) and sensitivity (SA: 76.1%, SI: 61.4%), significantly improving over the VSAIL model, which had PPV (SA: 0.6%, SI: 5.2%) and sensitivity (SA: 16.1%, SI: 20.9%).

Conclusion
Ensemble models combining C-SSRS responses and an EHR-based model performed significantly better than either alone in the prediction of suicide attempt and ideation at a variety of time intervals. By incorporating patient screening responses, the PPV for suicide attempt in the highest risk ventile surpassed an acceptable threshold required for effective clinical decision support. Our results suggest that traditional clinical assessment and predictive models can be used in complement to overcome their respective limitations, which currently hinder the ability of suicide risk detection systems to meaningfully inform clinical practice.

Classifying Infection Risk Following Pediatric Cardiac Surgery

Kaitlin C. Williamson, M.D.1, Daniel Fabbri, Ph.D.1
1Vanderbilt University, Nashville, TN

Introduction
Each year in the United States, approximately 40,000 children undergo cardiovascular surgery, with infections complicating as many as 30%.1,2 If patients at higher risk of infection could be identified prospectively, clinical decision support could prompt increased infection prevention measures and improve outcomes. A past study in this population estimated risk of post-operative septicemia, mediastinitis, and endocarditis, with fairly good performance (c index 0.79), but this study missed many clinically relevant infections, and used only regression methods.1 Our aims in this study were to generate a cohort of pediatric cardiac surgery patients, to generate models to classify the risk of infections in the 30 day postoperative period, and to compare the results of regression and machine learning methods.

Methods
We obtained our data via query of the Vanderbilt Research Derivative, a clinical data warehouse repurposed for research. We included any pediatric cardiac surgery performed on or after January 1, 2015, on patients under age 18. We included 36 predictors including demographics, lab values, comorbid medical conditions, and drug exposures. Outcomes included sepsis, bacteremia, urinary tract infection (UTI), surgical site infection (SSI), pneumonia (PNA), necrotizing enterocolitis (NEC), and a composite outcome of any previously listed outcome excluding NEC, occurring within 30 days of the procedure. We used Python’s scikit-learn package for analysis. We performed an 80-20 test-train split, then fit and ten-fold cross validated models using logistic regression, support vector machine (SVM), K-nearest neighbors (KNN), decision tree and random forest models. We assessed performance using area under the receiver operating characteristic curve (AUROC) and accuracy. We performed univariate analysis of predictors for each outcome and performed subgroup analyses of younger (<180 days) and older children (>=180 days).

Results
We obtained data for 1681 patients, undergoing 2080 distinct operative encounters. Our univariate analysis of the full data set, including all ages, showed that patient age was the strongest predictor for all outcomes. Table 1 describes the performance of each model in the test data, in classifying each outcome.

Table 1. AUROC in test set for full cohort (n = 222).

Discussion
Several of our models performed well in classifying post-operative infection risk. Compared to machine learning methods, logistic regression performed more consistently between the training and test data, with particularly high performance in classifying NEC, bacteremia, and sepsis. Several models demonstrated likely overfitting. If validated in real time data and applied clinically, these models could provide useful forecasts of infection risk.

Exploring EHR Diagnosis Recording Pattern Changes During a Pandemic

Kala S. Wilson, MPA,1 Brian J. Wells, M.D. Ph.D.,2 Jyoti Gangur, MS,1
Kristin M. Lenoir, MPH,1 Maria E. Mayorga,3 Franck Diaz-Garelli, Ph.D.1
1University of North Carolina at Charlotte, Charlotte, NC

3North Carolina State University, Raleigh, NC

Introduction
Improving learning health systems rests on reliable secondary use of Electronic Health Record (EHR) data;1 however, the consistency and validity of secondary analyses are directly reliant on the data’s quality (DQ).2 We hypothesized that an external societal change (e.g., COVID-19 and increased telemedicine) may be correlated with clinical data entry patterns. We tested this hypothesis on diabetes-related DX data given its chronic, varying nature over time (i.e., controlled vs. uncontrolled levels, complex comorbidities) and significance to public health. Specifically, we built statistical models predicting the odds of DX sequences occurring before or after an elevated hemoglobin A1c (HbA1c) based on the number of DX records that indicated uncontrolled diabetes to compare effects during regular and confinement operations.

Methods
We assessed changes in reporting rates of uncontrolled diabetes in structured diagnosis (DX) data preceding and subsequent to a lab indicating this transient condition was available in the EHR. We compared patterns during normal clinical operations and during the current pandemic’s Stay at Home orders of 2020 in North Carolina. After receiving approval from the Wake Forest University School of Medicine’s Institutional Review Board (IRB: IRB00062976), we extracted structured DX data from an EHR database covering five segments within electronic patient charts (i.e., primary encounter DX, encounter DX, billing DX, order DX, and problem list DX). We gathered patient DX sequences (i.e., a chain of chronologically ordered DX records in a patient’s EHR) including all diabetes DXs within 90 days before and after a HbA1c laboratory result greater than 9%.3 Every DX sequence contained specific ICD-10 codes for Type 1 or 2 diabetes (i.e., ICD-10 DX code, E10.* and E11.*) that indicated lack of control (i.e., “uncontrolled diabetes”, “diabetes with hyperglycemia”). We tested our hypothesis by building binomial statistical models using Stata’s generalized linear model (GLM).

Results
A total of 107,167 diabetes DX recordings for 12,620 patients and 6,574 diabetes DX recordings for 1,187 patients for regular operations and pandemic operations respectively were assessed. Our statistical models revealed changes in number of DX reporting uncontrolled diabetes between regular clinical operations and clinical operations during confinement. A 90-day DX sequence was 6.9% (adj-p<.0001) more likely to appear after a high HbA1c value during regular operations for each uncontrolled diabetes DX included. In contrast, it was 15.9% (adj-p=.0094) more likely to appear in the post-HbA1c timeframe during confinement operations. We also found statistically significant differences for number of providers and number of departments predicting whether a DX would appear before or after the elevated HbA1c between normal (OR=1.309; OR=2.405, adj-p<.0001) and confinement (OR=1.722, adj-p=.0101; OR=4.107 adj-p<.0001) clinical operations. After controlling for timeframe (i.e., normal operations and confinement operations), we found the effects were statistically different (adj-p<.0001) with an odds ratio of 1.20, revealing higher odds of uncontrolled diabetes DX appearance in the normal operations dataset.

Conclusion
We were able to uncover differences between regular and confinement operations, providing preliminary evidence to the idea that pandemic-induced alterations of clinical workflows may be associated with clinical data quality and entry patterns. Our findings emphasize the need to give particular attention to factors impacting clinical practice while generating secondary use of EHR data. Future work will verify the internal and external validity of these findings and further investigations will explore the causal relationship between data entry changes and the onset of external factors.

Prediction of Small Bowel Obstruction Outcomes with Machine Learning

Tanner Wilson, MD, MS1,2, Gilles Clermont, MD, MSc1,2, Harry Hochheiser, PhD2
1UPMC, Pittsburgh, PA; 2University of Pittsburgh, Pittsburgh, PA

Introduction
Small bowel obstructions (SBOs) are a common cause of hospital admissions for abdominal pain. Surgery is required for 24% of cases, and when indicated, early operation reduces mortality by half1. Unfortunately, clear indications for early operation are elusive. For example, CT sensitivity for intestinal ischemia, a clear indication, is as low as 75%2. One influential model of SBO3 based on symptoms and CT findings was 37% sensitive for need for operation and 46% sensitive for strangulated obstruction, with accuracy of 65% and 77%. We aim to leverage large-scale informatics and machine learning methods to improve the prediction of outcomes in SBO by creating a screening model using structured data available within the first day of admission to be deployed on all admissions with an SBO-like diagnosis.

Methods and Results
We collected electronic medical record extracts from 28,298 admissions between 2010-2019 across 15 UPMC hospitals with ICD9/10 coding consistent with small bowel obstruction of any cause, as well as possible mimics such as ileus, at any point during admission. From these records, day-of-admission observations were collected on the following: age, sex, race, BMI, medical comorbidities as defined by Elixhauser4, smoking status, and basic laboratory values (hematologic, electrolyte, renal/hepatic function, and coagulation panels). Any ICD9/10 code noting hernia as the cause of intestinal obstruction was also noted, as this was thought to influence outcomes. Chief complaints were reviewed to assure an appropriate cohort, with the top 5 explicitly specifying SBO or abdominal pain (not shown).

All computations were performed in Python 3.7.3 using scikit-learn 0.24.1. Admissions beginning in 2018 or later were treated as test cases, for 18% holdout. Numerical variables underwent mean imputation and standard scaling.

Outcomes of interest included: any relevant abdominal operation during the admission (50% of cases), as identified by ICD9/10 coding; any intestinal resection during the admission (23%), by ICD9/10; and patient death during the admission (5.7%), by date of death recorded in the EMR. For each outcome, we trained models using logistic regression with $L_2$ regularization, random forests, k-nearest neighbors with both uniform and distance-based weighting, support-vector machine classification using both linear and radial basis function kernels, and Gaussian naïve Bayes classification. Hyperparameter optimization was performed with 3-fold cross-validation to optimize the F1 metric. Balanced class weighting was used for all applicable models to account for class imbalances. For each outcome, models with at least 50% recall of positive cases were then combined into hard and soft voting ensemble classifiers, with the final voting method chosen for highest recall.

Conclusion
Our initial model achieved recall of 72% of operative cases, 57% of bowel resections, and 55% of inpatient deaths. As seen in the table, overall performance is promising for an initial screening model based exclusively on structured data, especially for the highly imbalanced inpatient deaths. This represents the first step in development of a decision support system for SBO at our institution. Future steps will expand to additional sources of both structured and unstructured data, including the text of radiology reports and clinical notes, to create more clinically informed models.

The Use of Integrated Medical Devices and Clinical Decision Support in the Acute Care Setting: A Scoping Review

Jennifer B. Withall, PhD, RN1, Jessica M. Schwartz, MPhil, BSN, RN1, John Usseglio, MPH2, Kenrick D. Cato, PhD, RN1,3

1Columbia School of Nursing, New York, NY; 2Columbia University Irving Medical Center, Augustus C. Long Health Sciences Library; 3Columbia University Department of Emergency Medicine, New York, NY

Introduction
Seamless data integration between point-of-care medical devices and the electronic health record (EHR) are elemental to clinical decision support systems (CDSS). CDSS directly aids clinical decision making by matching evidence-based computerized knowledge, contextual assessments, and individual patient characteristics to generate patient-specific recommendations to the clinician1. Previous reviews examined patient-generated data through consumer wearables and integration with the EHR in the community setting. This review will focus on integrated devices that clinicians encounter in the hospital setting. The objective of this scoping review is to examine the existing evidence pertaining to integrated medical devices and how the clinical decision support systems associated with these devices impacts clinicians and clinician decision making in the inpatient acute setting.

Methods
The guidelines for scoping reviews outlined in the JBI Manual for Evidence Synthesis and the Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extensions for Scoping Review (PRISMA-ScR) served as the framework for this review2. PubMed, CINAHL, IEEE Xplore, and Scopus were searched for scholarly, peer-reviewed journals indexed between January 1, 2010, to December 31, 2020. A priori inclusion criteria were empirical studies describing integrated medical devices impacting patients at the point-of-care or integrated medical devices that facilitated clinical screening that referenced solicited or unsolicited CDSS and clinician decision making, in the inpatient acute care setting. Articles that were excluded were those not available in English, situations where medical devices were not integrated with the EHR, guidelines, systematic reviews, conference proceedings, articles that examined diagnostic or imaging studies, and consumer (commercially available) wearables for physiological data (e.g., FitBit). Articles and data extraction were organized according to the initial use scenarios described in the modified Conceptual Model for Technology, Nursing and Patient Safety. The modification included changing “nurse” in the original model to “clinician” noted in this review (Figure 1)3.

