locus in C5orf56 showed the largest difference in patterns of association: it was convincingly associated with COPD in males but no signal was present in females. C5orf56 is a long non-coding gene known as IRF1-ASI that has not been mechanistically linked to COPD, but the nearby IRF1 gene encodes interferon regulatory factor 1, which has been associated with anti-viral defense in airway epithelium\(^6\). Given that respiratory viral infections are a common cause of exacerbations of chronic lung diseases and that viruses (e.g., Human rhinovirus, respiratory syncytial virus, and influenza) are often detected during COPD exacerbations specifically\(^37,38\), the associated locus may influence susceptibility to COPD via altered responses to virus exposure. Interestingly, the IRF1 locus has been proposed as a strong candidate region for male-specific asthma susceptibility that may attributable to sex-specific interferon responses\(^39\). Another male-specific significant locus we observed near PEL1 may be linked with response to airways viruses\(^40\) given that PEL1 is involved in IL-1 signaling and its expression was correlated with the number of exacerbations experienced by patients with obstructive airway disease\(^41\). Other regions with sex-specific associations in ARHGEF3, C1orf87, and C10orf11 are not easily linked to mechanistic hypotheses based on what is currently known about the function of these genes.

To obtain gene-based associations from SNP-level results, we developed the *snpsettest* R package that modifies the statistical test in the VEGAS software\(^15,17\) to compute gene-based p-values more efficiently. Although VEGAS can run in a reasonable amount of time if the maximum number of simulations is bounded (e.g., 10⁴), this truncation is not optimal when gene-based association statistics are needed for large-scale GWAS with many significant SNP
associations, and subsequently, many gene-based associations that are necessary as input for subsequent pathway and network analyses. We demonstrated that our package produces results consistent with those of VEGAS but with a much shorter runtime.

Figure 2. Regional association plots for the loci in (A) HHIP as an example of a finding present in male and female GWAS and (B) C5orf56, the locus with the greatest sex-specific difference. Left panels display the results of the male GWAS and the right panels display the results of the female GWAS.

By comparing gene-level associations obtained for sex-specific COPD GWAS, we found that C5orf56 had the strongest sex-specific COPD association, as it was present only in males. Other male-specific associations were found in CFDP1, TMEM170A, and CHST6 located in the non-overlapping significant GWAS locus on 16q23.1. This region has been implicated in coronary heart disease, whose mortality is higher among men\textsuperscript{42,43}, and was identified as having a potential genetic overlap with COPD susceptibility\textsuperscript{35}. Although OTUD4, ABCE1, and ANAPC10 on 4q31.21 and FBXO38 on 5q32 had male-specific associations, they had similar patterns of regional variant associations despite not reaching genome-wide significance levels in the female GWAS. The most prominent female-specific associations were observed in ASTN2 and TRIM32 on 9q33.1, a region previously reported as having sex-specific associations with neurodevelopmental disorders\textsuperscript{44}. Moreover, several genes on 16q22.1 were associated with COPD only in females, of which SMPD3 was previously

*P-values from logistic regressions with female as a reference group.
reported as having gene-by-smoking interaction effects on COPD\textsuperscript{45}, suggesting that the 16q22.1 locus may be involved in sex-related differences in lung function decline between male and female smokers.

Our study is limited in that some of the sex-specific associations may not be observed due to insufficient statistical power resulting from decreased sample sizes. We chose to perform stratified analyses for ease of interpretation of association odds ratios, and we note that identification of interactions in general requires more statistical power than that of a standard GWAS because effect sizes of interactions are expected to be smaller than their main effects. Future replication of results in independent cohorts could ensure generalizability of our findings. Our study lacks functional validation of sex-specific genetic components in support of the statistical associations, but future experimental studies can explore our findings to elucidate the mechanisms underlying the observed differences. Another limitation is that the UK Biobank is not representative of the general population with respect to a variety of health characteristics; participants were more likely to be older, to be female, and to be more health-conscious than nonparticipants\textsuperscript{46}. Additionally, our results were obtained from participants of European ancestry, and thus, may not generalize to other racial/ethnic groups. Our gene-based association tests did not fully utilize information from the GWAS results since the lead variants in some loci were not necessarily within boundaries of protein-coding genes.

In summary, sex-stratified GWAS of COPD found substantial overlap in the significant risk loci and genetic correlation of male versus female results, but evidence of sex-specific effects was found for several genes, the most prominent of which were \textit{C5orf56, CFDP1, TMEM170A, CHST6, ASTN2} and \textit{TRIM32}. We developed the \textit{snpsettest} package to conduct gene-based association tests with GWAS summary statistics and identified genes showing a sex-specific association. Contrasting the GWAS and gene-based association test results provided insight into what genetic components can be the topic of future studies aimed at understanding sexual dimorphisms in COPD.

Abstract
In this study we seek to determine the efficacy of using automated mapping methods to reduce the manual mapping burden of laboratory data to LOINC® on a nationwide electronic health record derived oncology specific dataset. We developed novel encoding methodologies to vectorize free text lab data, and evaluated logistic regression, random forest, and knn machine learning classifiers. All machine learning models did significantly better than deterministic baseline algorithms. The best classifiers were random forest and were able to predict the correct LOINC code 94.5% of the time. Ensemble classifiers further increased accuracy, with the best ensemble classifier predicting the same code 80.5% of the time with an accuracy of 99%. We conclude that by using an automated laboratory mapping model we can both reduce manual mapping time, and increase quality of mappings, suggesting automated mapping is a viable tool in a real-world oncology dataset.

Background and Significance
Health data collected in the course of routine clinical care (real-world data [RWD]) are becoming a valuable part of the clinical research armamentarium, complementing and/or supplementing traditional prospective studies, and providing insights on aspects such as patterns of care or treatment effectiveness in populations underrepresented in clinical trials.¹,² Electronic health records (EHRs) have emerged as a key oncology RWD source, with the potential to generate highly granular longitudinal data.³ The original purpose of EHRs however, is not research but patient care, administration, and reimbursement. Therefore, extraction of research-grade information from the EHR may become a multi-step process that requires optimization and quality controls.⁴

The utilization of EHR-derived data for research purposes involves extraction of structured and coded data, as well as unstructured data (narrative free text entered by users at the point of care). One domain in particular that requires significant pre-processing is that of laboratory (lab) data.⁵,⁶ Laboratory data is crucial in describing the longitudinal patient journey and thus high quality laboratory data is essential in many areas of oncological research. For example, laboratory data is necessary to understand the efficacy of a patient’s regimen or the performance of novel treatments.⁷ However inconsistent use of standards by laboratories and free text documentation leads to highly variable lab results data.⁶,⁸ The Logical Observation Identifiers Names and Codes (LOINC®)⁹ is a vocabulary standard used to identify and unify lab data under a common data model, but is often inappropriately or inconsistently used in clinical day-to-day settings.¹⁰,¹¹ Due to this, a manual mapping process where specialists assign laboratory data to LOINC codes is required before the data can be used in research datasets.¹²

This manual mapping process, however has some shortcomings:

1. Ingestion of standardized and non-standardized lab data from multiple vendors, free text data entry at practice sites, and abbreviations, typos, and practice-specific documentation norms lead to a potentially infinite set of source terms.⁵,⁸ In our study we have found that it takes an experienced clinical terminologist between 6-8 hours to map 1000 terms manually, meaning harmonizing large amounts of laboratory data to LOINC codes is an arduous process.

2. As with any manual process, there is inevitable error in the mapping process, in spite of having mapping guidelines. As any error affects the accuracy of data that will be used for research and analysis, multiple levels of mapping review are required, further increasing the manual workload.

3. Any free text terms that come in from source data not previously harmonized are required to be mapped before they are eligible for entry into research datasets. Depending on volume, harmonization can be a lengthy process, reducing the data recency of datasets.
Based on the above considerations, finding an automated approach to lower the burden and increase the accuracy of the mapping process has direct implications on the quality of real-world research datasets. As a single mapping can affect many rows in a database, high accuracy mappings are of top importance when examining automated approaches.

Previous studies have attempted to automate LOINC mapping in a number of different scenarios. One study attempted to use a local high quality corpus and was able to achieve a best case accuracy of 79%. A second study that relied on using lexical methods achieved similar accuracy. A more recent study trained a machine learning classifier on a large national EHR database with noisy LOINC labels, and was able to achieve relatively high accuracy. The best classifiers in this study predicted the correct LOINC code in 85% of the unlabeled data and 96% of the labeled data by test frequency. More recently in a study focused on mapping COVID-19 labs to LOINC codes, a rules based algorithm was shown to have accuracy of 97.4%, prompting further investigation into deterministic rules based algorithms. Other studies have been successful at higher level grouping of laboratory data into categorical values, but did not focus on the standardization of individual lab records.

To the best of our knowledge, there are no studies that have attempted to use automated LOINC mapping on a real-world dataset actively being used for clinical research, or on an oncology-specific dataset. These properties lead us to develop custom encoding methodologies, with the goal of high accuracy and high precision automated LOINC mappings. We used these novel encoding methodologies to process free text laboratory data for the use in supervised machine learning classifiers. We evaluated the ability for these classifiers to individually predict LOINC codes, as well as the ability for groups of classifiers to jointly make predictions through ensemble learning. Any reduction in manual mapping time or manual quality assessment work that an automated system can provide to clinical terminologists (without compromising accuracy) is our overall measure of success.

**Methods**

**Index Of Lab Data**

This study used the nationwide, longitudinal Flatiron Health electronic health record (EHR)-derived de-identified database. During the study period, the de-identified data originated from approximately 280 US cancer clinics (~800 sites of care). Flatiron Health creates EHR-derived research datasets comprising de-identified patient-level structured and unstructured data, curated via technology-enabled abstraction. Flatiron Health has a harmonization process whereby research relevant clinical and administrative data are mapped by clinical terminologists to their appropriate terminology standards. All free text laboratory data undergoes this process, getting assigned LOINC codes. Once data is harmonized, it is re-used to determine standard codes for any current and future free text data.

Flatiron Health lab data is manually harmonized using term, unit, and panel information, with each distinct combination corresponding to a different row that each requires harmonization. As all three fields can potentially be free text fields in EHRs, thousands of new combinations require mapping each month.

The “term” field of the lab data contains the name of the lab result. This can vary from a fully spelled out name to a local acronym. An example of the term field is “white blood cell count”, which also might appear as “white blood cell”, “wbc”, “wite bld cell”, or any other abbreviation with or without typos.

The “unit” field aptly contains information about the unit of measurement. Examples of a few possible unit values can be seen in Table 1. As shown in Table 1, rows that have the same term value but differing unit values can result in different target LOINC codes. Lab results can also be expressed in equivalent units, for example the units mg/mL, g/dL and ug/mL, all measure mass/volume, but create separate rows for mapping.

The “panel” field represents a group of lab tests/results that are ordered and reported together. There are several bases for grouping individual labs together. For example, by the medical condition they are intended to help diagnose (cardiac risk panel), by the specimen type (complete blood count, CBC), by the tests most frequently requested by users (comprehensive chemistry profile), by the methodology employed in the test (viral panel by polymerase chain reaction), or by the types of components included (urine drug screen). Since the specimen for the lab result is not available as a distinct data point, we use the panel name to determine the system. In the Flatiron Health dataset the panel field contains the concatenation of all the panels that were ordered, adding variance and further increasing the amount of data that requires harmonization.
Datasets

There are three catalogs we used in our experiments for automated lab mapping harmonization:

1. A source data catalog
2. A target LOINC data catalog
3. A mapping catalog containing associations between the source and target catalogs

The source data catalog contains all of the unique term, unit, and panel combinations that we have ever seen in our data, as well as an associated source ID. This table contains no LOINC code information. The “target” LOINC catalog contains all of the different LOINC codes that we might map the rows in the source data catalog to. Our harmonization team takes in the source catalog as input and manually determines which target code each row in the source catalog should map to.

Once a row from the source data catalog has been assigned an appropriate LOINC, it is added to the mapping catalog. Thus, this catalog contains the source ID and the associated target ID (LOINC) in a unique mapping. Despite the full LOINC catalog containing approximately 95,000 distinct LOINCs, because the source dataset is oncology specific we see only a small percentage of all possible LOINCs in our dataset. If the harmonization team determines that the information in the source row is insufficient to determine an accurate mapping, a label of “EXCLUDED” is attached and no target code is present. This provides an additional challenge for an automated system, as this label has a wide range of source data mapped to it, making it challenging to accurately predict.

There are different levels of LOINC interoperability, depending on the differences between two LOINC codes. Previous work has consolidated LOINC codes using these levels of interoperability\textsuperscript{17}, but since the Flatiron Health dataset requires the most granular version of LOINCs, we do not do consolidation. While this makes automated LOINC prediction more challenging, it is required to keep the dataset as precise as possible.

Deterministic Automated LOINC Prediction

Before using learning-based automated LOINC prediction algorithms, we first set baselines using two computation-based algorithms. The two algorithms, maximal target string matching and maximal source string matching, are described below.