Results
Of the 1924 articles screened, 18 were included for synthesis (Figure 2). Ten articles described patient assessment, monitoring, or surveillance use, with vital signs monitoring and CDS related to early warning detection comprising most of this subset. Three articles described patient protection from harm, all of which focused on CDS for medication safety. Four articles described direct care use scenarios, all of which described insulin administration and a CDS tool for insulin infusions. Finally, one article described a hybrid situation of patient communication and monitoring.

Conclusion
Integrated device data provides insight into user-device interactions and helps to illustrate healthcare processes. Considering the emphasis on patient safety, cost-effective and efficient care delivery, our results indicate that establishing closed-loop and/or bi-directional communication related to point-of-care devices remains an area of opportunity for healthcare organizations. Additional research may include integrated device log metadata, deep learning analytics, and situational awareness; artificial intelligence and CDSS; patient portals, mobile health, and incorporation of patient-generated data into the EHR and CDSS in alternate care settings; and interprofessional innovation for new knowledge generation. These future directions can broaden and extend the existing evidence related to integrated medical devices, CDSS, and patient outcomes.

Do Clusters and Sequence of Symptoms Predict COVID-19 Test Results?

Janusz Wojtusiak, PhD, Wejdan Bagais, BS, Hedyeh Mobahi, MS, Elina Guralnik, MS, Amira Roess, PhD, Farrokh Alemi, PhD
George Mason University, Fairfax, VA

Introduction
Despite wide availability of COVID-19 vaccines, the need for frequent screening will continue. A polymerase chain reaction (PCR) tests are considered the gold standard in terms of testing accuracy with reported recall (sensitivity) over 95%. Unfortunately, it typically takes 24-48 hours for individuals to get the PCR test results which is often perceived too long in many daily situations. In contrast, rapid (antigen) tests, including in-home tests, are less accurate with recall that varies between 49% and 80% depending on a source. Alternatively, symptoms can be used.

Methods
Data: Two independently collected sources of data have been used. The 461 data were collected by our group as part of a study to investigate the relationship between symptoms, demographics, and social distancing. The self-reported data include 23 symptoms, along with indicators which of the symptoms were present on the first day. The Mason Health™ is a symptom and exposure screening tool that was implemented by George Mason University as part of the response to COVID-19 pandemics. The data include 1,396,797 daily reports by 54,805 individuals, and 261,011 test results, transformed into symptom episodes by a time-series analysis, resulting in 703 symptom-test episodes with for 594 individuals. All data analysis has been completed using the 461 data, split into 80-20 training and testing sets, bootstrapped 30 times with average values reported. The Health™ data were used external validation only. Symptom Clustering: Three approaches have been used: (1) An exhaustive set of conjunctions of pairs and triples of symptoms have been created, and passed through 24-fold cross-validated LASSO to detect robust predictors. (2) A set of all hierarchical clusterings was extracted and passed through LASSO, as for the previous method. (3) A set of clusters created by cutting the hierarchical clustering dendrogram at a specified point was used. Supervised Learning: Logistic regression, random forest and gradient boosting were used. The predicted output is positive/negative test result for COVID-19. First, models were learned using all 23 symptoms in the 461 data. Then, a subset of 16 symptoms common among the datasets was selected. Final models were applied to the Health™ data for the external validation. Area under ROC (AUC), recall and precision averaged from the 30-time bootstrapped training/testing split were calculated. Models were checked for biases and performance within minority groups.

Results
The best result on the 461 data was obtained from logistic regression on data with first day symptoms and no clusters (AUC=0.7984; 12 symptoms). The selected best model externally validated on Health™ data achieved AUC=0.7125. Symptom clusters: Inclusion of clusters of symptoms slightly improves accuracy of the models, but at the expense of the numbers of variables and overfitting. The best model with symptom clusters reached AUC=0.7981 vs. 0.7903 (p<0.01) when using clusters of variables extracted from hierarchy and achieved AUC=0.6955 on Health™ data. First-day symptoms: The experiments also indicate that the inclusion of additional attributes that indicate which symptoms were present on the first day slightly improves model performance from AUC=0.7903 to AUC=0.7984 (p=0.02) without clustering and from AUC=0.7883 to AUC=0.8004 (p=0.02) with conjunctions of symptoms (0.7 on Health™).

Conclusion
The results indicate that it is reasonable to predict COVID-19 using self-reported symptoms. The inclusion of clusters and order of symptoms improves accuracy of the models. The constructed models tend to overfit the data because of small sample size and large number of variables, which is further confirmed by the best external performance on Health™ data achieved by the simplest model, yet still providing good results.

Implementing Real-Time Prescription Benefit Tools: Early Experiences at 5 Academic Centers

1Stony Brook University Hospital, Stony Brook, NY; 2 Yale University, New Haven, CT, 3Yale School of Medicine, New Haven, CT; 4Johns Hopkins University School of Medicine, Baltimore, MD; 5Froedtert and Medical College of Wisconsin, Milwaukee, WI; 6Yale New Haven Health, New Haven, CT, 7University of Pittsburgh School of Medicine, Pittsburgh, PA

Background: High drug costs in the U.S. negatively impact medication adherence and clinical outcomes1. Multiple e-prescription vendors now provide real-time prescription benefit (RTPB) tools that display patient out-of-pocket prices in the electronic health record (EHR) at the point of prescription. RTPB tools can retrieve cost information, then display therapeutic and/or pharmacy alternatives with lower costs. Health systems can customize how RTPB tools are implemented. As little is known about RTPB tool utilization, we aimed to describe the early experiences, implementation decisions, and outcomes associated with RTPB tools at five U.S. medical centers.

Methods: This is a cross-sectional study at three months after RTPB tool implementation at University of Pittsburgh Medical Center (UPMC), Yale New Haven Health (Yale), Froedtert and Medical College of Wisconsin (F&MCW), Johns Hopkins Health System (JH) and Stony Brook Medical Center (SB). We identified each institution’s implementation characteristics, rates of e-prescriptions where RTPB tools retrieved cost data (retrieval rate), and prescriptions that were adjusted using the tools. Characteristics included whether tool alerts displayed automatically, options for providers to opt out, and savings thresholds to display alternatives. Data sources included outpatient prescription and RTPB data from the EHRs.

Results: Implementation characteristics, RTPB data retrieval rates and prescription adjustment rates at each institution are summarized in table 1.

Discussion: Prior literature has shown that EHR tools can impact cost-related provider ordering behavior2. Rates of RTPB information retrieval across health systems were variable, which may reflect differences in the institutional payer mix, vendor mechanisms for obtaining RTPB information, number of RTPB vendors at an organization and the level of integration of its health system. Prescription adjustment rates were universally low and may be affected by a variety of factors: low RTPB retrieval rates, system design choices in creating meaningful thresholds to prompt adjustments, and implementation challenges such as lack of provider awareness or confidence in these new tools.

Conclusion: RTPB tools represent a paradigm shift in price transparency at the point of medication prescribing. Our early data demonstrate a range of implementation differences across sites. More research is needed to understand factors that affect retrieval of RTPB information, how to optimize tool utilization and their role in patient care.

An Interactive COVID-19 Vaccination Appointment Dashboard
Theodore B. Wright, MD, MBI, Charlene Davis, and Connor Rossier, PharmD
Central Virginia VA Health Care System, Richmond, Virginia

Introduction
COVID-19 dashboards have been used for exhibiting rising positivity and mortality rates1, showcase pandemic predictive models2, monitor for outbreaks and trends, and even to inform on returning to work or school3. With the release of the first COVID-19 vaccines, the challenge was to vaccinate as fast possible. The Veterans Affairs’ (VA) prioritized vaccine distribution using a multi-tiered approach4. The Central Virginia VA Healthcare System (CVHCS) provides services to nearly 70,000 unique Veterans yearly, many of which are at high-risk for complications5. Herein, we describe an interactive COVID-19 Vaccine Appointment dashboard meant to track vaccine administration rates as well as scheduling of vaccine appointments.

Methods
Our team maintains an operational reporting platform that allows rapid development and deployment of powerful, interactive visual dashboards for clinical and operational data. Using the VA’s Corporate Data Warehouse (CDW)6, we build tabular data models and interactive user reports with Microsoft’s Power BI software. Development of our dashboard started with the requirements listed in VA’s vaccination campaign and had two primary goals: 1) Identify Veterans in each vaccination cohort, and 2) delineate Veterans by vaccination appointment status. We later expanded on the output. Vaccination cohorts are risk-stratified by age, vaccination, and appointment status by leveraging EHR data. Veteran statuses were categorized for a simplified aggregate graphical display. The final dashboard was used by the CVHCS Incident Command Center (ICC) for review and action.

Results
The dashboard provides local COVID-19 vaccine appointment activity and vaccination rates by cohort (Fig. 1). To facilitate scheduling efforts, vaccination status categories can be selected which instantly display individual Veteran contact information in an accompanying data table. During the first 7 months of 2021, our data shows that, for Veterans with an assigned primary care team at CVHCS, over 50,000 total vaccine doses have been administered and nearly 25,000 of those Veterans are fully vaccinated as of this writing.

Discussion
In addition to usual data reporting, this dashboard’s interactive nature allows specific, actionable data to be located quickly. This key feature allowed us to create a unique tool that helped with facility vaccine scheduling efforts.

Conclusion
Here we demonstrate how visual analytics tools can supplement other information systems such as a scheduling software when new business requirements arise. Our dashboard continues to be used at CVHCS to help vaccinate our Veterans as well as inform clinic staffing and vaccine distribution needs.

The Spectrum of Engagement in Chronic Kidney Disease Care at a Large Healthcare System

YiFan Wu, MPH, Adam Wilcox, PhD
Biomedical and Health Informatics, University of Washington, Seattle, WA

Introduction

Chronic Kidney Disease (CKD) has placed a significant burden on society in the USA. Even with advances in information systems like electronic health records (EHR), the recognition rate of CKD remains consistently low. In 2019, researchers reported the recognition rate (both confirmatory lab results and ICD codes in EHR) of CKD was 11.8% among Medicare beneficiaries across ten states in the USA. Besides the low recognition of CKD, insurance coverage and geographical constraints on access to treatment have previously been identified as barriers for patients not seeking specialized care. Similar to HIV care, CKD care can be depicted as a continuum of engagement. In this paper, we assess the CKD recognition rate and the spectrum of engagement in CKD care at the University of Washington healthcare system (UW), as well as identify potential reasons for patients being lost-to-follow-up, where lost-to-follow-up is defined as those who had CKD ICD codes in EHR and clinical manifestation but didn’t seek for specialized care.

Data Sources and Methods

The CKD cohort was identified using EHR in the UW Medicine enterprise data warehouse from 2015 to 2020. We defined the study cohort as following: A. CKD determined by laboratory tests: a patient who had at least two eGFR <60 mL/min/1.73 m<sup>2</sup>, 90 days apart; B. CKD by diagnosis: a patient who received at least one CKD dx of ICD-10 codes N18(1-9); C. Patients who had both lab-confirmed results and dx and at least one renal clinic visit at UW Medicine; D. Maintained CKD condition: patients who met all the criteria above and had at least two UW renal clinic visits(D ⊆ C ⊆ B ⊆ A). We further investigated the patients who had clinical evidence but were missing a CKD dx by examining insurance status. Lastly, we randomly chose 15 patients who had CKD stage >3b (the higher the more severe) and who didn’t have a CKD ICD dx and reviewed the clinical notes in EHR to examine the potential reasons for lost-to-follow-up in CKD care.

Results and Discussion

We identified 39977 CKD patients based on the clinical criteria. 18861 (47.17%) patients had a CKD ICD dx in EHR, and 14900 (79%) of them had insurance coverage. Among the 21116 patients who didn’t have a CKD ICD dx in EHR, only 4434 (21%) of them had insurance coverage on file. Among the patients with CKD dx and abnormal lab values, 7171 (38.02%) had at least one encounter at the nephrology clinic, and 5199 (27.56%) had more than two encounters at the nephrology clinic. Since the insurance status varies significantly between the patients with dx vs. without dx in EHR, we initially thought that not having insurance coverage might be the primary driver of lost-to-follow-up. By conducting clinical notes biopsy, we found that the reasons for lost-to-follow-up can be summarized as 1) patients are getting specialized care from external hospitals out of UW system 2) geographical constraint 3) EHR data quality issue 4) recovered and no longer need renal care. Overall, by focusing on the structured EHR, the recognition rates remain low, that the % of patients without CKD ICD dx raised some concerns. The qualitative study showed that patients do not necessarily fall out of the spectrum of engagement but seek external care.

Conclusion

Our study followed a cohort longitudinally of the spectrum of CKD care in a single large healthcare system in 2015-2020. The study shows the limited engagement of CKD care at a 47.17% recognition rate. Our study shows that integrating both qualitative and quantitative analysis is essential to examine the reasons behind lost-to-follow-up.

Development and Validation of a Survival Score for the Emergency Department in Singapore

Feng Xie, BS¹, Bibhas Chakraborty, PhD¹, Nan Liu, PhD¹, Marcus Eng Hock Ong, MBBS, MPH¹,²
¹Duke-NUS Medical School, National University of Singapore, Singapore; ²Singapore General Hospital, Singapore

Introduction

Survival prediction for time-to-event outcome helps treatment determination and resource allocation, especially for patients with critical illnesses or emergencies. At present, survival scores have been pervasively used in healthcare for evaluating patients’ overall survival and represent them as a single indicative score, such as the survival prediction score (SPS) and the Palliative Prognostic Score (PaP). To the best of our knowledge, there is no survival score developed for the Emergency Department (ED), where the patients’ predicted overall survival could provide a valuable reference for clinician’s decision-making. In this study, we aimed to develop a survival score to predict ED patients’ overall survival based on a survival analysis framework.

Methods and Materials

All emergency admission episodes from January 1, 2009 until October 31, 2016 in Singapore General Hospital (SGH) were included in this study. We included demographics, comorbidities and clinical variables. Based on the survival analysis framework, survival time was measured from the time point of patients’ ED admission. Time to death within 365 days after ED admission from all causes was the primary outcome. Our survival score was developed on a novel AutoScore pipeline with machine learning-Random Survival Forest (RSF) for variable selection, Cox proportional hazards regression for score weighting and Kaplan–Meier methods for outcome analysis. The recent ED episodes in 2016 were assigned to the testing cohort for performance evaluation and comparisons. We compared it with the other scores such as Modified Early Warning Score (MEWS), National Early Warning Score (NEWS), Score for Emergency Risk Prediction (SERP) by applying concordance (C-index, D-index) and time-dependent receiver operating characteristic (ROC) analysis.

Results and Evaluation

A total of 337,000 unique emergency admission episodes were included. Seven components were selected by RSF to form the survival score (Table 1), consolidating patients' predicted overall survival into one single indicative score. The derived triage score outperformed several baseline scores (Table 2). It significantly predicted and stratified patients’ survival on the Kaplan–Meier Curve (Figure 1). Age and comorbidities were powerful predictors for patient’s overall survival in the aging population. Our survival score outperformed other comparators on various metrics.

Conclusion

We developed the survival score from EHR data of eight-year ED admission episodes by combining machine learning and the regression analysis. This score could help anticipate the patient’s overall survival when patients are admitted from the ED.
Risk Stratifying Heart Failure Readmissions of VAD-Eligible Patients Using Laboratory Data

Jinchen Xie, MS¹, Arman Kilic, MD², Rema Padman, PhD¹
¹Carnegie Mellon University, Pittsburgh, PA, United States; ²Medical University of South Carolina, Charleston, SC, United States

Heart failure represents a spectrum of disease severity with specific clinical criteria for advanced therapy, including heart transplantation and left ventricular assist device (LVAD) implantation. However, the transition between phases of HF severity and defining the timing for advanced therapies are subjective, lacks standardization and a data-driven approach, resulting in a missed opportunity for potentially impactful interventions. We hypothesize that a better understanding of the latent heterogeneous groups in the VAD-eligible cohort will lead to more accurate and clinically interpretable risk models for intervention timing and choice of therapy. In this study, we investigate this heterogeneity in HF patients with multiple readmissions by risk stratifying the population using routinely collected laboratory data during inpatient stay.

We applied multi-trajectory modeling² using six laboratory tests at each visit, across up to ten consecutive admissions, to identify distinct subtypes of HF patients eligible for VAD therapy and examine the differences across the resulting groups. We excluded patients from the study cohort who did not meet the criteria to receive VAD therapy at their initial encounters. Using the six laboratory tests, including estimated glomerular filtration rate (eGFR), sodium, hemoglobin, potassium, platelets, and white blood cell counts, we estimated a parsimonious, group-based, multi-trajectory model and evaluated multiple fitness criteria to cluster patients into an optimal number of distinct risk groups. Eleven risk factors established at the index admission, such as age and gender, were also included in the model as baseline covariates. Standard significance tests evaluated differences in key characteristics between groups.

The final analysis cohort included 1547 patients identified as VAD-eligible at their index admission. We identified five distinct trajectory groups evolving over multiple admissions using the six types of laboratory data (Figure 1). Groups 1 includes the most severely ill HF patients with the highest all-cause 30-day and 1-year mortality rates and the highest proportion with a history of multiple comorbidities. These patients also started at the lowest eGFR level compared to the other four groups. Group 2, the second-highest risk group, had the most patients on Anti-Platelet (P2Y12) and Class I Anti-arrhythmic prescription. Group 4, the lowest mortality risk group, had relatively young patients and the lowest proportion of multiple comorbidities and clinical events history. Group 3 and Group 5 formed an interesting comparison. While the two groups had similar average age and comorbidities, Group 3 patients, on average, received VAD just within the first year after index admission and had a lower all-cause mortality rate by the end of follow-up compared to those in Group 5 who received VAD, on average, several months later.

The group-based multi-trajectory model shows promise in risk stratifying patients with multiple HF readmissions into distinct HF severity groups using underutilized, routinely collected laboratory data and baseline covariates. The model also revealed eGFR’s impact as a dominant factor in identifying the higher mortality risk groups of VAD-eligible heart failure patients. We need to further examine the differences in the timing of VAD implantation across groups, and the adverse events occurring along patients’ trajectories to identify patterns in each group, both of which could help guide the selection of patients for early interventions.

Hand hygiene monitoring by positioning technology utilizing IoT devices

Keiko Yamashita¹, Shintaro Oyama¹, Satoshi Yamashita¹, Chiaki Funada¹, Kikue Sato¹, Taiki Furukawa¹, Aki Sugano¹, Daisuke Kobayashi¹, Hiroshi Tomozawa³, Yuji Sakamoto⁴, Yoshinori Ideno⁴, Kensaku Mori⁵, Yoshimune Shiratori¹

Introduction
Hand hygiene (HH) is important for infection prevention in the medical field, and WHO has been successful in preventing nosocomial infections by organizing the timing when HH is necessary in the patient care. Typical monitoring methods are the direct observation method and the hand sanitizer usage measurement method, but the problem is that it takes time and labor. In this study, we investigated whether HH monitoring using the Internet of Things (IoT) could establish a screening method for direct observation and a verification method for indications at each facility.

Methods
In the standard ward of Nagoya University Hospital, we have introduced a high-precision positioning system with an accuracy of 10 to 30 cm using the AOA (Angle of Arrival) method of BLE4.0 (Quuppa Intelligent Locating System, Quuppa Oy, Finland). The BLE locators (26 units) were placed on the ceiling at a height of 3 m in the center of the hospital room. We attached a BLE beacon to the pump part of my personal hand sanitizer. When hand sanitizer is pushed, the BLE signal transmitted from the pressed beacon is detected by the nearest locator (Figure 1). Two nurses were conducted in this study and surveyed for one week.

Results
The percentage of HH practices that defined HH practices by timing required for direct observation was 55.2% within 30 seconds of admission, 42.8% within the bed area, and 2.0% within 30 seconds after leaving the room. The HH execution rate was high, as the staying hour was longer (Figure 2).

Discussion
There is also a method of using images as an automatic HH monitoring system, but in order to replace the direct observation method, the timing of HH implementation is important, and we thought that location information was necessary for that purpose. Also, although it is difficult to identify the subject using the direct observation method, the IoT HH monitoring method can regularly observe the number of visits to the room by pump sensor and the HH implementation status at each timing, and is considered to be useful for improving effective HH implementation. In addition, it is effective in suppressing horizontal transmission of infection and may contribute to infection control, and it is considered to be one of the screening methods of direct observation, which is a conventional monitoring method.

Conclusion
From this research, HH monitoring using IoT will be an excellent future innovation through important technology for controlling nosocomial infection control.

\textsuperscript{1}Department of Biostatistics & Bioinformatics, Duke University, Durham, NC, USA

Introduction

Increasing attention has been drawn to the problem of racial disparity in clinical prediction models (CPMs). Some have suggested that one shouldn’t use race in CPMs\textsuperscript{1}. We characterize the problem and discuss how accounting for a grouping variable such as race in the model would affect algorithmic bias.

Methods and Results

We define algorithmic bias in a CPM via differential miscalibration, i.e. the model differentially under (or over) predicts risk for a particular group. Moreover, we frame the creation of such bias via a differential missing data process, where conditional on having the outcome of interest (e.g. asthma exacerbation) the outcome is differentially observed (i.e. via coming to the hospital). In such a scenario, we posit that one may learn a CPM that perpetuates algorithmic bias.

We sought to investigate how the inclusion of a grouping variable into a CPM could affect such bias. We performed a series of simulations, simulating a two stage process where the grouping variable may impact either the risk of the true outcome (stage 1) or probability of observing the outcome (stage 2). Suppose $X_1$ is any risk factor, $X_g$ is the grouping variable, $E$ is the true outcome and $Y$ is the observed outcome. The two stages are:

\[
\text{logit}(P(E = 1)) = \beta_0 + \beta_1 X_1 + \beta_g X_g
\]

and

\[
\text{logit}(P(Y|E = 1)) = \gamma_0 + \gamma_g X_g
\]

Here, $X_g$ potentially affects the true risk through $\beta_g$, and potentially affects probability of observing the outcome through $\gamma_g$. After simulating the true data, we learned a CPM, where both included and did not include $X_g$ as a predictor. We then compared learned risk to the true risk.

The results are shown as calibration plots. In (a) and (b), grouping variable does not impact stage 1 but does impact stage 2. Here including $X_g$ in the model does induce more algorithmic bias (b) Conversely, in (c) and (d), $X_g$ impacts the true risk of the outcome (stage 1) but not the observability (stage 2). Here ignoring it in the CPM (c) leads to algorithmic bias where including it leads to no algorithmic bias (d).

![Calibration plots](image)

Figure 1: True versus predicted risk by grouping variable $X_g$. $X_g$ impacts stage1 or stage2, including or excluding $X_g$ in model

Conclusion

We show that if the grouping variable impacts the true outcome, then including it reduces algorithmic bias. However, if the grouping variable only impacts the observation process, it is better to exclude it in model. Therefore, the advice to simply drop race from clinical prediction models\textsuperscript{1} may be too simplistic.