Maximal Target String Match

The first baseline algorithm we used compared source rows directly to the target LOINC catalog. We compared using Levenshtein distance, which is a string metric for measuring the difference between two character sequences.\textsuperscript{22} Specifically we used the Levenshtein ratio, which is a number between 0 and 1 representing how similar two strings are, with 0 being completely different and 1 being entirely the same. For each row in the source catalog, we compared the source term and source unit fields directly to the target LOINC catalog. We then combined the comparisons via a weighted sum of term and unit. This set of weights was evaluated against six other combinations ($\frac{4}{5}$ term and $\frac{1}{5}$ unit, $\frac{3}{5}$ term and $\frac{2}{5}$ unit, $\frac{2}{5}$ term and $\frac{3}{5}$ unit, $\frac{1}{5}$ term and $\frac{4}{5}$ unit, $\frac{2}{5}$ term and $\frac{4}{5}$ unit, $\frac{4}{5}$ term and $\frac{2}{5}$ unit) on a random sample of 100,000 rows from the source term catalog and had the highest performance of the six. Since the panel field contains a combination of all panels that were ordered, it has no directly comparable value in the LOINC catalog and was therefore excluded. For each row, the LOINC code
that was most similar via the weighted sum of term and unit Levenshtein ratios was the one assigned.

Maximal Source String Match
The second baseline algorithm attempts to find the source row in the training data that is most similar to the test row being evaluated. Similar to the Maximal Target String Match algorithm, it uses Levenshtein ratio to measure similarity. To compare two rows, the Levenshtein ratio of the term, unit, and panel fields are calculated and combined via a weighted sum of \( \frac{3}{5} \) term, \( \frac{1}{5} \) unit, and \( \frac{1}{5} \) panel. We again tried multiple weighted combinations of fifths, and this one had the highest performance of the combinations we evaluated. Computing the Levenshtein ratio is a costly operation, and so comparing each row in the training data to every row in the source data is prohibitively expensive. Due to this limitation, we instead first pre-compute the five most common source terms for each LOINC, with ties being broken by random selection. We then compare each row in the test data to all of the pre-chosen source rows, and choose the LOINC that has a source row with the greatest similarity.

Feature Encodings
As the source data is composed of free text fields, we must first encode the free text to make it possible to pass as an input to a supervised machine learning model. Since lab data free text fields have an unlimited set of potential values, and are often short abbreviations, we found that traditional string encoding methods that rely on a finite corpus to encode such as One-Hot tokenization, TF-IDF, and Word2Vec perform poorly.23–25 With this in mind, we developed two new encoding methods specifically for this domain.

Levenshtein Distance Encoding
As mentioned above, Levenshtein distance is a string metric for measuring the difference between two character sequences.22 To encode each row, we compared the rows source term and source unit to every target description and target units in the LOINC target catalog, for each distinct LOINC in the training data. The weighted sum of the Levenshtein ratio for term and unit between the source catalog and each row in the LOINC catalog is captured in a vector. To determine the optimal set of weights to use, we tried every tenth fold combination (\( \frac{1}{10} \) term, \( \frac{1}{10} \) unit, ..., \( \frac{9}{10} \) term and \( \frac{1}{10} \) unit) and settled on \( \frac{8}{10} \) term and \( \frac{2}{10} \) unit. The vector of weighted Levenshtein ratios, which has a column for each LOINC representing how similar the source row is to that target LOINC, is the encoded row. Similar to the Maximal Target String Match, we exclude using panel as it has no directly comparable value in the LOINC catalog to compare to with Levenshtein distance.

Frequency Tokenization Encoding
In a similar manner to TF-IDF, we created an approach to encode based on the frequency of distinct tokens in the source data. For each row in the training data set, we first clean the rows by removing any characters that are not alpha-numeric and replacing them with whitespace. This process is done for each of the term, unit, and panel fields. We then split the cleaned row on whitespace, creating a set of tokens for each field. These tokens are then mapped to the target LOINC, creating a token-LOINC map that details which source data tokens are associated with each LOINC. If tokens appear multiple times mapping to the same target LOINC, that count will be recorded in the token-LOINC map. This token-LOINC map can then be used to encode future rows.

To encode the term field, we first create tokens in the same manner as described above. These tokens will be used to create an encoded vector of length L, where L is the total number of LOINCs in the token-LOINC map. In this vector, each LOINC has a corresponding index, initialized at zero. For each LOINC that a token maps to, the corresponding index in the vector will be incremented by the count in the token-LOINC map. See Figure 1 for an example of this encoding. This process happens for each of the term, unit, and panel fields, resulting in a concatenated encoded vector of length 3*L.

Supervised Machine Learning Classification Models
For both of the feature encoding methods, we evaluate performance using Logistic Regression (L2 penalized)26, Random Forest27, and K Nearest Neighbors (KNN)28 classifiers. Model training and analyses were conducted using scikit-learn in Python 3.7.4,29
Figure 1: Tokenization Encoding process. Training data gets processed and tokenized, forming the token-LOINC map. This map is then used to encode both the training and test data, leading to vectorized rows. The encoded row has an index for each LOINC that exists in the training data catalog (here only 2 LOINCs), and the value at each index represents how many tokens overlap with training data tokens mapped to that LOINC. The first row gets encoded as \([3, 0]\) since there are 3 tokens in the source term that match a token for the LOINC 26464-8, and 0 tokens that match the LOINC 26499-4.

We used GridSearch to optimize key hyperparameters for each model. For logistic regression we focused on the number of iterations, and the inverse regularization parameter (C), and settled on values of 500 and 5 respectively. For random forest we focused on the number of estimators, and settled on 500. For KNN we focused on the number of nearest neighbors, and settled on 5.

Additionally, we evaluated the use of PCA to reduce the size of the input vectors and thereby decrease learning time. Using PCA with 95% variance we were able to decrease the total learning time by 50%. However, the increased efficiency came at the cost of a few percentage points of accuracy. As high accuracy is our top priority, the results in this paper do not use PCA or other compression schemes on the input vectors.

Ensemble Learning

Ensemble learning is the practice of using multiple learning algorithms together and then classifying new points based on a weighted vote of their individual predictions. We explore the use of ensemble learning to increase accuracy of predictions in cases where multiple models predict the same LOINC. Our ensemble models are assessed based on the percent of the test set with prediction overlap, and the accuracy of the predictions on the overlap. The percent of the test set with overlap is simply the number of rows in the test set where all models make the same prediction, divided by the size of the test set. The accuracy is then measured in the standard way on the subset: by taking the predictions that all models made and comparing with the labeled data. A high performing ensemble model will have both a high percentage of test set overlap, and high accuracy on the overlap.
It is important to note that adding additional models to an ensemble with these assessment criteria will not necessarily increase the ensemble’s performance. For example, because we define prediction overlap to be only predictions where all models make the same prediction, adding a poorly performing model may significantly reduce prediction overlap, decreasing the subset the ensemble is able to make a prediction on. Moreover, a poorly performing model may only overlap on incorrect predictions, significantly decreasing the ensemble’s accuracy. With this in mind, we evaluate various ensembles to attempt to find the set of models that most successfully complement each other.

Data Size and Model Performance

Models were trained using a subset of 450,000 randomly sampled and unique rows from the most recent two years of the labeled data corpus. We decided to use a large sample instead of training on the full dataset to increase investigative agility while maintaining high usability. Amongst the rows sampled, there are 482 distinct LOINCs that have been mapped to, including “EXCLUDED”. Models were validated using an 80/20 split for training and testing respectively, and results are the average of 5 randomly subsampled splits. Models were assessed based on accuracy, F-1 score, and precision. Since models are multiclass classifiers, F-1 score and precision are measured as weighted averages of the F-1 score and precision across all classes. While accuracy is of the highest concern for prediction usability, F-1 score is important to assess whether accuracy is overfitting due to class imbalance and thereby simply predicting the most frequent LOINCs.

Results

Deterministic Algorithm Performance

To establish a baseline we first built and tested the deterministic prediction algorithms. These algorithms do not take advantage of larger data sets to learn, so modifying the size of the dataset only affects the variance. With this in mind, we averaged predictions from 5 trials run using 10,000 randomly sampled rows. The performance of these algorithms is in Table 2. For Maximal Target String Match, accuracy is low, but still much higher than random chance, implying that there is some inherent similarity between the source data and the target data. Given the level of abbreviation in the source data, this result is expected. Comparing to other source data instead of directly to target LOINC data in the Maximal Source String Match algorithm, performed significantly better. When solely basing future predictions on the most similar previously seen terms, we saw an accuracy of just below 50%. Incorporating unit and panel information as well, we saw a small increase, implying that there is value in using more than just the lab name represented in the term field when making predictions.

Table 2: Deterministic (non-learning) algorithms performance for predicting LOINC, run on 10,000 LOINCs.

Cross Validated Supervised Model Performance

After determining a baseline, we moved on to assessing the performance of different learning based models using our two different encoding schemes. The results from the Levenshtein Distance Encoding method are in Table 3. We can see that we have significantly outperformed the baseline, and that while the random forest classifier had the highest accuracy, all models have comparable performance at greater than 93% accuracy. KNN has marginally worse performance using this encoding scheme, but it is worth noting that training time for the KNN classification model is on average less than 50% that of logistic regression or random forest. We also see that the weighted F1 score and weighted precision have similar values to that of accuracy, implying that our models are not overfitting due to class imbalance.

As we are focused on any reduction in manual work, it is also important to see if there exist particular subsets that our
models can reproducibly predict with higher success. One such subset we examined is the top 10% of LOINCs by labeled rows, a subset which on average accounts for over 84% of the test set. Unsurprisingly our models have a higher weighted precision on LOINCs in the top 10%, as these LOINCs have significantly more training data. However they still do relatively well on LOINCs that have less training data, once again suggesting that overfitting is not occurring.

Examining the results from the Frequency Tokenization Encoding in Table 4, we see that only the random forest classifier is able to outperform any model using the Levenshtein distance encoding. We also see that in this encoding method, random forest outperforms both logistic regression and KNN by a significant margin. Interestingly, when using the deterministic baseline algorithms, comparison to the LOINC catalog did significantly worse than comparison to the source data directly. Contrastly, when using supervised learning the Levenshtein encoding which encodes by comparing directly to the target LOINC catalog on average outperforms token encoding which encodes by comparing to previously seen source data. We also see slightly more variance between accuracy and weighted F1 Score as well as between the top 10% and bottom 90% of LOINCs, implying that there might be more class imbalance overfitting happening.

**Ensemble Learning Performance**

While supervised learning models did significantly better than baseline models, accuracy still has room for improvement. To increase usability, we attempted to use ensemble learning to see if we can achieve a higher accuracy for a subset of the predicted data. Results for different groupings of trained models are in Table 5. These results are extremely promising, with the combination of all trained models achieving an extremely high accuracy of 99% on the 80.5% of predictions that all models agreed upon. While using this method doesn’t allow for full automation as it is only applicable to a subset of predictions, it has the potential to significantly reduce the work of manual harmonization and quality analysis.

In these experiments we observe that the combination of models across encoding methods generally leads to better performance when compared to the combination of models within an encoding method. One potential reason for this is that a feature of the encoding method itself leads different models to make similar predictions. This would also explain the high prediction overlap of the models trained with the Levenshtein distance encoding. As the different encoding methods emphasize unique aspects of the source data, the combination of the encoding methods allows the

models to escape issues inherent to the encoding, generating a more robust prediction. We also observe that within encoding methods, increasing the number of models causes a drop in the overlap percentage, but results in a higher accuracy in the overlap.

Discussion

This study has shown that automated machine learning methods can be successful in mapping laboratory data to LOINC codes in a real-world oncology dataset. Overall our best performing model had an accuracy of 94.5% on the full hold-out dataset, and our ensemble method had an accuracy of 99.0% on 80.5% of the hold-out dataset. Additionally we have shown that it’s possible to make predictions to LOINCs with the same level of specificity as clinical terminologists, including marking rows with insufficient information as EXCLUDED. Success in mapping to EXCLUDED is of particular value, as having source data without enough information to map accurately is a tenant of a real world dataset, and provides an additional challenge for machine learning models.

We examined cases where our model’s predictions were incorrect and found that in the majority of cases, the incorrect prediction was extremely similar to the actual label. For example, in one instance the model predicted LOINC 20570-8 which has target term "Hematocrit Bld VFr Pt Qn", and the labeled LOINC was 4544-3 which has target term "Hematocrit Bld VFr Pt Qn Automated count". While these are very similar, because we want to maintain the highest degree of accuracy possible it still counts against the model’s performance. This highlights the importance of having both correct and consistent mappings in our labeled dataset. While we don’t have a measure of the accuracy of the manual mappings that we used to create our labels, in future work we plan to use the incorrect model predictions as a starting point to review the accuracy of existing labeled rows.

Our results are comparable in accuracy to the best reported results from prior studies involving automated laboratory data mapping. The high accuracy and precision of the ensemble learning allows for supplemental use of automated mapping methods alongside clinical terminologists in a range of potential applications. Aside from directly predicting new mappings, this method can also be used as an extra level of quality analysis for maps done manually. Additionally it can be used to verify existing maps, especially those done many years in the past, to identify potentially incorrect mappings to be reexamined. In summary this study has shown that using automated mapping methods has potential to not only reduce manual harmonization time by clinical terminologists, but also to provide an immediate quality improvement to real-world datasets.