Implementation of Medication Alerts to Reduce Wrong-Drug and Wrong-Patient Errors in CPOE Systems

Yuyang Yang, BS1, David Liebovitz, MD2, Bruce Lambert, PhD3, Bill Galanter, MD, PhD4, Jason Adelman, MD5, Thomas Byrd IV, MD6

1-3,6Northwestern University - Feinberg School of Medicine, Chicago, IL; 4University of Illinois at Chicago, Chicago, IL; 5Columbia University Medical Center, New York, NY

Introduction
Wrong-drug (WD) and wrong-patient (WP) errors occur at a rate of roughly one per thousand orders in inpatient and outpatient settings, resulting in millions of errors annually that can cause severe harm to patients1. Prescriber self-interception of errors can be measured using EHR system logs to detect two types of events: 1) abandon-and-reorder (AAR), where the prescriber starts and abandons an incorrect order before signing it, and then reorders for the correct drug or patient and 2) retract-and-reorder (RAR), where the prescriber cancels an incorrect order within minutes of signing, and re-orders for the correct drug or patient. Prior work by our collaborators found that creating indication alerts to notify prescribers when an ordered medication does not match the patient’s current problems (e.g., metformin order in absence of diabetes) was able to prevent errors2,3. This poster describes the implementation of indication alerts for the Northwestern branch of a multisite follow-up study to determine the effect of indication alerts on prevention of wrong drug/patient errors and addition of problems to patient problem lists during clinical encounters.

Methods
Indication Alerts - Alerts are delivered to clinicians during medication ordering via pop-up dialog (Figure 1). Alerts prompt prescribers to place diagnoses on the problem list when medication orders are initiated if no justification exists.

Identification of WD/WP errors - We used the electronic data warehouse at Northwestern to extract drug name, prescriber’s name, time of medication selection, patient identifiers, and content of problem lists at time of medication selection. We developed R scripts to identify WD/WP errors based on the Wrong Drug Retract and Reorder (WD-RAR) tool, a National Quality Forum (NQF Measure #2723) validated measure.

Results and Conclusion
As of submission of this manuscript, we have finished design of all indication alerts and have collected pre-implementation data on rates of WD/WP errors in our hospital system. We have recently turned-on indication alerts and are actively collecting post-implementation impact on error rates and problem list completion.

Using multivariate models to examine the impact of COVID-19 pandemic and gender differences on health and health care

Jiancheng Ye1*, Zhimei Ren2
1 Feinberg School of Medicine, Northwestern University, Chicago, IL, USA; 2 Department of Statistics, University of Chicago, Chicago, IL, USA

Introduction
The coronavirus disease 2019 (COVID-19) pandemic has uprooted conventional health care delivery for various care, such as routine ambulatory care and mental health care, requiring health systems to rapidly adopt new capabilities. With mandated social distancing policies in place during the COVID-19 pandemic, health care providers have been forced to get closely acquainted with virtual health. We drew data from the National Cancer Institute's 2020 Health Information National Trends Survey (HINTS). We described and compared the characteristics of social determinants of health, physical activity, mental health, alcohol use, and patterns of social networking service use and health information data sharing. All analyses were weighted to provide nationally representative estimates.

Methods
To understand the joint effect of gender and pandemic, we characterize the response of interest via multivariate models: for continuous responses, linear models are considered and for discrete responses, generalized linear models are considered. In the models, we include the effect of gender, the pandemic, and the interacting effect of gender and pandemic, along with demographic covariates to account for the potential confounding factors. Data used in this study were from the fourth round of data collection for HINTS 5 (Cycle 4), which began in February 2020 and concluded in June 2020. Because data collection for Cycle 4 started before COVID-19 became an international pandemic and continued after the pandemic was declared by the World Health Organization, the variable PANDEMIC was created to flag respondents whose survey was received after the COVID-19 pandemic declaration (March 11, 2020). This variable will facilitate the examination of responses before and after the COVID-19 pandemic that became a widespread issue of concern in the United States. The final HINTS 5, Cycle 4 (2020) sample consists of 3,865 respondents. Note that 73 of these respondents were considered partial completers who did not answer the entire survey.

Results
For the characteristic made appointments with a healthcare provider online, the effect of sex before the pandemic is not significant but becomes significant after the pandemic, where the aOR between the female and male population is e^{-0.36}=0.70 (this means the odds of making appointments with a health care provider online for females is 0.7 times that of male); the effect of the pandemic is not significant either before or after the pandemic, and the interacting effect of pandemic and sex is not significant either. As for looking for health or medical information for oneself, the effect of sex is significant before the pandemic, with an aOR between the female and male population being e^{-0.65}=0.52; the effect of sex is also significant after the pandemic, with an aOR between the female and male population being. Similarly, we see a significant effect of sex both before and after the pandemic in characteristics including look up medical test results, share health information on social networking sites, participate in an online forum or support group, visit a social networking site, use smartphone to track progress on a health-related goal and use an electronic wearable device to monitor or track your health or activity; we also see a significant effect of sex after the pandemic with regard to the characteristics have “apps” related to health and wellness.

Discussion
The COVID-19 pandemic has devastated communities of marginalized populations, exposing the deep inequities of the health care system. This study used multivariate models to understand the joint effect of gender and pandemic on mental health, physical health, and behavioral health. The findings of this study demonstrate that significant inequities are also present among patients in accessing necessary health care and relevant information. Responses to the pandemic should consider diverse perspectives, including sex and gender. Decisions that are informed by accurate data and include a gender perspective are more likely to be effective.

Predicting-30 Day All-Cause Unplanned Hospital Readmission of Patients That Developed Acute Kidney Injury During Intensive Care Unit Stay

Zaid K Yousif, PharmD, MAS1, Michael Hogarth, MD1, Linda Awdishu, PharmD, MAS2

1Division of Biomedical Informatics, Department of Medicine, University of California, La Jolla, San Diego (UCSD), California, USA; 2Division of Clinical Pharmacy, UCSD, Skaggs School of Pharmacy and Pharmaceutical, La Jolla, California, USA

Introduction: Hospital-acquired acute kidney injury (HA-AKI) is a frequent adverse drug event with short- and long-term complications. HA-AKI affects up to 50% of patients during their first week of intensive care unit (ICU) stay. It is estimated that 1 in 3 HA-AKI survivors will be readmitted to the emergency department or die within 30 days of hospital discharge. In this study, we describe developing a 30-day unplanned hospital readmission risk prediction model of patients who developed HA-AKI during ICU stay using electronic health record (EHR) data.

Methods: We conducted a retrospective cohort study using the Multiparameter Intelligent Monitoring in Intensive Care (MIMIC) IV database. Patients who developed HA-AKI during ICU stay meeting the 2012 Kidney Disease: Improving Global Outcomes Clinical Practice Guideline (KDIGO) criteria were included. The Centers for Medicare & Medicaid Services (CMS) criteria for readmission measures was adopted. Readmission was defined as all-cause hospitalization within 30 days from the index hospitalization. Per CMS guidelines, planned hospitalizations were not counted as readmissions. A total of 1136 potential variables were evaluated. To avoid overfitting, we excluded 712 variables with < 2% prevalence or > 60% missing, leaving 424 variables. Feature selection was performed using L1 (least absolute shrinkage and selection operator—LASSO) logistic regression. This resulted in the selection of 27 variables which included: demographics (1), healthcare utilization and socioeconomic factors (9), inpatient medications (7), labs (4), diagnoses (4), and procedures (2). An unpenalized logistic regression model was constructed with 30-day unplanned readmission as the outcome and the 27 variables above as predictors. The area under the receiver operator characteristic curve (AUC) was used to assess the model’s discrimination. Additionally, we compared our model discrimination to LACE index, a validated risk prediction score for hospital readmission.

Results: After applying the eligibility criteria, a total of 22,214 index hospitalizations were included. There were 4,217 (19%) 30-day unplanned hospital readmissions. Our model moderately predicted all-cause unplanned readmissions (AUC 0.66, 95% CI 0.64-0.68), and significantly outperformed LACE score (AUC 0.57, 95% CI 0.54-0.59). In general, variables reflecting increased healthcare utilization and unfavorable socioeconomic status increased the risk of readmission. Clinical findings associated with a decline in kidney function increased the risk of readmission.

Discussion: As the rates of HA-AKI survivorship increase, interventions to reduce unplanned readmission targeting this population are needed. To the best of the authors’ knowledge, this is the first effort to develop a 30-day unplanned hospital readmission risk prediction model of patients who developed HA-AKI during ICU stay. When designing our model, we included modifiable risk factors whenever possible. These variables can be utilized to guide the development of clinical interventions to identify and target high-risk patients following hospital discharge. Future work includes validating the model using an external dataset.

Electronic Health Records Reveal Statins Prescription Trends among Small to Medium Sized Practices

Jingzhi Yu1, Ann Andee Wang1, Huyen Vu1, Nicholas Soulakis1, Yacob Tedla1, Abel Kho1
1Northwestern University Feinberg School of Medicine, Chicago, IL

Introduction: Statins have been found to be very effective in reducing cardiovascular morbidity and mortality. While the 2013 ACC/AHA cholesterol management guidelines expanded criteria for patients eligible for moderate to high intensity statins therapy, prior research has found adoption rates leave much room for improvement. In our study, we examine the breakdown of prescribed statins dosage strength and the change across time in small to medium sized practices. These practices account for over 50% of primary care practices in the US; however, prior research in this patient population is lacking.

Methods: Our data was extracted from the EHRs of practices that participated in an Agency of Healthcare Research and Quality (AHRQ)-funded initiative, Healthy Hearts in the Heartland (H3), which aimed to improve quality through practice facilitation. The initiative obtained patient level data from 2013 to end of 2017. Statins prescription was ascertained by the patient’s current medication list or medication prescription table. Dosage was parsed from the descriptions of the medications prescribed. Based on actual numeric dosage, statins were categorized into low, moderate, and high intensity, according to the 2013 guideline. At each month, the number of unique patients was accumulated from the previous months and the percentage of each class of statins was calculated for each month. At any given month, patients with more than one class of statins prescribed leading up to that month were attributed with the highest class of statins prescribed for them. Furthermore, we compared the trends in independent practices and federally qualified health centers (FQHCs), which provide care to a different patient population.

Results: Our dataset included 48,059 unique patients from 70 practices in the northern Midwest U.S. Over the course of 4 years, we saw the percentage high intensity statins increase in the total patient population that were prescribed statins. FQHCs accounted for 33 practices and 20,849 patients. We saw a corresponding reverse trend in the percentage of low intensity statins, while the percentage of moderate intensity statins remained the same. When comparing independent practices and FQHCs, we found greater changes in prescription behavior in FQHCs. Independent practices saw a smaller increase in high-intensity statins, and a constant percentage for low-intensity statins.

Discussion and Conclusion: We found growth in high-intensity statins prescription in small to medium sized practices. However, FQHCs were found to be more likely to enact change in prescription habits compared to independent practices. Further research should be conducted to understand this discrepancy to guide future quality improvement work in small- and medium-sized practices.

Fig 1. Statins intensity trends for all practices (left), FQHC practices (middle), independent practices (right).

Prediction of COVID-19 Case Severity Using Synthetic Data Derived from the National COVID Cohort Collaborative

Noa Zamstein, Ph.D.¹; Andrew J. Neumann, M.B.A.²; Randi Foraker, Ph.D., M.A.³; Jason A. Thomas, B.S.⁴; Adam Wilcox, Ph.D.⁵; Jon D. Morrow, M.D., M.A., M.B.A.⁶,⁷

¹MDClone Ltd., Be’er Sheva, Israel; ²Univ. of Colorado, Aurora, CO; ³Washington Univ., St. Louis, MO; ⁴Univ. of Washington, Seattle, WA; ⁵New York Univ., New York, NY

Introduction: Broad access to data facilitates computational reporting capabilities during a pandemic. Such data are used to quantify daily tests, infections, hospitalizations, and deaths. The National COVID Cohort Collaborative (N3C) of the National Institutes of Health (NIH) brings together longitudinal patient-level data across multiple institutions from different geographic regions into a centralized repository. Synthetic data have been validated as functionally equivalent to original data for analyses.²,³

Objective: To demonstrate prediction of hospital severity and course of COVID-19 illness at admission using a synthetic data set, complementary to a published demonstration of N3C data capabilities.⁴

Methods: We included all adults from the N3C database who tested positive for SARS-CoV-2 who were admitted to hospital between March 2020 and July 2021. Patients were included if they had a hospitalization lasting for at least 24 hours and had at least one additional laboratory result recorded within 24 hours of admission. We defined severe cases as those involving mechanical ventilation or extracorporeal membrane oxygenation (ECMO) or ending in death or discharge to hospice. We included laboratory measures, vital signs, background conditions and demographics in the models. Data were extracted and synthesized using the MDClone ADAMS Platform [MDClone Ltd., Be’er Sheva, Israel]. The MDClone Synthetic Data Engine was used to create a synthetic data set that maintains the statistical properties and inter-relationships of the original data. We developed machine-learning models for predicting the maximum severity during the admission, including over 40 variables. We trained the models against both the original data and the synthetic derivative, and we tested the models against the same data set.

Results: 181,159 patients met the inclusion criteria, of whom 16.1% had severe disease. Median length of stay was 5 days for non-severe and 12 days for severe cases. Non-severe cases had a mean of 2.0 comorbidities and severe cases had 3.4. The area under the curve (AUC) and precision-recall AUC (PR-AUC) of the gradient-boosted-machines (GBM) models demonstrate that training on the synthetic data set achieves the same high degree of utility and predictiveness as the model trained on the original data (Fig. 1a). The feature importance of the predictors in the models trained on the original and synthetic data were highly concordant (Fig. 1b).

Discussion and Conclusions: Synthetic data can represent patient characteristics and support advanced predictive analytics with statistically equivalent results as an original data set. We used these synthetic data to train a non-linear model incorporating a very large number of variables, and we achieved similar results to models developed with the original data. Using synthetic data, we successfully studied hospitalized patient characteristics on the first day of admission and predicted disease severity. Our study was limited by the broader challenges of using data in a multi-institutional cohort. Use of synthetic data can make data accessible to “citizen scientists,” enabling a broader audience to generate pandemic-related knowledge. Future centralized data networks may benefit from the use of synthetic data to avoid the sharing of real human-subject data while maximizing utility.

Improving COVID-19 Vaccine Uptake of Mental Illness Patients using Learning Health System Framework

Xiaoming Zeng, MD, PhD, Austin Hall, MD, Victoria Jeffries, MSPH, Stacey Burgin, MA, John Gilmore, MD, Beth Rossi, BA, Thava Mahadevan, MS
Department of Psychiatry, University of North Carolina at Chapel Hill

Introduction
The nationwide rollout of COVID-19 vaccines has accelerated the pace of mitigating the pandemic. It is critical to have most of the population inoculated with the vaccines for achieving the "Herd Immunity." Studies using national data found that patients with existing mental illnesses are more susceptible to COVID-19 infections.\(^1\)\(^,\)\(^2\) As a result, people with severe mental health are advocated to receive the COVID-19 vaccine as a high-priority group.\(^3\) However, patients with mental illness often lack the needed resources and means to complete the vaccination process. Given the underlying mental disorders, they may also exhibit hesitancy for vaccinations. Therefore, this group requires extra help to overcome the barriers to getting vaccinated.

Description
Using the Learning Health System (LHS) framework, we report an ongoing quality improvement project to improve the uptake of COVID-19 vaccines for patients in the Center for Excellence in Community Mental Health at the University of North Carolina. LHS is defined by the Institute of Medicine as a system in which "science, informatics, incentives, and culture are aligned for continuous improvement and innovation, with best practices seamlessly embedded in the delivery process and new knowledge captured as an integral by-product of the delivery experience." A common framework to present LHS is repeated closed circles consisted of multiple steps. Figure 1 represents one of such cycles, and the steps of the project are specified below:

1. Assemble of data: We synthesize data from multiple sources to support the project – EHR, Master Patient Registry, Patient Feedback Tracker Form, and others.
2. Analyze the data: We use a data visualization tool to show the weekly progress of vaccinations among all eligible patients. We reported KPIs of proportions of patients receiving zero, first, or second dose.
3. Interpret the results: The visualization and progress of patient engagement are discussed at weekly steering committee meetings. New knowledge and insights often are gained during this step.
4. Feedback: Tailored messages are created for different groups – attendings, residents, therapists, office managers – to guide their activities in the next step.
5. Change: Changes are implemented at the end of each cycle based on steps 1-4. For example, the project team quickly realized that an increased number of patients have their second doses overdue. The workflow was adjusted accordingly to contact these patients to re-engage them into the process immediately.

Lessons learned
Multiple lessons have been learned from the ongoing project:

1. Not all data are readily available for tracking the vaccination process. Our EHR system does not capture all vaccine data for all patients. If a patient receives a vaccine dose outside our health system and does not have recent appointments, then that data is not captured. As of today (3/9/2021), the state vaccine tracking system has not been able to share data with the local EHR system yet. Some of the data, such as patients' readiness and hesitancy, must be collected and processed by contacting patients directly, becoming time-consuming, error-prone, and costly.

2. Engaging stakeholders is critical. The project involves multiple stakeholders in our center – physicians, therapists, clinic managers, social workers, and even patients. The project’s leadership frequently communicates with the different stakeholders to inform them of the latest status of the vaccination among patients. Buy-in from and quick action of all involved is critical for the success of the project.

**Introduction:** There is an increasing interest in examining social and behavioral determinants of health (SBDoH) in health outcomes research to understand their roles in shaping people’s health and reduce potential confounding issues and misclassification errors. However, SBDoH information is captured in heterogeneous data sources and is rarely being effectively used. One potential source for SBDoH is the clinical narratives. To facilitate the extraction of SBDoH information from clinical narratives, we developed a formal ontology for SBDoH with 7 high-level classes and 38 subclasses to help organize SBDoH in electronic health record (EHRs). This ontology will be used for developing information extraction pipelines to help organize and normalize SBDoH information from clinical notes in a consistent way with standardized and shared vocabularies.

**Methods:** We started with the Basic Formal Ontology (BFO), a well-established upper-level ontology, as the basis. Following best practices in ontology engineering, we aim to define the entities (classes and relations related to SBDoH), reusing and adapting existing ontological resources as much as possible. We systematically reviewed concepts and terms relevant to SBDoH through literature search such as the World Health Organization (WHO), Healthy People 2020, and Centers for Disease Control and Prevention (CDC), as well as existing knowledge of SBDoH such as ICD-10 and NCI thesaurus. Based on these concepts and terms, we identified key classes and relations with domain experts. On the other side, we recruited domain experts to annotate SBDoH concepts captured in clinical notes from the University of Florida (UF) Health system. The classes developed in the SBDoH ontology were used to guide manual annotation. The annotation results were used to verify and improve the ontology in an iterative developing procedure. Currently, we are working on identifying and reusing classes and relations in existing ontologies to represent SDoH (i.e., a review of existing widely accepted ontologies will be conducted using Ontobee \cite{7} to find relevant classes and relations) while maintaining clear semantics. When there is none that can be reused or there are new SBDoH concepts identified from UF health clinical notes, we will create new classes and relations in the hierarchy. Following our annotation procedure, this ontology will be iteratively developed to support organizing the SBDoH in real-world electronic health records.

**Results and Conclusion:** We developed an SBDoH ontology with 7 main classes and 38 subclasses. Figure 1 shows the architecture for organization SBDoH related classes in SBDoH ontology. We verified and further improved this ontology through annotating SBDoH concepts from a total number of 500 clinical notes. The proposed ontology will be a valuable resource to help organize SBDoH concepts in EHRs.

**Figure 1.** Classes and subclasses identified in SBDoH ontology.

Predicting Next-Day Discharge via Electronic Health Record Audit Logs

Xinneng Zhang*, BS1, Chao Yan*, MS1, Mayur B. Patel, PhD2,3, Bradley A. Malin, PhD1,3, You Chen, PhD1,3

1Vanderbilt University, Nashville, TN; 2Veteran Affairs Tennessee Valley Healthcare System, Nashville, TN; 3Vanderbilt University Medical Center, Nashville, TN (* First authors)

Abstract

EHR audit logs data capture clinicians’ interactions with patient records and provide clues into clinicians’ assessments and insights into patients’ clinical status. It has been utilized to support many endeavors, including clinical task analysis, time-motion studies of clinician activities, and care structure analysis. Machine learning models trained on the audit log data can significantly improve hospital-wide next-day discharge prediction performances, which provides an excellent opportunity for more efficient hospital capacity management.

Introduction

Hospital capacity management depends on accurate real-time estimates of hospital-wide discharges. [1] This study aims to support next-day discharges predictions with EHR audit log data, which is a resource that captures EHR users’ granular interactions with patients’ records. [2]

Method

This study focused on the EHR data for all adults admitted to Vanderbilt University Medical Center in 2019. We learned three light gradient boosting machine (LGBM) models [3] to 1) assess the value that EHR audit log data adds to the daily prediction of discharge likelihood within 24 hours and 2) compare different representation strategies. We applied Shapley additive explanations (SHAP) [4] to identify the most influential types of user-EHR interactions for discharge prediction.

Results

The data includes 26,283 inpatient stays, 133,398 patient-day observations, and 819 types of user-EHR interactions. The model (N-INT) using the count of each type of interactions in the recent 24 hours and other commonly used features, including demographics and admission diagnoses, achieved the highest area under the receiver operating characteristics (AUROC) curve of 0.921 (95% CI: 0.919-0.923). The model (ONLY-INT) that only includes user-EHR interactions also achieved a high AUROC of 0.890 (0.888-0.892). By contrast, the model (NO-INT) lacking user-EHR interactions achieved a significantly worse AUROC of 0.862 (0.860-0.865) than those with interactions (p-value <0.001). Among the 20 most influential factors (in terms of SHAP values) of the best performing model, 50% were user-EHR interaction features with distinct semantics.

Conclusion

EHR audit log data contains rich information such that it can improve hospital-wide discharge predictions. This study is limited that it focused on the raw sequence of user-EHR interactions and did not relate them to the corresponding clinical tasks.

CCF-CL: Forecasting the Clinical Status of a Patient Through Contrastive Learning

Ziqi Zhang, BS¹, Chao Yan, MS¹, Xinmeng Zhang, BS¹, Steve L. Nyemba, MS²,
Bradley A. Malin, PhD¹,²
¹Vanderbilt University, Nashville, TN; ²Vanderbilt University Medical Center, Nashville, TN

Objective

An individual’s health status changes over time, such that it is useful to forecast what, if any, health problems an individual is at risk of developing. Over the past several years, deep learning models have made significant progress in clinical concept forecasting. However, the efficacy of these models is limited in practice, particularly when they are trained with a small case group, which is a typical problem due to the low prevalence of many diseases. In this paper, we introduce CCF-CL, a framework to support clinical concept forecasting in the face of a limited number of positive training instances.

Method and materials

CCF-CL is composed of two components. The first component, which possesses almost all parameters in the model, is trained to learn informative patient representations in an unsupervised manner, with ground-truth labels not involved. The second component, which is composed of a limited number of parameters, is trained to fit the derived patient representation with ground-truth labels. In doing so, the training process is encouraged to neglect the labels to the greatest extent possible and, thus, focus on the relationships between features. Figure 1 illustrates the traditional supervised paradigm and CCF-CL.

To enable such a learning paradigm, we introduce contrastive learning into the representation modeling of EHR data. We also develop a data augmentation strategy specifically to adapt contrastive learning into EHR modeling. We evaluate the CCF-CL’s performance by comparing it to current state-of-the-art model architectures trained in the supervised manner, with EHR data from 48,000 and 16,000 patients, each with more than 25 distinct healthcare episodes, from Vanderbilt University Medical Center and the All of Us research program, respectively. Specifically, we perform forecasting for 181 and 120 clinical concepts (each corresponds to a CCS diagnosis code) selected from the two data sources.