The novelties and areas of strength in this study include (a) assessing the place of automated laboratory mapping methods in a real-world dataset, (b) demonstrating the efficacy of such methods on an oncology-specific dataset, (c)
implementation of two novel laboratory free text encoding schemes, and (d) high prediction accuracy using ensemble learning. In future work, we would like to explore other encoding methods, as well as attempt to use multiple encoding methods for different fields within the same model. Furthermore, we would like to explore the extensibility of these techniques to other domains, such as free text medication administration data.

This study has a few notable limitations. Firstly, while the methods in this study are reproducible at no cost, the labeled dataset of oncology laboratory data to LOINC codes used in this study is not publicly available. However, there may be opportunity in the future to open source some of these mappings for the larger research community. A second limitation is that while these encoding and models performed well on oncology data, there may be oncology-specific aspects about laboratory data that would cause these methods to perform poorly in other medical domains. A limitation with our encoding methodology is that the encoded vectors created are very wide, which can lead to long model train times and reduced development speed. Encoding with Levenshtein ratios further increases this issue, as comparing strings is an expensive operation. Another limitation is that because machine learning classifiers can only predict LOINCs that they have been trained on, any new additions to the LOINC catalog or changes in mapping policy would be impossible for the classifier to predict. Whenever this happens all models would need to be retrained on additional applicable training data. Lastly, our primary focus is reducing the burden of clinical terminologists and we are therefore satisfied with high accuracy on a subset of data. Other applications however might require full automation, for which our study has comparably high accuracy, but decreases the applicability of our ensemble learning methods.

Conclusion

As the use of real-world data continues to grow, automated methods that allow for accurate aggregation and harmonization of data from EHRs become increasingly important. Mapping free text laboratory data to LOINC is important before the data can effectively be leveraged for use in research, however the manual mapping process is extremely time intensive. This study has shown that through the use of automated methods, we can significantly lower this burden. Free text medical data is challenging to encode for existing NLP methods, and so we developed specific encoding methodologies to effectively capture and encode the information required to map laboratory data. We demonstrated that with these encodings and the use of ensemble learning, training an automated laboratory data classifier with high accuracy is not only possible, but can provide immediate value to the creation of a high-quality real-world oncology dataset.

Human Factors Considerations in Transitions in Care Clinical Decision Support System Implementation Studies.
Erin E. Kennedy, BSN, RN, Kathryn H. Bowles, PhD, RN, FAAN, FACMI
University of Pennsylvania School of Nursing, NewCourtland Center for Transitions and Health Philadelphia, PA

Abstract
Objective: Review transitions in care clinical decision support system (CDSS) implementation studies and describe human factors considerations in users, design, alert types, intervention timing, and implementation outcomes.
Methods: Literature review in PubMed guided by subject matter experts.
Results: Twelve articles were included. Targeted users included physicians, nurses, pharmacists, or interdisciplinary teams. Alerts were deployed via email, cloud-based software, or the EHR in inpatient and/or outpatient settings. Outcome measures varied across articles, with mixed performance. There were six readmissions-focused, two prescribing, one laboratory, two prescribing and laboratory, and one discharge disposition CDSS. Few articles reported statistically significant differences in outcomes, and many reported alert fatigue.
Discussion and Conclusion: Despite the increasing prevalence of CDSS for transitions in care, few articles describe implementation processes and outcomes, and evidence of clinical practice improvement is mixed. Future studies should utilize implementation science frameworks and incorporate appropriate implementation outcomes in addition to traditional clinical outcomes like readmission rates.

Background and Significance
In 2017 alone, 3.5 million potentially preventable 30-day hospital readmissions cost the United States healthcare system $33.7 billion. Readmissions are a multifactorial problem involving patients’ clinical and social history prior to hospitalization, during hospitalization, and in post-discharge life. Readmission reduction remains a central focus in health policy because it holds the potential to improve quality and reduce costs, and discharge planning plays a key role. Discharge planning is complex, individualized, and ultimately determines if the patient will receive any post-acute care (PAC). PAC includes long-term acute care hospitals, inpatient rehabilitation, skilled nursing facilities, and home health care. A human factors study found that patients often have up to six people directly involved in the process, spanning different clinical specialties, family members, and outpatient providers. There are no clinical practice guidelines for this complex process. Variation in clinical decision making can exacerbate health disparities and affect outcomes when patients who need PAC do not receive it.

Coordinated discharge planning and transitions in care from hospital to the post-acute phase are successful readmission reduction strategies, and numerous informatics solutions such as clinical decision support systems (CDSS) have successfully been developed to support this goal. Most early CDSS research prior to 2010 described the benefits of CDSS but did not explore any adverse consequences of this new technology. Early studies found that the use of CDSS improved uptake of consultant’s recommendations by 30%. Bright’s early systematic review of the effects of CDSS systems identified 148 randomized controlled trials and found that the use of commercial CDSS tools improved ordering of laboratory tests, drugs, and preventative services, but did not identify any negative consequences. A study that developed a taxonomy of front-end CDSS tools in commercial and local EHRs found that 53 unique types of CDSS exist, but only 8 were present in all EHR systems. The most common CDSS tools were for medication dosing, and the least common tools were for complicated decisions like discharge planning. As CDSS research became more prolific, articles began to include information about the negative side of CDSS. In 2014, Dhiman et al. attempted to create an evidence-based guide to CDSS purchasing for health systems, but struggled to find much evidence in the literature. The article called for increased transparency from vendors to promote the building of such tools, but many of the barriers that he faced like diversity of EHR systems, legal troubles, limitations in the marketplace, and conflicts of interest continue to exist today.

Although CDSS is ubiquitous in most US health systems, research articles typically focus on variables and model development rather than measuring the effects of CDSS design and implementation on clinicians and patients. Reviews of prediction models that might drive CDSS for discharge planning in acute care including readmissions and discharge disposition have been published, but little information exists about other elements of care transitions like medications, laboratory results, or post-acute settings. The goal of this paper is to review transitions in care CDSS implementation studies and describe human factors characteristics in users, design, alert types, intervention timing, as well as implementation outcomes. Future studies can use this evidence to design more effective implementation strategies.
Methods

Subject matter experts were consulted to refine search terms in PubMed with the following strategy:
(implement* OR satisfaction OR acceptance OR "provider use" OR workflow) AND clinical decision support AND
(discharge planning OR readmission). Articles published before November 1, 2020 were evaluated. Characteristics of
CDSS, outcomes, and insights from the implementation process were extracted and summarized.

Results

The PubMed search returned 373 results. Five additional articles were identified and included for
evaluation from reference lists. Study abstracts were reviewed and 12 were included in the analysis. Inclusion
criteria aimed for studies that implemented CDSS for care transitions from acute care hospitalization to post-acute
settings for adults ≥18 years in the US and described implementation processes. Study selection is described in
Figure 1.

The earliest study was published in 201215 and the most recent were
published in 2020,11, 16, 17
While most studies were
conducted in academic medical centers,15-19 there
were two in regional hospitals,11, 20
and three that included both a hospital and outpatient
facility22-23. Three studies
utilized commercial tools,11, 16,
23 while nine built their
own,15, 17-22, 24, 25 Six studies
tested passive alerts,11, 16, 17, 19,
21, 22 five tested active alerts,15,
20, 23-25 and one18 tested both
types. Study characteristics
are described in Table 1.

**CDSS Description, Intervention Timing, and Alert Type**

Care transitions are multi-faceted and interdisciplinary, so the CDSS in this review target different aspects and actors in the process. Six articles implemented tools to predict 30-day hospital readmissions[^11^, ^16^, ^17^, ^19^, ^24^, ^25^] two implemented prescribing tools[^18^, ^23^] one implemented a tool to predict discharge disposition[^20^] one implemented laboratory alerts[^15^] and two articles from the same study implemented both prescribing tools and laboratory tools[^21^, ^22^]. These tools were designed to improve discharge planning, communication between inpatient and outpatient providers, post-acute care, or a combination of settings. Although most CDSS were only implemented in one setting, some leveraged health system EHR integration or regional health information exchanges.

Most readmission prediction tools were designed to be used during the hospitalization. Gallagher et al.[^16^] argued that ideal readmissions prediction tools are “closely integrated with the electronic health record; pull data real-time from the EHR, update continuously, and present the score for clinical teams to act upon.” Their tool was built as a passive alert available in the EHR from admission to discharge for all clinicians with a focus on physicians and case managers. The team conducted quarterly interdisciplinary meetings over two years to monitor the implementation[^16^]. The Horne et al.[^17^] tool was designed similarly, with a daily EHR report for interdisciplinary rounds within 24-hours of admission to discharge with specific tasks for bedside nurses, charge nurses, pharmacists,
social workers, dieticians, care coordinators, and heart failure clinic nurse providers in a multidisciplinary team-based care process (MTCP) in the inpatient setting only. The Romero-Brufau et al.\textsuperscript{11} tool was not implemented in the EHR due to information technology resource limitations, but it was available in an external web portal to discharge planners and physicians from admission to discharge as a passive alert, similar to Gallagher et al. Their team conducted workflow mapping for six months prior to implementation and conducted informal qualitative interviews with physicians in the post-implementation period. Similarly, Cochran et al.\textsuperscript{19} developed and implemented their readmission risk-prediction tool in a web-based platform. The dashboard was used throughout the inpatient hospitalization, but authors did not specify the frequency or types of clinician users. They also developed prediction models for mortality and serious complication.\textsuperscript{19} Bowles et al.\textsuperscript{11} implemented a CDSS tool to predict discharge disposition, and tested its impact on readmission. Their CDSS was an active twice-daily alert in the form of an email to discharge planning clinicians (case management). The study team worked extensively with case management to design the intervention prior to the intervention phase.

Hewner et al.\textsuperscript{24, 25} took a different approach to readmission prediction by implementing the Patient-Centered Assessment Method (PCAM) platform across the transition from hospital to the outpatient setting, and made the tool interoperable throughout other health systems in the region with an EHR-agnostic web-based platform. The clinical data repository received hospitalization information, computed a readmission risk profile based on comorbidities and Medicaid status which triggered a CDSS alert to the outpatient nurse case manager to call the high-risk patients within 48 hours of discharge, complete the PCAM questionnaire, and intervene as necessary. This was the only article targeting nurses only. The team designed the intervention over 6 months prior to implementation, assessed implementation for 12 months, and continued to monitor the intervention after study completion.\textsuperscript{24, 25}

Two articles reported on CDSS tools focused on medications, and one focused on the hospitalization period. Blecker et al.\textsuperscript{18} developed and implemented a CDSS tool to increase prescriptions of ACE inhibitors at discharge among heart failure patients and tested both passive and active alerts in the pre-post study. The alert was designed for use by physicians only and was available in the Epic EHR system throughout the entire hospitalization even though the focus of the study was the discharge medication list. Authors claim to have used user-centered design in development and testing but did not provide details or collect qualitative data. In addition to heart failure diagnosis, CDSS logic incorporated ejection fraction, medication list, blood pressure, and pregnancy status.\textsuperscript{18}

Similar to the Hewner et al.\textsuperscript{24, 25} articles for readmissions, Elliot et al.\textsuperscript{23} designed a pilot laboratory intervention to recruit patients at discharge and deploy the YouScript CDSS intervention targeting older polypharmacy patients with potential drug-gene based interactions during home care. Their team did not use user-centered design or collect any qualitative data, but the intervention was designed for pharmacists only and included automated prescription recommendations for patients in the intervention group. Dalal et al.\textsuperscript{15} designed and implemented a laboratory CDSS tool to notify both the inpatient physician and outpatient primary care provider (if in the same health system and present in the EHR) of pending laboratory results at discharge. The study was designed to address the chasm between inpatient and outpatient settings, because lack of follow up to tests pending at discharge can contribute to readmissions, delays in diagnosis or treatment, and adverse patient outcomes. Even though this was one of the earliest articles in the review, its design truly bridged the gap between inpatient and outpatient settings. The team applied user-centered design in the pre-implementation period and the intervention was deployed to inpatient physicians and outpatient providers after discharge to facilitate communication and patient handoff.\textsuperscript{15} Gurwitz et al., 2014 assessed the impact of primary care EHR-based passive alerts (development described elsewhere)\textsuperscript{26} about drug-drug interactions, medication recommendations, and laboratory recommendations for older adult patients 3 days following discharge to the community in a randomized controlled trial. Amroze et al., 2019\textsuperscript{22} later analyzed the alert types, opening of, and response to these alerts. Although the original trial did not use user-centered design, Amroze et al.\textsuperscript{22} did perform simulation testing with a physician and data manager.

**CDSS Design**

All of the CDSS tools in this review were implemented electronically, either embedded in EHRs, external portals, or emails. EHR and email were the most common alert types across articles. Although most were implemented in inpatient hospital settings only, others were designed to facilitate communication with post-acute care or outpatient settings. For readmissions on the inpatient side, the Gallagher et al.\textsuperscript{16} readmission prediction tool was implemented as a column called “Readmission Risk” in Epic work lists with a red (high risk), yellow (medium risk), or green (low risk) circle that the clinician can click to see an expanded view of their readmission risk percentage, factors contributing to score in order of importance, and changes to readmission risk over time. The score was updated every four hours and the tool was not customized to their health system. Similarly, the Horne et al.\textsuperscript{17} readmission-risk daily report (passive alert) was run at 9:00am each day in the EHR which classified patients...
into high- or low-readmission or mortality risk. Nurses later reviewed the lists and emailed them to pharmacists and charge nurses each day to begin the MTCP pathway, with a separate process for weekends and holidays. Although it was not possible for the Romero-Brufau et al.\textsuperscript{11} team to implement their tool in the EHR, their portal was designed similar to the Gallagher et al. team with a purple dot next to patients’ names to identify those in the top 20\textsuperscript{th} percentile of readmission risk that clinicians could click to view the risk factors contributing to the score and up to 26 possible recommendations for interventions. The score was updated every 24 hours each morning before shift change, and discharge planners were instructed to contact physicians daily to discuss the recommendations. Cochran et al.\textsuperscript{19} developed an interface in REDCap with five data collection forms related to patient characteristics and Enhanced Recovery After Surgery protocol reporting requirements, and output forms with probability, clinical, and cost predictions for clinicians to improve decision making. Risk categories included high, low, and expected.\textsuperscript{19} Other discharge disposition and readmission-risk CDSS tools were implemented via email. Hewner et al.\textsuperscript{24, 25} implemented the CDSS alert for patients at high-risk of readmission as a secure email to the outpatient nurse case manager with information about the patient, hospitalization, and pre-existing comorbid conditions. Initially the PCAM assessment was completed on paper, but clinicians were so satisfied with the tool that they digitized it by the end of the study. Bowles et al.\textsuperscript{20} fired the CDSS algorithm recommendation for discharge disposition as a twice-daily report via email to the inpatient discharge planning team along with characteristics associated with the recommendation.

The medication and laboratory CDSS followed similar approaches with EHR-integration and emails in acute care and/or post-acute settings. The Blecker et al.\textsuperscript{18} team aimed to increase discharge prescriptions of ACE inhibitors among HF patients and implemented CDSS within Epic into existing prescribing workflows. Rather than delivering the alert at discharge, the team tested two versions of the CDSS throughout the entire hospitalization to see if it would lead to the continuation of the ACE inhibitor on the discharge medication orders. The active alert intervention group received a pop-up in the ordering screen that stated the patient was not on an ACE inhibitor, recommended the therapy, and included the patient’s blood pressure, creatinine, potassium, eGFR, and ejection fraction. Providers had the option to mute the alert every six hours. The passive alert was located in the daily provider checklist with the same explanation and details as the active alert, but never popped up or interfered with the clinician’s EHR workflow.\textsuperscript{18} Elliot et al.\textsuperscript{21} reported delivering the YouScript CDSS to home health care pharmacists to reduce drug-gene based interactions among older polypharmacy patients. However, they did not provide any details or screenshots of their CDSS intervention, nor did they state the frequency of reports. They claimed that the reports contained drug-gene interactions and recommendations with no further details. The Dalal et al.\textsuperscript{15} laboratory CDSS tool was implemented as one email per test grouping (chemistry, biology, etc.) per patient per day to each inpatient and outpatient provider. They designed customizable settings so that physicians could suppress certain notifications and added a feedback link within the email to address provider concerns in real time. The medication and laboratory CDSS from Gurwitz et al., 2014\textsuperscript{21} and Amroze et al., 2019\textsuperscript{22} were implemented as noninterruptive EHR InBasket alerts to primary care providers of patients aged 65 and older 3 days after discharge from acute care to the community. The alert types were classified as information only (drug-drug interaction), medication recommendation, or laboratory recommendation, while the control group received usual care.\textsuperscript{21, 22}

\textbf{Outcomes Studied}

Most articles in the review reported clinical outcomes rather than implementation outcomes. The gold standard in implementation science research is to select implementation outcomes based on frameworks such as RE-AIM\textsuperscript{27} or PRISM.\textsuperscript{28} Although all of the articles completed implementation, only two articles in this review cited a specific implementation framework (Proctor’s taxonomy\textsuperscript{19} and the Quadruple Aim\textsuperscript{28}). This aligns with prior research demonstrating a lack of theoretical underpinnings in implementation science research as a whole.\textsuperscript{29} Therefore, the implementation-focused outcomes will be described as process outcomes in this review and Table 1.

For the readmissions and discharge disposition-focused CDSS, clinical outcome measures included model performance, readmissions, mortality, emergency department utilization, cost, and outpatient visits. Although model performance was fair to good in these articles, the implementation outcomes demonstrated mixed success. Gallagher et al.\textsuperscript{16} reported a stable area under the curve (AUC) of 0.716–0.760 for their readmission risk prediction tool in overall adult patients from pre-implementation to two-years post-implementation, but no statistically significant change in 30-day readmissions or number of interventions performed relative to risk score. The Romero-Brufau et al.\textsuperscript{11} tool which predicted readmission risk and recommended interventions reported model sensitivity and specificity of 65% and 89%, respectively and a 25% relative (3% overall) reduction in readmission rates over the six-month implementation period. Authors argued for setting a low sensitivity threshold to reduce alert fatigue. For process outcomes in the Romero-Brufau et al.\textsuperscript{11} article, staff expressed frustration that readmission reduction interventions in the CDSS were inappropriate and the tool would be better off without the clinical recommendations. Authors noted that this is consistent with other studies that showed artificial intelligence tools perform well with
discrete tasks (like readmission risk) but poorly with complex tasks like care planning.\textsuperscript{11} Horne et al.\textsuperscript{17} reported 21\% lower readmission and 52\% lower 30-day mortality (both statistically significant) among high-risk MTCP patients compared with high-risk controls, and no significant increases in either outcome among lower-risk patients. The team successfully implemented the MTCP across health systems and identified a process outcome of significantly higher proportion of home healthcare discharge disposition compared with controls (24\% vs 22.6\%).\textsuperscript{17} For clinical outcomes, Cochran et al.\textsuperscript{19} reported moderate to good model discrimination for 30-day readmissions (AUC 0.641) and 30-day mortality (AUC 0.856), readmissions decreased 15.8\% among high-risk patients after implementation (4.4\% overall), mean length of stay decreased by 2.7 days, and post-operative laboratory test costs were projected to decrease $150,000 in 5 months post-implementation. For process outcomes, compliance tracking improved by 5.7\%. In terms of adoption, 73.1\% of monitored events in the application were browsing and 26.9\% were action, of which 67\% were record updating, and the majority of users completed actions in ≤43 seconds.\textsuperscript{19} The Hewner et al.\textsuperscript{24,25} readmission prediction CDSS for outpatient case managers measured changes in emergency department utilization, 30-day readmissions, outpatient utilization, and cost. Their transitional care intervention reduced emergency department visits by 35\%, 30-day readmissions by 25\%, and increased outpatient visits by 27\%, which led to an overall savings of $664 per patient and $71,289 in overall revenue from outpatient visits.\textsuperscript{24} Although authors did not conduct a rigorous qualitative study, they reported improvements in patient experience, work life of clinicians, and value of the nurse. The Bowles et al.\textsuperscript{20} discharge disposition CDSS evaluated the impact on readmissions and found a statistically significant 22\% relative reduction (3\% overall) in 30-day readmissions, but no statistically significant impact on 30-day emergency department utilization. For process outcomes, they found that the CDSS recommended 24-25.6\% more patients for post-acute care than clinicians.\textsuperscript{20}

For the medication-focused CDSS, clinical outcome measures included readmissions and process outcomes included adoption and fidelity. Blecker et al.\textsuperscript{18} defined adoption as the “percentage of hospitalizations with at least one alert that included an action to an alert that was not a dismissal” and fidelity as “the percent of hospitalizations with at least one alert that led to signing an order.” The active alerts triggering ACE inhibitor prescription for HF patients in acute care had higher adoption (40.6\% alerts were addressed) compared to passive alerts (13.1\% were addressed), but there were no statistically significant differences in fidelity between intervention groups. The alerts were triggered nearly 26 times per hospitalization (response rate <2\%), the 12-hour alert ordering rate was 0.8\%, and the alert was fired 405 times for each ACE inhibitor to be prescribed. Although alert fatigue was not discussed, it is likely that this CDSS tool was contributing to physician alert fatigue.\textsuperscript{18} The tool did not have any feedback channel for end-users, so a future study might consider adding capability for feedback, altering alert frequency, and/or conducting qualitative interviews in the post-implementation period. The Elliot et al.\textsuperscript{23} home care polypharmacy CDSS intervention did not lead to significant reductions in 30-day readmissions, but there were significant differences in 60-day readmissions (0.33 vs 0.70 per patient in tested vs untested group). Differences in OASIS quality outcomes including overall health status, pain, confusion, anxiety, depression, disruptive behavior, and assistance with activities of daily living were non-significant between groups. Authors reported 77\% of drug therapy recommendations that went to clinicians were followed.\textsuperscript{23}

Outcomes in the pending laboratory results CDSS tool included physician satisfaction and number of alerts. In the Dalal et al.\textsuperscript{15} study of emailing pending laboratory results at discharge to inpatient and outpatient providers, they reported 1.6 emails per patient and 84\% satisfaction among the physician end users. They credited physician feedback for their ability to reduce possible alert fatigue and achieve high satisfaction rates. For the medication and laboratory-focused CDSS in primary care after hospital discharge, clinical outcomes included outpatient visit rates within 30-days of discharge (27.7\% for intervention and 28.3\% for the control group) and 30-day readmissions (18.8\% for intervention and 19.9\% in the control group), both of which were not significantly different.\textsuperscript{21} This unexpected result prompted the follow-up article about types, opening of, and response to alerts, which are process outcomes. Authors reported 74.2\% of alerts were information only, 4.6\% were medication recommendations, and 21.2\% were laboratory recommendations. 78.5\% of alerts were opened by the target physician and 33\% prompted immediate action. After including other providers in the practice and expanding the time point to the end of the following day, an additional 41.3\% of all alerts had follow-up action and 32.7\% had no action. Odds ratios for action by the end of the following day were higher for medication and laboratory recommendations compared with information only. Authors identified two implementation challenges (capturing and interpreting historical data elements) and recommended that future studies plan how to collect EHR audit data prior to implementing an intervention.\textsuperscript{22}

**Limitations**

The search was limited to articles referenced in PubMed. Limited search terms may have missed articles. Future studies should include additional databases and broader search terms. The articles were not evaluated for quality.
Conclusion

Over the last decade, healthcare policymakers and administrators have invested in more predictive analytics tools to target various aspects of discharge planning to reduce hospital readmissions and costs. While many of these tools have been implemented as CDSS in health systems, the published academic literature on this topic is sparse. This review represents a starting point summarizing the current state of implementations to assist potential developers and purchasers of CDSS in their design and implementation processes.

The CDSS tools in this review were designed to reduce readmissions and improve prescribing or laboratory follow up with great variation in designs and outcomes studied. End-users varied with the majority targeted at physicians only, while others focused on nurses, pharmacists, or interdisciplinary discharge teams. While most tools were implemented in hospitals, some incorporated inpatient and/or outpatient settings. Design characteristics included alert frequency, EHR integration, information included in the alert, and active versus passive alerts. Email was a common alert type, which might be the result of workarounds in health systems where EHR-integrated CDSS capability is limited. A CDSS taxonomy study in 2011 called for increased interoperability and customized alerts for different clinical situations. Unfortunately, this remains a barrier in 2020 and only two articles in this review addressed interoperability with mixed success and one article focused on customizable alerts. All of the articles in this review tempered their positive results with limitations and described areas for future improvement. Very few articles reported statistically significant differences in outcomes after the post-implementation period and alert fatigue was a major focus in the discussion sections. Only two articles mentioned outcomes based on implementation science frameworks (adoption and fidelity), and most articles measured traditional clinical outcomes like readmissions. Future studies should focus on the implementation process with special consideration for the CDSS users, design, alert fatigue, and incorporate implementation science outcomes in addition to traditional clinical outcomes.

Abstract

Many clinical natural language processing methods rely on non-contextual word embedding (NCWE) or contextual word embedding (CWE) models. Yet, few, if any, intrinsic evaluation benchmarks exist comparing embedding representations against clinician judgment. We developed intrinsic evaluation tasks for embedding models using a corpus of radiology reports: term pair similarity for NCWEs and cloze task accuracy for CWEs. Using surveys, we quantified the agreement between clinician judgment and embedding model representations. We compare embedding models trained on a custom radiology report corpus (RRC), a general corpus, and PubMed and MIMIC-III corpora (P&MC). Cloze task accuracy was equivalent for RRC and P&MC models. For term pair similarity, P&MC-trained NCWEs outperformed all other NCWE models ($\rho$ spearman 0.61 vs. 0.27-0.44). Among models trained on RRC, fastText models often outperformed other NCWE models and spherical embeddings provided overly optimistic representations of term pair similarity.