Result

Our experiments indicate that the average performance improvement, in terms of area under the receiver operating characteristic (AUROC) curve, for clinical concept forecasting tasks is 0.045 (7.8%) and 0.067 (10.9%) for VUMC and AOU data, respectively. We also found that the improvement is particularly pronounced when for clinical concepts where the proportion of positive to negative cases is large.
Deep Learning Approaches for Breast Cancer Characteristics Extraction from Electronic Health Records

Sicheng Zhou, MS¹, Liwei Wang, MD, PhD⁵, Nan Wang⁵, Sunyang Fu, MHI⁵, Chetan Shenoy, MD⁴, Anne Blaes, MD⁴, Hongfang Liu, PhD⁵, Rui Zhang, PhD¹,²

¹ Institute for Health Informatics, ²Department of Pharmaceutical Care & Health Systems, ³School of Statistics, ⁴Department of Medicine, University of Minnesota, Minneapolis, MN, USA; ⁵Department of Artificial Intelligence and Informatics, Mayo Clinic College of Medicine, Rochester, MN, USA

Introduction

Breast cancer is one of the most prevalent and lethal cancers for women in the US. Precision medicine and related translational research need the support of a large amount of cancer specific clinical information of patients. Effective and automatic extraction of the target information from clinical narratives of EHR remains an important research topic. The objective of this study is to develop and evaluate a set of NER algorithms, i.e., conditional random fields (CRF), bidirectional long short-term memory + CRF (BiLSTM-CRF) and Bidirectional Encoder Representations from Transformers (BERT) fine tuning models, to extract breast cancer characteristics from clinical narratives in EHR.

Methods

The data used in this study was obtained from the EHR of the University of Minnesota Clinical Data Repository. 200 pathology reports and clinical notes of breast cancer patients were randomly sampled and annotated by two annotators. The annotation followed the BIO format. The extraction of breast cancer characteristics from texts can be framed as an NER task. The CRF model were developed as the baseline model. The specific features used for CRF include the length of each token and the pre-trained word embeddings of each token. BiLSTM-CRF models were developed to finish the NER task. The input features for the BiLSTM-CRF model were 6 different pre-trained word embeddings. 3 of them are Word2Vec word embeddings while 3 of them are GloVe word embeddings. And in this study, we fine-tuned and evaluated the BlueBERT pre-trained model on our NER task. The BlueBERT model was pre-trained on PubMed abstract and public available clinical notes, i.e., MIMIC-III that contain over 4500 million words, which is suitable for transfer learning task in clinical domain [1].The BlueBERT model was pre-trained on PubMed abstract and public available clinical notes, i.e., MIMIC-III that contain over 4500 million words, which is suitable for transfer learning task in clinical domain. We applied the name entity level evaluation for all NER models. 70% of the annotated data was used as training set, 10% was used as development set and 20% was used as test set. F1 score was used as evaluation metric. We evaluated the performance using both exact match and lenient match on various name entities.

Results

Table 1—NER evaluation measured by exact and lenient match F1 scores (in parenthesis) for all models.

Comparison of Natural Language Processing Approaches Identifying Opioid Overdose from Clinical Notes for Emergency Department

Vivienne Zhu, MD,1 Jingqi Wang, PhD,4 Jenna McCauley, PhD,2 Lindsey Jennings, MD,3 Hua Xu, PhD,4 Kathleen T. Brady, MD, PhD,2 Leslie A Lenert, MD, MS1

1Biomedical Informatics Center, 2Department of Psychiatry & Behavioral Sciences, 3Emergency Medicine at Medical University of South Carolina, Charleston, South Carolina, and 4School of Biomedical Informatics, University of Texas, Houston, Texas

Background. Over the last ten years, the number of individuals presenting to the emergency department (ED) as a result of intentional or unintentional opioid-related overdose (OD) has dramatically increased in the US. We developed and evaluated natural language processing (NLP) approaches for OD case identification and clinical characterization to support research and clinical practices.

Methods. The study cohort includes patients who were 12 years or older and visited the Medical University of South Carolina (MUSC) ED between 01-01-2013 and 12-31-2019. Patients with cancer or surgical visits were excluded. Selected clinical note types include ED note, ED provider note, ED nurse note, ED follow-up, progress note, discharge summary, and consultant note. Four NLP approaches were developed: 1) Named Entity Recognition (NER) + Rules: Leveraging CLAMP’s built-in default function modules (i.e., sentence detection, tokenizer, POS tagging, named entity recognition, assertion), we developed customized pipelines to extract information relevant to OD events. The customized OD dictionary consists of opioid medications (e.g., “narcotic,” “opiate,” “heroin,” “OXY,” “fentanyl,” “Oxycodone”), terms representing overdose (e.g., “overdose,” “OD,” “poison”), treatment for OD (e.g., “Naloxone,” “Narcan”), and patient’s positive response to Naloxone/Narcan (e.g., “reverse,” “respond,” “improve in mental status,” “awake”). We also included ICD-9/10 codes for OD (e.g., “T40.2X5A,” “T40.601A), as well as the descriptions of ICD-9/10 codes (e.g., “adverse effect of unspecified narcotics,” “poisoning by other opioids”) in the OD dictionary. After mining a small sample of data (clinical notes from 1,000 patients), we developed initial Apache Ruta rules to identify candidate OD cases at the sentence level when any one of the following criteria met: 1) mention of opioid medication and overdose irrespective of their order; 2) mention of Naloxone/Narcan administration and patient’s positive response to Naloxone/Narcan regardless of their order; or 3) mention of OD ICD-9/10 codes or its description. Ruta rules also excluded false positives. This approach also generated candidate sentences for other three approaches; 2) A Support Vector Machine (SVM) classifier based on java libsvm library, with unigrams, bigrams, and tri-grams as feature; 3) A Neural Network approach based on pre-trained context embeddings: Bidirectional Encoder Representations from Transformers (BERT) was used for the classification task; and 4) BERT+ Rules. Modifiers, such as OD for opioid, response for Narcan, subject, condition, hypothesis, or intentionality, were detected for two primary entities (opioid and Narcan). Inference rules were applied to further eliminate false positives, including situations, such as the subject is not the OD patient, an OD event did not happen (e.g., condition, hypothesis), or there is a negation (e.g., “no,” “deny”). Their performances were evaluated using the gold standard (manual review), and precision, recall, and F-score were reported.

Results. NER+ Rules identified 1,513 candidate OD sentences from the randomly sampled 2.47 million clinical notes. These sentences were annotated as True or False of OD case and then partitioned into three datasets: training (1,213), development (150), and test (150) with equally distributed True and False cases. In the test dataset, 114 true positive cases and 36 true negative cases (determined via expert chart review) were used to measure the performance of NLP approaches (Table 1).

Conclusion. NLP approaches could effectively extract OD information from ED clinical notes. The deep learning approach BERT with post-processing rules achieved the best performance.

Feasibility study of audio recording patient-clinician verbal communications in home healthcare settings
Maryam Zolnoori1, Sasha Vergez2, Zoran Kostic1, Siddhartha Reddy Jonnalagadda3, Maxim Topaz1
1Columbia University, 2Visiting Nurse Service of New York, 3Amazon Company

Background
Humans use speech as a communication tool to express their thought, intent, and emotion. Artificial intelligence methods, such as speech recognition, have the potential to capture and process speech. Emerging studies show that patients’ spontaneous speech in clinical encounters can provide indicators for mental disorders, patients’ emotional status, and cognitive impairment.1 However, currently, audio-recording of patients’ spontaneous speech in interaction with healthcare providers is not part of clinical workflows, and there is limited knowledge about the best practical approaches for audio-recording high quality patient-clinician verbal communication. This is particularly the case in home healthcare settings. This feasibility study aimed to identify the optimal audio-recording device that will be useful for audio-recording verbal communications of patient-clinician communication in home healthcare settings.

Method
This study was conducted at a large not-for-profit home health care organization located in New York, NY. The study was approved by an institutional review board at the organization. Initially, two members of our research team evaluated six voice recording devices (Black Vox 3652, SOTA Surveillance-USR5003, INSTAMIC PRO4, Sony ICD-TX6, Mini Wristband Voice Activated Recorder5, and Apple Watch) using criteria of ease of use, functionality (battery life and memory size), and quality of recorded voice in a controlled setting. Two recorders, Sony ICD-TX6 and Black Vox 365 were selected for further evaluation in home healthcare settings. Further, we worked with home healthcare nurses to record several patient-nurse encounters. We used the system usability scale (SUS) questionnaire and open-ended interviews to investigate nurses’ opinions about usability (ease of use and functionalities) of two selected recording devices. In the next step, two randomly selected audio files from each device were transcribed manually by our research assistant and automatically using the Amazon Medical transcribe system. We then used the word error rate (WER) to measure the quality of transcription by the AWS transcribe system. As a rule of thumb, the quality of the AWS transcribe system increases when there is an improvement of quality within the audio recorded data.

Results
We excluded the apple watch and INSTAMIC PRO in the first step of evaluation due to limited battery life (less than 2 days). Limited the battery life of recording devices might increase clinician workload because of the need for frequent charging. The ease of use and functionality of SOTA Surveillance-USR500 was similar to Black Vox 365, but the quality of recorded audio was lower, therefore this device was also excluded. We also excluded the Mini Wristband due to low quality of recorded audio. In the next step, the results of evaluation of Sony ICD-TX6 and Black Vox 365 in clinical setting showed that nurses prefer the Sony ICD-TX6 because of the inclusion of an indicator showing the status of recorders (on or off), sufficient battery life (up to 14 days) and good memory size (16 hours) for recording. Additionally, the total SUS score computed for Sony ICD-TX6 and Black Vox 365 were 97.5 and 42.5 respectively. The WER for Sony ICD-TX6 and Black Vox 365 were 0.36 and 0.53, indicating that the quality of automatic transcription by Amazon AWS service was higher for Sony ICD-TX6 compared with Vox 365.

Discussion and conclusion
Audio-recording of patient-clinician verbal communication in home healthcare settings is a challenging task. Selecting proper voice recording devices with high usability and capacity for recording high quality audio can improve the possibility of integrating audio-recording patient-clinician verbal communications into clinical workflows. Good quality of audio recording can improve the accuracy of downstream tasks built on analysis of this data, such as identifying patients with certain medical conditions such as depression. Our next steps will include further audio-recording of patient-nurse home healthcare encounters and extracting informative acoustic and linguistic features that can be used to analyze the patient’s voice and language for identifying signs (e.g., low speech rate) and symptoms (e.g., stress) associated with negative health outcomes (i.e., risk for rehospitalization).

SHARE-NW: An Innovative Public Health Informatics Tool

Uba Backonja, PhD, RN¹, Anne M. Turner, MD, MLIS, MPH¹, Betty Bekemeier, PhD, MPH, RN¹
¹Northwest Center for Public Health Practice, University of Washington, Seattle, WA

Introduction
Public health systems in the rural/frontier areas confront unique challenges improving health compared to urban areas. Rural communities have the highest rates of risky behaviors, the worst health outcomes of any U.S. population, and public health systems far more understaffed and poorly funded than urban areas.¹ Rural local health departments (LHDs) face barriers in identifying which populations face the greatest inequities to prioritize allocation of scarce resources. A major barrier is there are few rural-specific tools to easily access and analyze data, which is needed given rural LHDs often do not have personnel trained in data analytics.² To address this gap, we developed an innovative public health tool, Solutions in Health Analytics for Rural Equity across the Northwest (SHARE-NW). The aim is to support rural LHDs in the Northwest (Alaska, Washington, Idaho, and Oregon) by providing access to and training in using data to identify and address health inequities. The tool includes a web-based data dashboard and training resources. In this session we will describe our practice-centered approach, demonstrate features of the dashboard to identify inequities, and describe how our approach can be applied to a variety of public health issues. SHARE-NW is novel in applying user-centered design with rural public health staff and with a focus on equity.