Introduction

Quantitative evaluation of natural language processing (NLP) models can generally be categorized into intrinsic and extrinsic evaluation methods. Intrinsic evaluation reflects the correlation between the algorithms and human judgment. This may include testing for syntactic or semantic relationships between words. While much emphasis in NLP-related research is on extrinsic evaluation of NLP methods, it is vital to conduct rigorous intrinsic evaluation. For instance, intrinsic evaluation using word vector analogies has highlighted gender, racial and religion-based biases in word embeddings trained using Google News or Reddit corpora.¹²

Often in the context of NLP methods, intrinsic evaluation tasks judge the similarity or relatedness of pre-selected word pairs. Semantic relatedness or semantic similarity based upon human judgment is often computed as a correlation coefficient by comparing aggregate human assessed scores to similarity metrics, such as cosine similarity, using word vectors. The models in greater agreement to human judgment are considered better models.³–⁵ By contrast, extrinsic evaluation relates to the effect of word embedding input features on the performance of downstream tasks, such as document classification.⁶

Existing clinical benchmarks comparing similarity or relatedness of clinical concepts include Hliaoutakis’ work, MayoSRS, original and modified UMNSRS.⁶–¹⁰ The concept pairs that comprise each of these benchmarks were manually curated by a physician from existing medical ontologies, such as Medical Subject Headings (MeSH) or Unified Medical Language System (UMLS). To assess human judgment of concept pair similarity or relatedness, the researchers conducted surveys of medical coders or clinicians. These benchmarks are publicly available and have been used by others to study the effects of different training corpora or other training strategies.¹⁰–¹³ Importantly, these were created before word2vec and subsequent non-contextual word embedding (NCWEs) models were introduced.

In the general NLP domain, additional intrinsic evaluation tasks have been proposed. The use of pre-specified analogies is a popular approach for intrinsic evaluation of embedding models.¹⁴–¹⁵ Schnabel et al. proposed the comparative intrinsic evaluation task and also recommend other methods for intrinsic evaluation of word embedding models: relatedness, analogy, categorization and selectional preference.¹⁵ Ye and Fabbri use a similar design to the comparative intrinsic evaluation task for clinical NLP assessment.¹⁶

Contextual word embedding (CWE) models, such as BERT, use a different training objective than NCWEs. Specifically, BERT-based models include a masked-language modeling (MLM) pre-training strategy.¹⁵ Given the different training objective of CWEs, Devlin suggests that these models may not provide meaningful cosine similarity measurements.¹⁶ Researchers have proposed intrinsic evaluation tasks in keeping with the BERT modeling approach.
Goldberg and Ettinger respectively evaluate BERT models using previously published cloze (‘fill-in-the-blank’) tasks and compare the ‘gold-standard’ masked word with BERT word predictions.

Few available clinical NLP benchmarks for CWEs exist. The Biomedical Language Understanding Evaluation (BLUE) benchmark contains 5 extrinsic evaluation tasks: sentence similarity, named entity recognition, relation extraction, document classification and inference. We were unable to find any publicly available intrinsic evaluation tasks designed to examine CWEs for the clinical or biomedical domains.

Here, we present our work on the development of intrinsic evaluation tasks for NCWEs and CWEs from a radiology report corpus. We then use these tasks to study the agreement between clinician judgment and embedding models trained using different algorithms or training corpora.

**Methods**

**Study Cohort/Corpus:** We curated a corpus of radiology reports from the Vanderbilt University Medical Center (VUMC) Research Derivative, an extract of the electronic health record from legacy and Epic record data, normalized to the OMOP common data model. We selected only those radiology reports with study descriptions corresponding to computed tomography (CT) scans inclusive of the chest. Report collection was limited to those for patients 18 years of age or older. This study was approved by the VUMC Institutional Review Board.

Text from the publicly available Fleischner Glossary of Terms for Thoracic Imaging was also collected to represent a corpus containing terms more relevant within radiology reports.

![Algorithm for data-driven generation of term pairs from a radiology report corpus using custom non-contextual embedding models.](image)

**Figure 1:** Algorithm for data-driven generation of term pairs from a radiology report corpus using custom non-contextual embedding models.
**Pre-processing:** Pre-processing of the raw clinical text included removal of unicode characters and HTML parsing to plain text using the Beautiful Soup library. We concatenated hyphenated terms by converting '-' characters to '\-', e.g. ‘status-post’ was converted to ‘status_post.’ We also scrubbed dates and times, age, medical record numbers, email addresses, phone numbers, social security numbers and location information. Methods for de-identification included custom regular expressions, the spaCy library tokenizer and our own customizations to the presidio Python package. We also used spaCy for text tokenization using the provided blank English model. Stop words for our radiology report corpus were not excluded. We pre-processed text from the Fleischner glossary using the same process above except that we also performed stop word exclusion using the spaCy English stop word vocabulary.

**Custom NCWEs:** We used the gensim library implementations of the word2vec and fastText models. Spherical embedding models were created using the source code provided by the authors. Each of our word2vec and fastText models were trained using the skip-gram method. We used similar training parameters for each of our custom embedding models: fixed dimension of 200, initial learning rate of 0.025, context window of 5, excluded words occurring fewer than 5 times, sampling threshold of 0.001, negative sampling rate of 5 and trained for 10 epochs.

**Public NCWEs:** We used BioWordVec, which is a 200-dimensional fastText model trained using both a PubMed corpus and text from the Medical Information Mart for Intensive Care (MIMIC-III) dataset and made available by the authors. Additionally, we used a publicly available gensim word2vec model trained using the skip-gram method on the English Wikipedia corpus (February 2017) obtained from the University of Oslo’s Nordic Language Processing Laboratory word vector repository. We also used a spherical embedding model trained on the English Wikipedia corpus provided by Meng et al.

**Custom CWEs:** The pre-processed text of our radiology report corpus was exported to a txt file with each document per line. We used the transformers library to create a custom tokenizer and for pre-training on our radiology report corpus. For training our custom model, we used the same configuration parameters as the original BERT model. Pre-training our custom model took approximately 2.5 days using 2 12GB GPUs.

**Public CWEs:** We compare our custom BERT-based model to the original BERT model and a publicly available BERT-based model pre-trained using a PubMed and MIMIC-III corpus, BlueBERT. Each of these models was downloaded from the HuggingFace Models repository.

**Term pair selection:** We compared the pre-processed Fleischner Society Glossary tokens with the vocabulary of each of our 6 NCWE models. We retained only those terms shared between the Fleischner Society Glossary that were present in all 6 embedding vocabularies. The resulting 1,059 shared terms (‘query words’) were manually reviewed by a physician (MSK), and a subset of these terms (326 terms) were manually selected for possible inclusion in our survey. For each of the 326 query words, we randomly select the $k$th most similar term using each of our 3 custom embeddings, where $k \in \{1, 5, 50\}$. This method was adapted from Schnabel et al. As the examples in Table 1 show, for each query word, we retrieved 3 candidate terms. One of these three was then selected to construct a term pair. A physician (MSK) then manually reviewed the three candidate terms, i.e. the $k$th most similar term to the query word for each of our custom embedding models. For each of our 326 query words, if 2 or 3 of the embedding generated candidate terms were similar, we selected this term to form a term pair. If all 3 of the proposed candidate terms was different, a candidate term was arbitrarily selected by MSK. As we used our custom embeddings to generate term pairs, some of the selected terms for each query word were not present in the publicly available embeddings. For accurate comparison and generation of correlation coefficients, we excluded those term pairs where the word was not present in each of the 6 embeddings being evaluated.

**Table 1:** Example use of the $k$th most similar term from custom embeddings to inform term pair creation.

**Cloze Task generation:** A physician (MSK) selected a random subset of radiology reports, from which representative
selections of text were extracted and modified to reflect commonly seen radiographic descriptions and findings. A total of 20 cloze prompts were created for use in the survey. Each cloze task prompt was 1-3 sentences in length to provide sufficient context for human and models to identify the masked term. BERT-based models use WordPiece tokenization, which may generate sub-words. Accurate comparison between the CWEs requires that the masked word be present in its complete word form as a token within each model’s vocabulary, i.e. not as a subword. To assess this, each cloze task prompt was tokenized with each of the 3 BERT-based models being studied using the transformers library. Only overlapping complete word forms from each model were selected for masking.

Survey administration: We created and administered a survey of our 281 term pairs and 20 cloze task prompts using the Research Electronic Data Capture (REDCap) tool hosted at VUMC. A convenience sample of 15 healthcare students or professionals were asked to participate in the survey. The instructions provided to participants was adapted from another concept similarity survey, WordSim353. Study data were collected and managed in REDCap.

Human judgment of term pair similarity was assessed using a 7-point Likert scale. For the cloze task portion, survey participants were asked to enter only a single word for each prompt for accurate comparison to BERT-based models because these models have single word vocabularies.

Survey Analysis: Upon completion, survey results were analyzed using R (version 4.0.3). For each term pair, the mean and standard deviation was calculated. Pearson and Spearman correlation coefficient values were calculated with the gensim library using the mean values from our survey and cosine similarity for each NCWE. We also calculate Pearson and Spearman correlation coefficients using the original and modified versions of the UMNSRS-similarity and UMNSRS-relatedness benchmarks introduced above. If either concept in a concept pair was not present in the embedding model vocabulary, that concept pair was not used to calculate the correlation coefficient.

To evaluate CWE models, we composed 20 fill-in-the-blank prompts that reflect text that may appear in a CT chest radiology report, e.g. “Infiltrate in the right middle lobe is seen concerning for ____.” To assess human judgment, survey participants were asked to input free-text for what they determined to be the most likely single word. Survey results were manually reviewed and tabulated to construct a list of the words provided for each cloze task prompt ordered by frequency. Each of our CWE models were then used to also predict the expected word for each cloze task. For word prediction accuracy, we designate the word entered with the highest frequency from our survey as the “expected” word. Accuracy was defined as the percentage of items for which the “expected” word is among the CWE model’s top $k$ predictions for $k \in \{1, 5\}$. We then compared the accuracy for each of our CWEs. We use the transformers library to find the top $k$ predicted words by also providing special tokens as detailed by Goldberg.

Results
Our corpus contained 479,850 documents and comprised a total of 124,892,727 tokens. These documents included other associated clinical documents, including critical result messages. For the NCWEs, our custom models developed using the word2vec and fastText methods each had a vocabulary of 51,002 words, whereas our custom spherical embedding model vocabulary comprised 51,126 words.

Comparison to Fleischner glossary: Using exact matching, the overlap between each of our 3 custom embedding models and words from the Fleischner glossary was 1,207 distinct words. The intersection between the Fleischner glossary vocabulary and BioWordVec, word2vec (Wikipedia) and spherical embedding (Wikipedia) models was 1,272, 1,138 and 1,124 words, respectively. The overlap of all of the embedding model vocabularies with the Fleischner glossary yielded a shared 1,059 words (Figure [1]).

NCWE similarity: The cosine similarity distribution using our term pair selection approach returned an approximately normal distribution for our custom word2vec and fastText models and BioWordVec centered near 0.5. Our custom spherical embedding model and the public models trained using an English Wikipedia corpus were skewed (Figure [2]).

Survey participant characteristics: We had a total of 13 participants who completed the survey. Of these 13, 9 identified as attending physicians. The remaining identified as a medical student (1), resident (1), fellow (1), nurse (1) and advanced practice provider (1). Clinical background for the resident, fellow and attending physicians included anesthesiology (1), emergency medicine (1), family medicine (1), internal medicine (5) and radiology (1). The number of years in practice post-residency for the fellow and attending physicians was a median of 3 years. Participants
reported currently practicing or training in different regions within the US: Northeast (1), Midwest (7), South (4) and West (1).

**Term pair similarity:** The computed Pearson correlation coefficient ($\rho_p$) and Spearman correlation coefficient ($\rho_s$) values comparing mean survey similarity scores to cosine similarity for each model are shown in Table 2. Of each of the 6 models studied, BioWordVec provided the highest $\rho_p$ and $\rho_s$ of 0.60 and 0.61, respectively. Among the embedding models trained using our radiology corpus, the word2vec model yielded the lowest correlation between human and model similarity scores ($\rho_p$, 0.34; $\rho_s$, 0.35). $\rho_p$ and $\rho_s$ values from our custom fastText were 0.40 and 0.41; for our spherical embedding model, $\rho_p$ and $\rho_s$ were calculated as 0.40 and 0.44, respectively. For the English Wikipedia trained word2vec model, $\rho_p$ and $\rho_s$ were 0.31 and 0.32, respectively; the spherical embedding Wikipedia model returned a $\rho_p$ of 0.26 and $\rho_s$ of 0.27.

Discussion
Our term pair creation approach yields a near normal distribution of cosine similarity scores for our custom word2vec and fastText models and the BioWordVvec model. This supports the ability of our approach to capture a normally distributed breadth of similarity scores using word2vec or fastText models trained on biomedical text. We also find that models trained using an English Wikipedia corpus are right skewed in Fig. 2. Additionally, these models consistently performed least well in relation to those models trained using a domain-specific corpus on the RadSim 281, original UMNSRS and modified UMNSRS term similarity benchmarks. These findings suggest poor agreement between models trained using general corpora and clinical judgment.

To our knowledge, our analysis is the first to use spherical embeddings trained using clinical text documents. In contrast to the excellent performance of spherical embeddings reported on general NLP text similarity benchmarks, we find that spherical embeddings often performed less well than other models (Table 2 and 3). The only exception being
that our custom spherical embedding model performed better than our custom word2vec model and at least as well as our custom fastText model on RadSim281. The spherical embedding model proposed by Meng et al. uses directional similarity and jointly learns word and paragraph embeddings. This has been shown to provide improved word similarity and document clustering over other text embedding methods by leveraging both word-word and word-paragraph co-occurrence information. Relative to other text documents, clinical text often contains disparate information in neighboring paragraphs, and this may be an ill-suited substrate for this training strategy. This may cause the model to consider truly dissimilar words as being somewhat similar and may explain the left skew of cosine similarity scores from our spherical embedding model relative to the other 5 models as shown in Fig. 2. Additional study is required to attempt to replicate the benefits of spherical embedding models for document clustering or document classification in the clinical domain.

Among our custom NCWE models, we find that our fastText model performed about as well as our spherical embedding model on RadSim281 (Table 2) and achieves the highest $\rho_p$ and $\rho_s$ on the original and modified UMNSRS benchmarks (Table 3). One of the primary benefits of fastText embedding models is that each word can be represented as a bag of character $n$-grams, which gives these models the ability to handle out-of-vocabulary words. Bojanowski et al. assess the correlation between human judgment and cosine similarity comparing word2vec and fastText models with and without sub-word information using 10 different benchmarks covering 7 different languages. Similar to our own findings, they found that fastText models tend to outperform word2vec models on most term pair similarity benchmarks including the English Rare Word dataset.

We report both Pearson and Spearman correlation coefficients for comparison to earlier studies, some of which provide only the $\rho_p$ and others only the $\rho_s$. The originally proposed BioWordVec fastText model was trained using PubMed and Medical Subject Headings (MeSH). We use the publicly available BioWordVec model trained on PubMed and MIMIC-III corpora. On the UMNSRS benchmarks, we find similar, but slightly lower, $\rho_p$ and $\rho_s$ values compared to the published values (Table 3). Pakhomov et al. evaluate performance on the modified UMNSRS benchmarks using a continuous bag of words (CBOW) word2vec model. Results of their analyses using different training corpora in comparison to our own are shown in Table 2. Our findings for $\rho_s$ using our skip-gram word2vec model and the spherical embedding model trained using an English Wikipedia corpus are much lower on both the UMNSRS-similarity and UMNSRS-relatedness benchmarks compared to their findings (Table 3). Yet, our results from the BioWordVec model are comparable to the $\rho_s$ values they computed using model trained on a PubMed corpus. Although we used the skip-gram training approach and they used the CBOW method, others have found that the skip-gram method provides better or equivalent performance on the UMNSRS benchmarks. This discrepancy is less likely explained by the use of the skip-gram modeling technique instead of CBOW. For models trained on our radiology report corpus or Wikipedia, we were unable to account for one or both concepts for approximately 50% of the modified UMNSRS concept pairs (Table 3). Given that half of these embedding vocabularies are not adequately represented among the concept pairs, our results are likely suffering from bias. This highlights that intrinsic evaluation performance can suffer if a large proportion of the term pair vocabulary is not present within the embedding vocabulary. This discrepancy may also reflect sensitivity of term pair similarity on training parameter selection between the studies. Prior studies show a tradeoff between intrinsic and extrinsic evaluation based upon hyperparameter choice. Chiu et al. find that larger context windows lead to gains in intrinsic evaluation measures with decreased performance on certain downstream tasks. Thus, one must be aware of this and select parameters best suited for the desired objective.

NCWE models can also be augmented with knowledge-based graphs and have been shown to lead to better representations. We attempted to enrich our embedding models using the RadLex ontology, but were met with little success as we found limited RadLex term coverage in our corpus, which is a challenge noted previously. This difficulty may be offset with expansion of the RadLex terminology or by using other existing ontologies that provide improved term coverage.

To our knowledge, this is the first attempt in clinical NLP towards developing intrinsic evaluation benchmarks for CWEs. We find that the original BERT model performs poorly on cloze tasks that reflect radiology report text. We also show equivalent top-1 and top-5 cloze task accuracy between BlueBERT and our custom BERT model (Table 5). These findings appear to suggest that the publicly available BlueBERT model pre-trained using the PubMed and MIMIC-III corpora perform well even in comparison to a model pre-trained using a targeted domain corpus of radiology reports.
from which the cloze task prompts were established. Further study of the generalizability of BlueBERT on other intrinsic evaluation tasks is required. The implication of a generalizable clinical BERT-based model may mitigate the need to pre-train custom BERT-based models for different clinical purposes. This becomes especially important given the sizable financial and environmental costs incurred by language model training. One of the limitations of the BlueBERT model is that it uses the original BERT model vocabulary, rather than training a custom tokenizer using the PubMed and MIMIC-III corpora. BERT-based models can only accept a maximum sequence input length of 512 tokens. Many clinical terms are not present within the original BERT vocabulary and are thus tokenized to subwords for model input. This restricts the number of words that may be used as input for the BlueBERT model, whereas a custom tokenizer would have helped mitigate this issue to some degree.

It remains unclear if a tradeoff between intrinsic and extrinsic evaluation performance exists for CWEs as is reported in NCWEs. Moreover, further study is required to determine if and to what degree the differences in cloze task performance persist after model fine-tuning.

Few, if any, benchmarks exist for intrinsic evaluation of CWE and NCWE models in the clinical domain. Given the potential impact these and other models may have on medical decision making, it is vital to probe models to identify potential flaws and biases. Furthermore, we must be cognizant of existing biases inherent within the clinical data used to train these models. If our models encode biased representations, their deployment may propagate these biases forward and maintain or exacerbate existing healthcare disparities. Probing of models trained on general corpora using intrinsic evaluation methods have unearthed gender, racial and religious biases. With limited model probing tasks within clinical NLP, we contend that this area requires further study especially given the evidence of racial and other disparities present within clinical documentation, management and outcomes. Moreover, while models trained using the MIMIC-III corpus (BioWordVec and BlueBERT) perform admirably, these documents primarily reflect an intensive care patient population and may present an additional source of bias worth consideration.

Among this study’s limitations is that we restricted intrinsic evaluation tasks for NCWE and CWE models to single words. Future studies may use methods to generate multi-word terms while still allowing for comparison within the embedding space. Moreover, our term pair generating method excluded term pairs that were not present in all of the embedding vocabularies. Most terms were excluded because they were not in the NCWE vocabularies trained on a Wikipedia corpus. This design choice may have biased our term pair selection away from relevant medical terms and towards common English words. Another limitation is that our radiology report corpus was primarily limited to CT scans inclusive of the chest. One may find improved results using a corpus of radiology reports from all imaging modalities. Likewise, our corpus was curated from a single academic medical center, which limits the size of our corpus and influences the conditions and findings identified in reports to those found within the region.

Conclusion
Our work introduces two new intrinsic evaluation methods for use among clinical NLP researchers: term pair similarity to compare NCWEs and cloze task accuracy for CWE models. For NCWEs trained on a domain-specific corpus, our results highlight that fastText models tend to outperform word2vec and spherical embedding models. We also demonstrate that the gains afforded by spherical embedding models in general NLP intrinsic evaluation tasks fail to translate to the clinical domain. This emphasizes the need for caution and rigorous evaluation prior to adoption of methods that may excel in general NLP tasks. Importantly, we find that embedding models trained using PubMed and MIMIC-III corpora - BioWordVec and BlueBERT - perform at least as well and often better than models trained on a targeted domain corpus on intrinsic evaluation tasks. This provides additional evidence in support of these biomedical corpora capturing word representations in agreement with clinician judgment. Further study is needed to the establish additional benchmarks and probing tasks. These will help to facilitate language model evaluation to assess for potential biases and determine agreement with clinician judgment. Such analyses are necessary to engender trust and promote understanding of NLP models for broader clinical adoption.

Abstract

Advancing diagnostic testing capabilities such as clinical next generation sequencing methods offer the potential to diagnose, risk stratify, and guide specialized treatment, but must be balanced against the escalating costs of healthcare to identify patient cases most likely to benefit from them. Heme-STAMP (Stanford Actionable Mutation Panel for Hematopoietic and Lymphoid Malignancies) is one such next generation sequencing test. Our objective is to assess how well Heme-STAMP pathological variants can be predicted given electronic health records data available at the time of test ordering. The model demonstrated AUROC 0.74 (95% CI: [0.72, 0.76]) with 99% negative predictive value at 6% specificity. A benchmark for comparison is the prevalence of positive results in the dataset at 58.7%. Identifying patients with very low or very high predicted probabilities of finding actionable mutations (positive result) could guide more precise high-value selection of patient cases to test.

Introduction

Next generation sequencing (NGS) has revolutionized research in the biological sciences and has expanded the type of medical care we can provide. NGS based testing has made it possible to detect disorders in their early stages and has opened the gateway towards precision medicine¹. Ideally, such tests can be used frequently for early detection of a disorder and utilized to personalize as much of the disease management process as possible. However, with rising healthcare costs and the already overburdened healthcare system, physicians must and are striving to limit ordering to only when they are at a decision point and believe the outcome of the test will strongly affect the path they choose to go down. However, there is often too little information or too much information to synthesize when the decision has to be made. This is only further exacerbated when these tests are utilized for highly specialized clinical scenarios as is the case with the Heme-STAMP. Heme-STAMP (Stanford Actionable Mutation Panel for Hematopoietic and Lymphoid Malignancies) is a next generation sequencing based test panel. Hematopathologist often utilize Heme-STAMP for diagnostic purposes when there are hematolymphoid process where clinical, histologic, immunophenotypic, and sometimes cytogenic (FISH) information is insufficient to either render a diagnosis of malignancy, or to subtype it in a manner that is useful for sufficiently personalized clinical management. It is also used to map the progression of such disease states and to evaluate if identified laboratory abnormalities (such as cytopenias) are potentially due to hematological malignancies or something else. And is also commonly used to monitor the progression of a disease state (Figure 1). Heme-STAMP uses PCR or hybridization-based DNA capture methods alongside a “targeted sequencing” approach to detect recurrent gene fusions and to screen somatic mutation hotspots of cancer genes².
Given that there are a number of factors considered when determining whether to order a Heme-Stamp test, the objective of this study is to assess how well Heme-Stamp pathological variants can be predicted given electronic health records data. An accurate prediction could add the same level of informational value to care management while saving the cost of running an actual test. Because in many cases the value of the Heme-Stamp test lies in uncovering pathogenic variants, it is likely that a negative prediction will add value to the care management process while reducing the need to have the actual test ordered. A positive prediction by contrast may support the need to order the test in order to identify the specific pathogenic variants and their variant allele frequencies. Given that a negative prediction could result in not ordering the test, an inaccurate prediction might mean that a disease could bypass detection and thus progress. Because of the weight of this consequence, the negative labels were evaluated closely.

Methods

Data. A total of 2,026 Heme-Stamp clinical test results completed between June 2018 and 2020 were used. These samples were drawn from 1,743 Stanford Healthcare patients. Of these patients, 192 patients had multiple tests run over the roughly two-year period. The maximum number of tests run on a single patient was six, but the majority of these multi-test-patients (96%) had four or less tests run. Every sample in the dataset corresponds to a unique specimen. Tests for ctDNA and MRD panels were not included. All specimens underwent a routine sample quality assessment before reporting. Specimens that failed clinical quality control criteria were not included in the dataset.

These Heme-Stamp clinical test results were retrospectively combined with their respective electronic health record data from Stanford Medicine Research Data Repository (STARR)\(^3\). Patient features included prescribed medications, lab values of diagnostic tests, past diagnoses, demographics, and family medical history. Heme-Stamp results were overall categorized as “positive” if a pathogenic mutation was found at a variant allele frequency of \(\geq 5\%\) and “negative” if no pathogenic mutations were found at that variant allele frequency or if the only mutations found were variants of unknown significance (VUS).

The prevalence and rate of negative results of certain diagnoses and sample types were of particular interest. As described earlier, when clinicians order the Heme-Stamp test they may have an existing diagnosis that they want to further subclassify (or check the progression of) or they may have a suspected diagnosis that the Heme-Stamp would be used to verify. Leukemia and Myelodysplastic Syndrome (MDS) are the common hematological malignancies that the clinicians are trying to monitor or evaluate as demonstrated in Figure 2. Respectively, we categorized patient populations into those with a known diagnosis of leukemia (but not of MDS), diagnosis of MDS (but not of leukemia), diagnosis of both MDS and leukemia, or no diagnosis of either disease. Patient history of diagnosis of either disease was identified from free text diagnosis summaries stored in the EHR. Because of the variety of forms and stages of leukemia and MDS, we used regular expressions (such as “%leukemia\%” and “%MDS\%” in various abbreviations and upper/lower case variations) to parse the diagnosis descriptions to best encapsulate patients into their correct disease categorizations. To reflect their relevance in different clinical workflows, we included specimen sample type as a key categorical feature as well.

Predictors. Demographic information, past diagnoses, lab orders, prescribed medications, and family histories were
selected as indicator features that the model could use to predict positive or negative labels. The specific diagnoses, lab orders, prescribed medications, and family histories to use were found by selecting those that were most common among the patients in this study. These features were incorporated by indicating the presence or absence of the listed diagnoses, medications, and family histories using binary labels and by doing simple calculations to include derivatives of lab result values for each selected lab test. These derivatives were found by looking at the results of all past incidences of the specific lab test to find the minimum and maximum result values, the oldest and most recent result values, the average, the sum, and the slope across all the past lab result values. The feature values are summarized in Table 1.