The methods used to develop the SHARE-NW tool
We engaged end users (public health officials and health equity experts), through an iterative design process which included: a needs assessment completed in 2018,² paper mockup evaluations completed in 2019, and usability testing completed in 2020 and 2021. We identified publicly available datasets that included data on rural LHDs’ priority health outcomes identified during our needs assessment (e.g., state health departments, CDC, National Environmental Public Health Tracking Network Data, Feeding America); these data were used to generate visualizations. Due to the vast geographic distribution of our end-users, studies were conducted remotely using phone and teleconferencing software (Adobe Connect, Zoom). We developed the tool to include (1) visualizations to support data understanding and (2) trainings to support data use. To develop visualizations of publicly available data, we used Tableau and applied research on visualizing quantitative data and Munzner’s nested model for visualization design.² For curated trainings, we vetted existing trainings available online, applying the Public Health Learning Network’s Quality Standards for Training Design and Delivery Tool (mphli.org/phln/). We also developed trainings to address identified training gaps.

The resulting SHARE-NW tool
The SHARE-NW tool (available at nwcphp.org) showcases a dashboard that provides interactive visualizations of rural public health data. The dashboard includes data at the county level and multi-county level depending on each state’s unique way of organizing LHDs. There are dashboards for demographic data and health indicators organized by LHD health priority area. Users use the dashboard to view health outcomes and inequities in their county to compare their health jurisdictions with others in the 4-state catchment area. Users can download images of the graphs, download data, and view health indicator data by social determinants. The tool includes high quality trainings to enhance skills in health equity and social determinants, health priorities common to rural jurisdictions, and data-driven decision-making. The tool will be evaluated after launch to assess use, utility, and impact at the individual and LHD level.

Conclusion
SHARE-NW is an innovative informatics tool addressing a critical need among rural health practitioners to identify and address health equity. The session will demonstrate key features developed with end-users. SHARE-NW is funded by the Department of Health and Human Services Office of Minority Health (5 CPIMP171144-02-00).

The predominant model for data capture in multicenter clinical trials is for clinical research coordinators (CRCs) to abstract data from Electronic Health Records (EHR) and manually complete structured electronic case report forms. It is inefficient and usually retrospective; resulting in delays to availability of data, costly manual reviews, and risk of inaccurate/incomplete results. Greater utilization of eSource integrations can lead to enhanced site experiences, more efficient monitoring, more rapid identification of safety signals, and increased data integrity and quality.

OneSource reduces documentation burden by automating capture of regulatory-grade structured data, and supporting streamlined workflows that are integrated with healthcare delivery systems. Its implementation in the I-SPY COVID adaptive platform trial aids increased trial participation for critically ill COVID-19 patients in busy ICUs. A scalable design, built on the Substitutable Medical Apps – Reusable Technology on Fast Healthcare Interoperability Resources (SMART on FHIR) standard and on a general-purpose, configurable electronic data capture (EDC) platform (OpenClinica), allows use across multiple trials and sites. We will demonstrate user-centric EHR-integrated workflows and automated data acquisition that minimizes many of the inefficiencies and quality risks of today’s ‘swivel chair interoperability’ practices. It automatically logs users in and launches the proper EDC participant record based on the active EHR patient. Structured data from the EHR populates the eCRF, with workflows for user review/validation. eCRFs that cannot be directly populated are accessible for entry. Mobile support enables direct data capture at the point of care. The EDC’s proven 21 CFR part 11 compliant features support regulatory-grade evidence of data integrity.

Despite this significant level of integration, OneSource is deployable across heterogeneous sites and trials. Many eSource approaches rely on locally installed middleware and/or difficult-to-audit system-level APIs. OneSource uses a recognized security model, requires no software installs, and implements a user-driven and audited model for data transfers. This reduces burden and risk on hospital IT and security staff, currently a major barrier to eSource. The EDC’s study design tools allow mid-study eCRF and data mapping updates with audited publishing and change control - ensuring data integrity without involving site research or IT staff. Streamlined change management is a goal in all trials, and essential in a multi-arm adaptive platform trial like I-SPY COVID. The app is published in the Epic App Orchard and user testing has been completed in the test EHR environment at UCSF. Production rollout in I-SPY COVID will begin April 2021 at UCSF and scale to other Epic sites, followed by sites using Cerner and to other studies.

This work was supported, in part, by the Biomedical Advanced Research and Development Authority (BARDA), part of HHS within the office of the Assistant Secretary for Preparedness and Response, and Joint Program Executive Office, a part of the Department of Defense, under the Medical Chemical, Biological, Radiological, and Nuclear (CBRN) Defense Consortium (MCDC).

System purpose and description

An increasing number of pathology labs are moving to digital scanning and on-screen slide visualization. At the same time, machine learning promises to automatically perform time-consuming and complex tasks, from biomarker quantification or mitotic count to grading or subtyping. However, these promises come at the cost of an interpretability gap for pathologists: tissue samples are abstracted to pixels, analyzed by non-interpretable machine learning techniques like CNNs. We propose to reduce this gap with a web service that uses a representation of tissue samples based on biologically relevant entities, going back from pixels to cells and tissue types; and the use of an explainability method to quantify relevant concepts for the entities that were identified as the most important for the decision.

We propose to demonstrate the use of Histocartography for breast cancer lesion classification, including atypical cases, using HACT-Net\textsuperscript{2} and explain the decisions using a set of pathology-relevant concepts such as nucleus size, nucleus shape variation or chromaticity\textsuperscript{2} for the most important nodes. Evaluation of the results by a limited number of pathologists has shown that the cells identified as most discriminative also correlate with prior knowledge: e.g., the most important cells for malignant lesions have larger nuclei than those that are important for benign tissue.

Deployment degree

At the date of submission, the models are fully trained and the results can be accessed through the provided references. A REST API prototype is already deployed and an user-friendly interface is being developed. For developers, Histocartography has been released as an open source Python library at \url{https://github.com/histocartography/}

Generalizing Dynamic Dashboards for Community-Engaged Interventions

Daniel R. Harris, Ph.D1,2, Daniel T. Redmond2, Jeffery C. Talbert, Ph.D2,3
1Institute for Pharmaceutical Outcomes and Policy, University of Kentucky, Lexington, KY.
2Center for Clinical and Translational Sciences, University of Kentucky, Lexington, KY.
3Institute for Biomedical Informatics, University of Kentucky, Lexington, KY.

Abstract
We present our web-based system that allows communities to configure, create, and customize visualizations based on their needs and interests when participating in a data-driven community-engaged intervention. The Communities That Heal (CTH) intervention was developed by the HEALing Communities Study (HCS) to significantly reduce opioid overdose deaths in 67 communities across four states. We leveraged open-source technologies to generalize a framework for dashboarding which enabled communities in the first wave of the intervention to select and customize visualizations most relevant for monitoring the opioid crisis in their community.

Introduction
The Communities That Heal (CTH) intervention required keeping community coalition leaders and members up to date on the local impact of the opioid overdose epidemic; by sharing community-specific dashboards, communities were able to have a localized view of measures and findings specific to the study. Communities were given an initial dashboard containing five high priority measures, such as the number of resident opioid overdose deaths or the number of high-risk opioid prescriptions. Communities were able to select additional measures defined by the study or to suggest new measures; each community independently explored topics most relevant to their own needs. For example, if a community wishes to link more individuals treated for overdoses in their emergency departments (ED) to medication for opioid use disorder, then they would focus on ED-related evidence-based practices and data; a community without an ED could focus on something more meaningful to their community.

Methods and Discussion
We organize data in accordance with pivotal elements of the intervention itself (a menu of evidence-based practices). Our web-based system allows users to interactively explore their data by offering customizable views and side-by-side comparisons. Users can dynamically filter by year, filter by reporting interval (monthly, quarterly, yearly), control graph types, size, and switch between raw counts and rates per population. A graph builder allows the creation of a customized graph containing data from several sources. We focused on open-source technologies to minimize the cost of ownership and to eliminate financial barriers for communities to adopt and continue the dashboards after the study concludes. In 2020, we had 164 users from 8 different communities. We are currently analyzing site usage metrics and usability to further improve our system; we wish to open-source our solution so other studies may benefit.

Figure 1. An interactive graph builder merges and visualizes different data sets based on user selections.

Integrating Informatics for Integrating Biology and the Bedside with tranSMART: Flexible Data Warehousing with Complex Analytics

Jeffrey G. Klann, PhD; Michael Mendis; Peter M. Rice; Rudy Potenzone, PhD; Louisa May Klann; Griffin M. Weber, MD, PhD; Diane Keogh; Shawn N. Murphy, MD, PhD; Harvard Medical School; Partners Healthcare; Massachusetts General Hospital; Beth Israel Deaconess Medical Center; i2b2-tranSMART Foundation – Boston, MA; Oryza Bioinformatics Ltd, Royston, UK

Informatics for Integrating Biology and the Bedside (i2b2) is a well-established open-source clinical data warehousing and analytics platform in use at over 200 locations worldwide. [1] It was first released in November 2007, and over time it has evolved from a single-site cohort identification tool into an enterprise-ready, network-enabled analytics platform with a diverse open-science community. Originally funded by the National Institutes of Health, it is now maintained by the i2b2-tranSMART foundation, which continues to refine the core software according to users’ needs.

i2b2 serves a variety of user needs across the enterprise. i2b2 is an ideal cohort finding tool, frequently used as a self-serve clinical research portal for investigators. Its flexible data model makes it ideal for data ingestion and integration across a variety of source systems (from Electronic Health Record - EHR - to laboratory to gene expression data), and its application programming interface (API) allows it to serve as the backbone for large clinical research networks like the Clinical and Translational Science Award’s (CTSA’s) 50-site Accrual to Clinical Trials (ACT) network.

TranSMART was developed in 2008 by Johnson & Johnson from i2b2 to load and analyze data from clinical trials, including gene expression and other ‘omics’ datasets. They saw a lack of translatability of preclinical models into meaningful biological knowledge, so they extended i2b2 to support translational research studies by adding R-based data exploration and advanced analytics (e.g., correlation analysis, heat maps, principle component analysis, etc.). Clinical data and expression/proteomics/metabolomics and other data can be analyzed with a set of 20+ R-based workflows or exported as subsets to pass to local pipelines. The underlying database used i2b2 schemas for clinical data with new schemas for omics data, biomarkers, searches, and study metadata. tranSMART is used worldwide for translational research. For example, in the Human Hereditary Health in Africa Consortium (https://h3africa.org/), coordinators visit African villages and are able to input patient’s genomic information directly into tranSMART, for analyses of Chronic Kidney Disease’s genetic markers in African populations.

While i2b2 loads clinical data for all patients under a common terminology tree, tranSMART loads each study under an upper-level ‘study’ node with demographics, lab results, etc. as study-specific nodes below. Studies are not limited to human subjects: they can be for model organisms (e.g. mouse), cell lines or organoids.

Over time, the data model of tranSMART diverged, and the application software was never integrated with i2b2. Therefore, there is a need to harmonize the two tools so that they are compatible and interoperable. This would provide i2b2 users with a set of powerful R analytics tools, enabling data analytics across entire enterprise-wide i2b2 data repositories, and it would streamline the pipeline between cohort selection and data analysis.

The Foundation is engaged in several efforts to harmonize its two leading tools, so they can both be run on the same data. We developed the i2b2 Common Data Model, largely based on i2b2 version 1.7.12, with modifications to tranSMART 19 to use the same set of database tables and fields. The lack of guidance in the past on how to best represent patient data in i2b2 is part of the reason why i2b2 and tranSMART lost interoperability over time. The new Common Data Model documentation provides both descriptions of the core tables as well as information on how to use the data model with the i2b2 ontology, best practices and examples for different data types, and tips for extending the core data model. The i2b2 Common Data Model Guide is available at https://community.i2b2.org/wiki/display/i2b2/i2b2+Documentation.

Next, we aligned the tranSMART and i2b2 applications, so that the platforms can leverage each other’s strengths for both broad cohort-finding and complex genomic-enhanced data analyses. The latest tranSMART release used the full i2b2 data model, with additional tables added. The common schemas are now identical, and tranSMART creates all the additional i2b2 schemas and procedures to allow the two platforms to run on the same database. We are currently enhancing tranSMART so it can explore i2b2 native data as a single study.

Here we will demonstrate i2b2, tranSMART, and their integration, running on a single data set. The Common Data Model work is complete at the time of this writing. The application modifications to tranSMART to explore and analyze i2b2 datasets will be completed before the Symposium.
Interactive Model Report Card for Visual Exploration of Performance Heterogeneity and Biases on Population Subgroups

Bum Chul Kwon PhD¹, Uri Kartoun PhD¹, Shaan Khurshid MD²,³, Amit V Khera MD MSc²,³, Patrick T Ellinor MD PhD²,⁴, Steven A Lubitz MD MPH²,⁴, Kenney Ng PhD¹

¹Center for Computational Health, IBM Research, Cambridge, MA, USA; ²Cardiovascular Disease Initiative, Broad Institute of the Massachusetts Institute of Technology and Harvard University, Cambridge, MA, USA; ³Division of Cardiology, Massachusetts General Hospital, Boston, MA, USA; ⁴Cardiac Arrhythmia Service, Massachusetts General Hospital, Boston, MA, USA.

It is critically important for clinical researchers and practitioners to understand the differences and limitations of machine learning models within various subgroups of a population. To address this unmet need, we have developed an interactive visualization system to facilitate the identification of possible performance heterogeneity and biases. Recently, researchers investigated the concept of a model report card which summarizes how a model was trained and how it performs on a fixed set of subgroups in a static report (1,2). These approaches are significant milestones; however, they do not allow users to apply the model to local patient data sets, define custom subgroups, and explore how the model behaves within the subgroups.

The goal of the current system is to allow clinical researchers and healthcare data analysts to apply existing risk models to local patient data sets, visually inspect the performance and fairness of models within subgroups defined by key patient characteristics, such as comorbidities, age, sex, and race. The system includes multiple coordinated, and interactive visualizations so that users can freely define subgroups, explore model performance and fairness within and across subgroups, and understand how such metrics are associated with patients' clinical and demographic attributes. The system (Figure 1) is developed as a web-based prototype.

Figure 1. The design of interactive model report. Users can select a risk model and a local patient data set to launch the system. In the system, (a) users define subgroups by choosing comorbidities and/or demographic attributes; (b) users explore model performance (e.g., concordance index and calibration slope) and fairness measures (e.g., true positive rate differences and statistical parity differences); (c) users inspect features affecting model behavior using SHAP (SHapley Additive exPlanations) values and feature distributions.

The SMART Cumulus Text-to-FHIR NLP Pipeline

Timothy A Miller, PhD1,2, Bin Mao, PhD1, Daniel Gottlieb, MPA1,2, Kenneth Mandl, PhD1,2
1Boston Children’s Hospital, Boston, MA; 2Harvard Medical School, Boston, MA

Introduction

Unstructured text represents a large chunk of the important information in electronic health records, but is difficult to compute over due to the complexity of human language. Natural language processing (NLP) can convert unstructured text into structured texts, extracting references to diagnoses, signs and symptoms, procedures, and relations between these elements. We demonstrate implementations that map clinical notes directly to FHIR (Fast Healthcare Interoperability Resources) and compare two open-source NLP tools, Apache cTAKES and MedSpacy.

Background

FHIR has become the de facto standard for interchange of data between electronic health record (EHR) systems. The recent FHIR Bulk Data Standard extends the FHIR standard into population health, with application programming interface (API) hooks that support retrieval of large FHIR data sets. Regulations requiring EHR vendors to implement FHIR APIs portend a future where EHR data can be easily brought into analytics platforms for streamlined data analysis. However, these regulations do not resolve the issue of how to transform the unstructured content of clinical notes into FHIR resources. NLP tools exist for extracting concepts from notes and various other tasks, but modeling NLP outputs in FHIR is an unresolved problem. Existing mappings are closed source, use too-general resource types (Apache cTAKES fhir module) or do not track provenance of concepts (NLP2FHIR).

Implementation

We have developed mappings that convert outputs from broad semantic groups in the Unified Medical Language System (UMLS) to FHIR resources, and designed FHIR extensions to capture NLP-specific information. Procedures are mapped to the Procedure Resource, Signs/Symptoms are mapped to Observation Resources, Diseases/Disorders are mapped to Condition Resources, and Medications are mapped to MedicationStatement Resources. The extensions include versioning information for all processing software, document identifiers, and character offsets into the text where the concept was found. One of the primary goals of our implementation is that the automatic and less-certain nature of NLP-extracted resources is highlighted, and that provenance information is preserved so that downstream users can manually validate if required for their use cases. The existence of the modifier extension serves as the flag that the information is NLP-derived, and the document ID and concept span information serve as the link back to the provenance of the resource in the text.

Status of Implementation and Presentation Plans

We have developed two NLP systems that can both use the same NLP-to-FHIR mappings for their output, Apache cTAKES and MedSpacy. cTAKES is one of the most widely used open-source clinical NLP tools, and has a large existing userbase. MedSpacy is a relatively new tool that extends the widely used python-based Spacy NLP system to handle clinical text. It includes clinical specific sentence segmentation and a UMLS dictionary lookup similar to that in cTAKES. cTAKES has an existing REST server implementation, with an ad hoc json-formatted output string. Our new implementation maps from that output string to our proposed FHIR representations. We modified MedSpacy output to resemble the cTAKES REST output so that we can use the same mapping code to create FHIR resources from MedSpacy output as well. The cTAKES implementation is wrapped in a Docker container for ease of deployment, while work on containerizing the MedSpacy implementation is expected to finish shortly.

We first give a high-level overview of the mapping of NLP outputs to FHIR that we have proposed and implemented. We then show running versions of our container implementations, demonstrating how they can be queried with REST from standard browser tools and showing the FHIR output. We will show a pipeline on synthetic data that includes both structured and unstructured components, and show how our tool integrates the structured data with the FHIR output from the NLP systems, including sample queries that highlight use cases enabled by this framework.

Conclusion

We have developed a schema for representing information extracted from EHR notes into FHIR resources, and have created two implementations for open-source clinical NLP tools. The software will be made available open-source on GitHub.
Is your clinical decision support moving the needle on outcomes that matter?
Novel software for evaluating quality improvement initiatives

Evan Orenstein, MD1, Naveen Muthu, MD2, Marc Tobias, MD3
1Children’s Healthcare of Atlanta, Atlanta, GA; 2Children’s Hospital of Philadelphia, Philadelphia, PA; 3Phrase Health, Philadelphia, PA

Description: We present a novel system for associating clinical decision support (CDS) interventions with their intended clinical outcomes. This system ultimately uses a singular dashboard with these interwoven data elements in order to support quality improvement efforts within a health system. To do this, the software architecture streams data for CDS intervention performance, patient cohorts, and process and outcome measures to a cloud-based data pipeline that populates a web application. Ultimately, the software aims to lower the barrier to evaluate the effectiveness of CDS, like alerts and order sets, on complex and evolving clinical workflows and processes.

Problem: Although CDS has the potential to improve clinical outcomes, their actual impact has been inconsistent.1 Continuous evaluation is critical to achieve consistent improvement in outcomes that health systems, clinicians, and patients care about.5 However, most CDS initiatives are not assessed holistically due to limited resources and, when they are, many improvement efforts do not use rigorous methods to evaluate their processes.3 Existing approaches often use custom dashboards that require significant technical resources for each improvement initiative.

Innovation: Through funding from the National Library of Medicine, a multi-institutional research initiative coupled academic health systems and an industry partner to tackle issues related to data accessibility, data standardization, and human computer interaction. The resultant software utilizes a patent-pending extraction architecture to securely stream data from multiple data stores to a custom Amazon Web Services (AWS) data pipeline. System end-users can then apply the Institute for Healthcare Improvement’s model for improvement by constructing quality improvement projects with the data streams of choice and, with the help of directed questions, evaluate CDS effectiveness and receive recommendations for next steps.4

Adoption: The team embarked on user research in 2020 by interviewing over 30 informatics, quality, and IT stakeholders from two separate health systems. Following over 25 iterations, a live version is planned for implementation in Spring 2021 at 3 health systems participating in an implementation study of the platform.

Conclusion: Monitoring individual CDS elements is considered a best practice for electronic health record systems.5 However, CDS is invariably implemented to drive target downstream clinical processes and outcomes. Our system integrates data from a variety of sources and walks users through an evaluation framework to assess the impact of CDS on outcomes that are meaningful in patient care delivery rather than the individual CDS elements alone. Future efforts will aim to automate the effort to monitor process deviations and system changes.

VITAL: A semantic search engine for clinical text

Jingqi Wang, MS\textsuperscript{1}, Yaoyun Zhang, PhD\textsuperscript{1}

\textsuperscript{1}Melax Technologies, Inc; Houston, Texas, United States

Introduction

The last few decades see an explosion of unstructured clinical documents in electronic health records (EHRs). There is a great need for an easy-to-use tool that can effectively find useful information from EHR notes. Here we introduce VITAL, a newly developed semantic search engine for clinical text. By leveraging state-of-the-art information extraction technologies in the CLAMP natural language processing (NLP) toolkit\textsuperscript{1} and the clinical data standard of OMOP Common Data Model (CDM), VITAL provides a powerful yet user-friendly platform for quickly searching millions of clinical documents in EHRs, thus, to efficiently identify cohorts of patients of interest and their specific phenotypes. Use cases of VITAL include clinical chart review, healthcare quality reporting, disease registry curation, and clinical and translational research.

Overview:

VITAL is designed for efficient semantic search from clinical text, with configurable and scalable settings to support practical use cases. As illustrated in Figure 1, the workflow of VITAL includes several steps: data source preparation, NLP model deployment, information extraction and normalization, semantic indexing, query processing and search, and search result visualization.

Features of VITAL are as follows:

- **Customizable NLP models**: (1) adopt various existing NLP models following the UIMA framework (i.e., disorder attributes, medication-attributes, smoking status, breast cancer-recurrence etc.); (2) build new NLP pipelines (i.e., pathology notes processing) in CLAMP using lexicons, rules and state-of-the-art deep learning models. CLAMP built-in pipelines can be deployed to VITAL directly.

- **Data source management**: (1) support major relational databases including MySQL, PostgreSQL, Oracle, SQL server; (2) support user defined SQL to select and filtering on the input tables.

- **Multiple search modes**: (1) keyword-based search; (2) clinical concept-based search; (3) OMOP CDM-based query expansion; (4) Boolean search with combined queries (Figure 2).

- **Multi-view of search results**: (1) aggregate longitudinal data of the same patient (Figure 3); (2) highlight clinical variables in text with colors; (3) review patient lists to add tags and comments; (4) export results in the format of OMOP CDM table.

- **Task management**: (1) schedule and monitor automatic tasks of incremental processing and semantic indexing of new clinical documents; (2) support multiple common relational databases; (3) scalable architecture for processing millions of documents in parallel.

- **Flexible deployment**: (1) docker download with detailed implementation document on local servers; (2) cloud-based deployment based on AWS HIPAA compliance architecture.

Conclusion

Our studies have shown that Vital dramatically improves efficiency of manual chart review in both operational and research tasks. It will be freely available to the biomedical research community.