**Model Development and Specification.** The primary model used was an XGBoost (eXtreme Gradient Boosting) classifier, using a gradient boosted decision tree algorithm. This means that the model builds and aggregates the results of multiple learned decision trees in an ensemble approach to make final predictions. Instead of allowing every tree to see the entire dataset, each tree only sees a subset of the training data so that each captures a different signal which can overall be combined to have a more finely tuned model. Additionally, each tree may use a different subset of features. The subset used for each decision tree may be chosen through random selection or based on some sort of metric such as accuracy, Gini index, entropy, etc. that results as a consequence of using different subsets of features. Trees are built sequentially so that each successive tree focuses on properly classifying the observations that were misclassified by the previous tree. The model has various hyperparameters that can be adjusted, prompting us to evaluate multiple combinations: learning rate (0.01, 0.03, 0.1), n_estimators (100, 300, 600, 1000), max_depth (3, 5, 10), and subsample (0.5, 0.75, 0.9). Ultimately the following hyperparameters yielded the best results:

- N_estimators = 300 (number of decision trees used in the ensemble)
- Learning_rate = 0.03 (multiplier for the contribution of each successive classifier in the ensemble)
- Max_depth=5 (maximum depth any decision tree is allowed to have)
- Subsample = 0.5 (fraction sampled from the total dataset to build each tree)

XGBoost and Random Forest both use a decision tree algorithm but differ in how they ensemble the decision trees used. As described earlier in the paper, XGBoost Classifiers build trees sequentially. Random Forest Classifiers on the other hand build trees independently and then average the results of all the trees at the end. To see if the unique ensemble approach of XGBoost contributed to model performance, we compared results to that of Random Forest. We trained a Scikit-Learn Random Forest classifier with the following hyperparameters: n_estimators = 300 and max_depth = 5.

We trained a simple logistic regression model from the Scikit-Learn library in order to compare performance from decision tree-based models to linear models and experimented with sample weights inputted to the XGBoost model. As described earlier in the paper, there is a greater interest in model performance on the negative values so XGBoost models with modified sample weights were tested. Positive values were kept at a weight of 1 but weights of 1.5 and
2.5 for the negative values were experimented with. This difference in weighting would translate to greater importance placed on negative labels during the model’s training/optimization process.

In some of our initial work, we also explored LASSO (a regularization-based model) and Support Vector Machine (a max margin classifier) but found their performance to be lacking so for the rest of the study we moved forward with only the decision tree algorithms and logistic regression model described above.

Model Evaluation. The prediction model was designed to output the pre-test probability of a positive Heme-STAMP result given all the available feature information. If the pre-test probability was greater than a certain threshold, a positive result was predicted, otherwise a negative test was predicted. The accuracy was generated based on a threshold of 0.5 but the AUROC was generated by identifying the threshold that yielded the best balance between the false positive rate and the true positive rate. The false positive rate (FPR) represents the probability that a truly negative result is predicted to be positive and the true positive rate (TPR), also known as recall or sensitivity, presents the probability that a truly positive result is predicted to be positive. The negative predictive value (NPV) and true negative rate (TNR) of these pre-test probabilities at various thresholds were used to generate the TNR vs. NPV graph. The NPV represents the probability that a predicted negative result truly is negative, and the TNR represents the probability that a truly negative result is predicted to be negative (i.e., specificity). The TPR and precision of these pre-test probabilities at different thresholds were also used to generate the Precision-Recall Curve. Precision represents the probability that a predicted positive result is truly positive (i.e., positive predictive value).

We used 10-fold stratified cross validation⁸ with shuffling to train and evaluate the model. For each of the 10 folds, the data was shuffled and then 90% was selected to be part of the training set and 10% to be part of the test set. The data was stratified so that each fold contained a class ratio similar to that of the overall dataset. This was to limit the amount of class imbalance in each fold. The training dataset was used by the model to explore and learn to differentiate between samples with positive and negative labels, indicating identification or lack thereof of a pathogenic variant by Heme-STAMP testing. The test dataset was used to evaluate the performance of the now trained model on new data.

Results

The model was tested on 2,026 Heme-STAMP clinical test results using the 10-fold stratified cross validation method described above. The top 5 features were age, leukemia diagnosis, myelofibrosis diagnosis, sex, and hypertension diagnosis. Table 2 compares the performance of the random baseline and the different models: Logistic Regression, Random Forest, XGBoost (weighted), and XGBoost (unweighted). The random baseline makes only positive predictions and as expected has an accuracy equivalent to the 59% prevalence of positive test results in the dataset. All the models demonstrate accuracy levels greater than the upper limit of the 95% confidence interval for the random baseline.

Table 2. Accuracy and AUROC with 95% Confidence Interval (C.I.) for different models and random selection
Figures 3 and 4 respectively demonstrate the Receiver Operating Characteristic Curve and Precision-Recall Curve for the XGBoost model with no weighting (each class is by default weighted the same and thus effectively has no weights).

Among the models experimented, the weighted XGBoost had closest performance to the unweighted XGBoost model (Table 2). The main intention of the weighted XGBoost model was to see if more heavily weighting negative labels would improve the model’s performance on negative samples. So, in Table 3, we compare the NPV/TNR values of the weighted and unweighted XGBoost models to see that the values are nearly identical. The uneven weighting seems to have had no effect on the model’s performance on the negative test results. Because the NPV/TNR results are so similar, only the NPV vs TNR plot for the unweighted XGBoost model is shown in Figure 4.

Table 2. NPV/TNR values of XGBoost weighted and unweighted models

The prevalence and rate of negative results of diagnosis categories and sample types described in the Data section of the paper are shown in Table 3. The unweighted XGBoost model performance on these subgroups is also shown in this table. To evaluate performance, the data samples corresponding to each subgroup was identified for each fold. The AUROC for each subset was found and then averaged over all ten folds to find the average AUROC and the 95% confidence interval.
Table 3. Prevalence of each subgroup in the total dataset (n = # samples), percentage of negative labels in each subgroup, and the AUROC plus the 95% confidence interval for each subgroup.

Figure 5 plots the top twenty features utilized by the unweighted XGBoost model relative to each other. A built-in feature weight function was used to identify the top twenty most important features based on the 300 decision trees fitted by the model (recall that the model was parameterized with n_estimator=300).

Discussion

Results and Implications. When a negative or positive result can be predicted with high accuracy, it is worth considering replacing the actual test with the predicted result since the outcomes are likely similar. And so in theory, the most high-yield diagnostic ordering strategy would be to only order tests where the predicted outcome is not able to be predicted with high accuracy. In the case of the Heme-STAMP, where it is not just the positive/negative outcome but rather the pathogenic variants detected by the test itself that matters, predicted positives should still be ordered as part of high-yield testing even if they’re predicted with high accuracy. This study sought to understand what types of features, models, and subgroups would demonstrate highest performance, especially among the negative labels. We found that the XGBoost model did best with AUROC 0.74 (95% CI: [0.72, 0.76]). Among the various subgroups, model performance was highest on the subgroup with no diagnosis of leukemia or MDS (AUROC 0.74 (95% CI: [0.71, 0.77])) and the subgroup whose specimen type was blood sample (AUROC 0.76 (95% CI: [0.73, 0.80])). And we were able to obtain 99% negative predictive value at 6% specificity.
**Interpretations.** In Table 2 we can see that XGBoost models (weighted and unweighted) boasted marked performance over the accuracy demonstrated by the random baseline. This shows that the model is indeed identifying patterns to make data-driven predictions. While the XGBoost models had higher accuracy than the Random Forest model, the AUROC confidence intervals greatly overlapped. This demonstrates that while XGBoost’s sequential ensemble method improved the overall accuracy of the model, this didn’t necessarily correlate to how well the model was able to differentiate between the positive and negative cases. Interestingly, while the Random Forest model had similar accuracy as the logistic regression model, all three decision-tree-based models (Random Forest, XGBoost weighted, XGBoost unweighted) had higher AUROC values than the logistic regression model did. This suggests that the ensemble tree approach is better than the linear model approach at distinguishing between classes and potentially that it takes an ensemble tree approach particularly with a sequential ensemble method to see accuracy improvement over that of a linear model.

Among the models experimented, the weighted XGBoost had closest performance to the unweighted XGBoost model (Table 2). The main intention of the weighted XGBoost model was to see if more heavily weighting negative labels would improve the model’s performance on negative samples. So, in Table 3, we compare the NPV/TNR values of the weighted and unweighted XGBoost models to see that the values are nearly identical. The uneven weighting seems to have had no effect on the model’s performance on the negative test results. Because the NPV/TNR results are so similar, only the NPV vs TNR plot for the unweighted XGBoost model is shown in Figure 4. Because the XGBoost models had the higher performance among the models but there was minimal difference between the weighted and unweighted XGBoost models, the unweighted XGBoost model was analyzed for the rest of the study.

Among cases where the physician ordered the Heme-STAMP so they could diagnose, subtype, or monitor a malignancy, leukemia and MDS were the most common such malignancies. However, we can see in Table 3 that they compose less than 50% of all the Heme-STAMP cases. Furthermore, the average negative rate across all subgroups with one or both of the malignancies is about 29% which is lower than the negative rate of the subgroup that has neither of those diagnoses. This is equivalent to saying that the average positive rate across all subgroups with one or both of the malignancies is much higher than that of the subgroup with neither diagnosis. This observation matches the clinical scenario because for patients with one or both of the malignancies, it is either known or highly likely that the patient still has the malignancy, and it is often the case that the Heme-STAMP is sought to further characterize the variants driving the malignancy. As described earlier in the paper, our model is focused on making accurate negative predictions, so it is encouraging to see that the model performance on the subgroup that has neither diagnosis and that also has the higher percentage of negative tests is closest to the overall model performance. Model performance on the subgroup with both diagnoses and on the “Other sample” subgroup is highly variable likely because of the small size of the subgroups.

In Figure 5 where we identify the top 20 features, we can see that aside from demographic information such as age and sex, biological markers such as diagnosis of leukemia and myelofibrosis were heavily utilized by the model. Both are diagnoses of hematological malignancies. Additionally, diagnoses of hypertension and thrombocytopenia indicate abnormalities with your blood circulation and blood work. Other hematological malignancies such as lymphoma and other labs related to abnormalities in blood work can be seen among these top 20 features. The model’s incorporation of these features that have clinical relevance provides assurance and credibility to the factors that the model is considering in its prediction.

**Case Reviews.** While we were able to reach high negative predictive values on the tests the model predicted to be negative, qualitative analysis of some of these patients highlighted some reasons why clinicians may still choose to order the test. In one such case, the clinician agreed the patient was very unlikely to have an actionable mutation, but the patient was very anxious and had the financial flexibility to take the test even if it was unlikely to be useful. In another case, the clinician had realized that the patient had a certain baseline mutation and wanted to use the Heme-STAMP to see if there were any other mutations that should be identified and used as a baseline to track changes in the patient’s condition. While some of these nuances may be grappled out free-text notes in the EHR, the complexity required to successfully do so would quickly outweigh the benefits. However, for most cases, a negative prediction from the model can actually lead to the same net information gain as an actual negative test without the cost of it. And even in nuanced cases, such as those listed above, the predicted result can still provide value to the clinician’s thought process and can serve as an additional piece of evidence to support their suggestions as they discuss various potential next step options with patients.
Even as we expand the use of NGS testing and reduce its cost, patients who do not have an established diagnosis, the population types of Next Generation Sequencing tests. Confidence will increase. As the number of Heme-Stamp tests ordered continues to increase, the number of patients for which we can prevent a low probability of having a negative result (i.e., patients with high probability of having a negative result) and thus potential candidates for testing exclusion. We identified patients that have very low probabilities of having a test outcome with an AUROC of 0.74 electronic health records data. We found that by using electronic health records data readily available by the time of the sample, we allowed the model to utilize an ensemble of a high number of estimators. We balanced the cost brought to training time by utilizing XGBoost instead of a different ensemble decision tree model because XGBoost has shown to run with better expediency than other, similar such models.

To mitigate the pitfalls of overfitting, the data was randomly split into a train/test set and the maximum depth of the trees and subsample ratios were kept low. Additionally, early stopping rounds were established so that during the training process the model needed to demonstrate improvement in its evaluation metric (used log loss) every 20 rounds to continue training. This helped to ensure that the model did not continue to fit the model once it had reached a plateau in performance. The literature has shown that implementing early stopping rounds helps to keep overfitting at bay. Due to the limitations in sample size, we allowed the model to utilize an ensemble of a high number of estimators. We balanced the cost brought to training time by utilizing XGBoost instead of a different ensemble decision tree model because XGBoost has shown to run with better expediency than other, similar such models.

Although sample quality and tumor content are routinely assessed before sequencing, the results may not always be accurately determined so the effect of poor sample quality on the number of negative sequencing results cannot be ruled out. However, the fact that the model can predict a subset of negative results with very high accuracy suggests that there are clinical factors characteristic to the patient’s health condition that can be learned from the electronic health record. If the majority of these negative results were due to poor sample quality, there would be no underlying factor that the model could learn from to thus make these predictions with such high accuracy.

Additionally, it is worth noting that algorithmic decision support systems such as the one described here should and can only be used to augment but never to replace clinical judgment. Only a well-trained physician can account for the complex clinical context for each individual patient. In the long-term, a combination of excellent education and data-driven tools will yield the best possible care for the greatest number of patients.

**Conclusion**

The objective of this paper was to see how well Heme-Stamp pathological variants could be predicted given electronic health records data. We found that by using electronic health records data readily available by the time of testing we could predict test outcome with an AUROC of 0.74 (95% CI: [0.72, 0.76]). Furthermore, we were able to identify patients that have very low probabilities of having a positive Heme-Stamp result (i.e., patients with high probability of having a negative result) and thus potential candidates for testing exclusion. These patients accounted for about 6% of all the negative tests but they could be predicted with 99% accuracy. As the number of Heme-Stamp tests ordered continues to increase, the number of patients for which we can prevent a low-yield test with high confidence will increase. This work also demonstrates promising potential to build similar prediction models for other types of Next Generation Sequencing tests. Additionally, because this predictive algorithm can also be used for patients who do not have an established diagnosis, the population it is able to provide value for will continue to grow even as we expand the use of NGS testing and reduce its cost.

Abstract

Deep brain stimulation is a complex movement disorder intervention that requires highly invasive brain surgery. Clinicians struggle to predict how patients will respond to this treatment. To address this problem, we are working toward developing a clinical tool to help neurologists predict deep brain stimulation response. We analyzed a cohort of 105 Parkinson’s patients who underwent deep brain stimulation at Vanderbilt University Medical Center. We developed binary and multicategory models for predicting likelihood of motor symptom reduction after undergoing deep brain stimulation. We compared the performances of our best models to predictions made by neurologist experts in movement disorders. The strongest binary classification model achieved a 10-fold cross validation AUC of 0.90, outperforming the best neurologist predictions (0.56). These results are promising for future clinical applications, though more work is necessary to validate these findings in a larger cohort and taking into consideration broader quality of life outcome measures.

Introduction

Parkinson’s disease (PD) is a relatively common movement disorder and affects 572 per 100,000 people worldwide.1 PD symptoms vary by patient and often include tremor, rigidity, stiffness, and trouble walking.2, 3 Deep brain stimulation (DBS) is a highly complex surgical intervention for PD and other movement disorders, such as essential tremor, and dystonia.2 DBS uses an implanted electric pulse generator to deliver electrical stimulation to specific areas in the brain that control movement.2 Successful electrode implantation and programming is highly complex and requires collaboration from several neurological and neurosurgical disciplines.4-6 Despite undergoing invasive surgery, many DBS patients do not experience an improvement in symptoms4-6 DBS may also worsen symptoms, such as those stemming from dementia7, and lead to adverse reactions, of both minor and major significance.8 Occasionally, additional invasive surgery is required to remove or replant the pulse generator.8

Researchers have identified many factors which affect PD progression and DBS responsiveness. Active lifestyles, caffeine consumption, and moderate alcohol consumption are associated with less severe PD symptoms.9 Conversely, family history, pesticide exposure, rural living, and well water drinking are associated with higher rates of PD onset.10 Interestingly, patients with left-sided symptoms experience less severe motor symptoms, while patients with right-sided symptoms experience less severe cognitive symptoms.11-13 Reduced volume of the brain region called the putamen is also associated with more severe PD progression.14 Strong DBS responsiveness (defined as reduction of symptoms post-DBS) is associated with higher responsiveness to treatment with levodopa, lower baseline tremor severity, and lower age.15 These associations are often contradicted and debated between studies,16-18 a fact which underscores the need for a better understanding of the factors influencing PD and DBS. These challenges and the risks of surgical implantation necessitate a better system for predicting DBS response so that weak responders can be screened out prior to surgery.

Machine learning (ML) is a computational method for identifying patterns in datasets, and has made a large impact in clinical settings from clinical decision support to surgical assistance.19 We are interested in applying ML to improve candidate evaluation and patient counselling prior to DBS. Habets et al. trained a logistic regression ML model to identify strong and weak responders to DBS within a population of 86 PD patients (AUC: 0.79).20 ML has also been used to improve DBS pulse generator programming and electrode placement.21, 22 In this study we build on existing PD, DBS, and ML research to construct a predictive model which distinguishes strong (likely to improve) and weak (unlikely to improve) responders to DBS. We incorporate a wide selection of preoperative variables informed by
clinically known and suspected relationships to PD and DBS. Preoperative variables are chosen to maximize the final model’s applicability to preoperative patient analysis. Finally, we compare our model to clinical specialists to validate its clinical relevance.

Table 1: Categorized overview of available data. Cells may represent multiple variable fields in the database. Not every variable shown is used in model training. Imaging volumes are reported for left and right areas (L/R).

Methods

Overview and Cohort

We analyzed health records from the Vanderbilt University Medical Center (VUMC) neurocognitive research database. We included a cohort of PD patients who underwent DBS at VUMC. We excluded any patients who had missing on-medication UPDRS III benchmarks before and after surgery. The final supervised-learning cohort contained 105 patients. Patients who did not meet the UPDRS III benchmark requirements for inclusion were reserved in a secondary cohort intended for applying semi-supervised learning. We engineered binary and multcategory target variables to distinguish strong and weak responders to DBS. Last, we trained binary and multcategory machine learning classification models to predict motor improvement. To assess clinical significance, we compared our models’ predictions with those of trained neurologists.

Variables and Data

Table 1 categorizes and summarizes the data available in the VUMC neurocognitive and movement disorders databases. From these databases we extracted preoperative demographic, medical, medication, imaging, and neurocognitive variables. Surgical settings were excluded from analysis, since they do not serve an informative role in deciding to undergo DBS.

This study also examines pre-to-post operative changes in neurocognitive function assessments. The neurocognitive assessments we analyzed include: the Parkinson’s Disease Questionnaire (PD-Q-39)\(^{23}\), the Unified Parkinson’s Disease Rating Scale (UPDRS)\(^{24}\), the Delis-Kaplan Executive Function System (DKEFS)\(^{25}\), the Wechsler Test of Adult Reading (WTAR)\(^{26}\), and the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS)\(^{27}\).

The PD-Q-39 is a 39-question survey which scores quality of life for PD patients.\(^{23}\) The UPDRS is a four-part test which scores non-motor experiences of daily living, motor experiences of daily living, motor examination, and motor complications.\(^{24}\) UPDRS section three (UPDRS III) quantifies motor function and is divided into body subregions.\(^{24}\) UPDRS III also includes body-area subscores, which quantify motor fluctuations in the right upper, right lower, left upper, left lower, right, left, and facial extremities. UPDRS III assessment is performed pre- and post-operation, and on and off medication. DKEFS is a broad set of tests which assess a variety of executive functioning areas, such as verbal fluency. WTAR is a cognitive test for assessing intelligence quotient in traumatic brain injury patients. RBANS assesses cognitive decline in several categories, such as naming, word list recall, and semantic fluency.

Feature Engineering

We defined the age (in years) of symptom onset to be the difference between date of birth and date of symptom onset, which was obtained from the patient during clinical evaluation. We defined pre-operation symptom duration (in years) to be the difference between age pre-operation and age of symptom onset. We defined strong DBS response as improvement (score decrease) in on-medication UPDRS III preop to postop. Weak DBS response is defined as
on-medication UPDRS III worsening (score increase) or staying the same. We did not consider cognitive changes, due to lack of benchmarking data. We also defined a multicategory operation success parameter, using three classes: UPDRS III worsened greater than 25%, UPDRS III improved greater than 20%, and UPDRS III change between 25% worse and 20% better. These class boundaries were chosen to divide the cohort into three evenly sized groups, and to differentiate between high and low magnitude of response with as few classes as possible.

Data Preprocessing and Feature Analysis

We preprocessed our data by imputing missing numeric variables (henceforth features) with each feature’s mean value. Missing boolean and categorical features were labeled with missing-indicators. Categorical features were one-hot encoded into boolean representations of each categorical option. Variance filtering was performed by robust-scaling the feature set and filtering out any features with variance below 0.03. We chose the robust-scaling method, which removes the median and scales to the interquartile range, because it produces boolean and numeric variances on a similar scale for even comparison. Select-K-Best filtering was performed by scaling the feature set to zero mean and unit variance (standard scaling) and choosing the features with the highest DBS-improvement correlation by Pearson’s Chi-squared test (figure 1). The number of features chosen was tuned for performance, and a value of 30 was determined to be optimal. Standard scaling was chosen because chi-squared scores are scaled relative to each feature and we wanted an even weighting of boolean and numeric features in the correlation analysis.

After variance and correlation filtering, we tuned the preprocessing pipeline alongside each predictive model through grid search parameters. The features selected above were fed into the preprocessing pipeline without scaling, so that the pre-classifier scaling method could be tuned as a hyperparameter. We considered standard scaling, minimum-maximum scaling, robust scaling, and no-scaling as preprocessing options. Next, we applied the Synthetic Minority Oversampling Technique to generate 21 synthetic observations of the minority class (weak DBS-response) for an even class balance (63 in each class). The oversampling step’s k-neighbors parameter was tuned within the model grid search. Due to low data quantity (n=105), conjugate undersampling of the majority class was not applied in this study. Last, we considered dimensionality reduction via linear and kernel principal component analysis.

Binary Classification

We trained and compared several supervised and semi-supervised binary classifiers. We trained four model types well studied in the clinical domain, including support vector, logistic regression, k-neighbors, and random forest classifiers. We also trained conjugate semi-supervised classifiers via pseudo-labeling on the reserved semi-supervised cohort. Pseudo-labeling is a technique which uses a trained supervised classifier to predict targets on unlabeled data, so that the newly labeled data can be used to retrain a more generalizable model. The proportion of labelled to pseudo-labeled data used was 10:1; thus 11 additional patients were sampled from the semi-supervised cohort for pseudo-labeling.

Models and preprocessing pipelines were analyzed via grid search with cross validation test scores averaged across 10 stratified hold-out testing folds. Standard deviation across the testing folds was also collected for each metric. Binary metrics included the receiver operating characteristic area under the curve (AUC), accuracy, precision, and recall. The best model was selected to maximize mean cross-validation test AUC.

Multicategory Classification

We trained the same supervised and semi-supervised models as before, but as multiclass predictors. Models were analyzed with cross validation test scores averaged across 10 stratified testing folds. Standard deviation across the testing folds was also collected for each metric. AUC is poorly defined in multiclass problems, so we instead relied primarily on f1-score and mean-squared-error to evaluate the multiclass models. We also evaluated precision and recall scores. F1, precision, and recall scores were macro-averaged across the three classes. The best model was selected to maximize mean f1-macro.

Clinical Performance Comparison

With the goal of deploying a clinical model to reduce the risk of poor outcomes in DBS candidates, we compared the performances of our best models with trained movement disorder experts. Two board certified neurologists reviewed the patients and training features analyzed in this study to predict whether each patient’s motor function would improve after DBS. The neurologists made both a binary (will they improve: yes/no) and multicategory (in which range will they improve) prediction for each patient. The most accurate predictions from both neurologists were combined to form a neurologist-best-case prediction set.
We compared binary AUC, accuracy, recall, precision, and kappa scores, along with multiclass f1, mean squared error, precision, and recall scores. Metrics were averaged across 10 stratified held-out cross validation test sets. Multiclass metrics were macro-averaged between classes.

Additional Statistical Analyses

Two board-certified neurologists reviewed the results of our analyses to identify features of interest for further study. Features of interest were explored with two-sample independent t-tests, allowing unequal variances to make as few assumptions about the data as possible. From these t-tests we obtained 95% confidence intervals for the true differences in mean measures between groups, as well as p-value estimates of statistical significance.

Results

Summary Statistics

1,893 (64.5%) of 2,935 total patient records in our database were diagnosed with PD. Of those with PD, 105 (3.58%) patients had records of both pre- and post-operative UPDRS III scores. Table 2 summarizes demographic data of our final cohort. Most study participants were male (69.5%) and white (91.4%). Black, Hispanic, and Asian participants made up 4.8% of study participants. 27.6% of the cohort were prescribed anxiolytics, and 38.1% of the cohort were prescribed anti-depressants.

Feature Analysis

Figure 1 depicts the top-30 features by Person’s chi-squared correlation with motor improvement. Preop total and extremity tremor scores were highly correlated with DBS response. Also highly correlated were left putamen volume, symptom side, race, and histories of cardiac, psychiatric, and diabetic complications (figure 1).

Table 3 describes the differences in variable ranges between the weak and strong response groups. Strong DBS responders were lower in median levodopa equivalent prescription range, but were higher in median left putamen volume, UPDRS III (on and off) scores, and WTAR scores (table 3, figure 2).

Table 2: Select summary statistics of count and percent of final cohort.

Figure 1: Bar graph representing the top-30 features, ranked by chi-squared correlation with improved UPDRS III score. The column variance is listed above each column. Features with zero variance are ignored. The white column text shows the calculated p value for the feature.
Independent two-sample t-tests allowing unequal variances found statistically significant differences in mean left putamen volume, UPDRS III off-medication score, UPDRS III on-medication score, and WTAR score between weak and strong DBS responders (p<0.01, 0.05, 0.01, 0.01, respectively). From these tests we are 95% confident that the true difference in feature means lay between 244 and 926 mm$^3$, 0.4 and 8.4, 3.8 and 11.0, and 0.0 and 12.4, respectively, between response groups. Figure 2 shows a boxplot comparing left putamen volume between DBS response groups.

Figure 3 shows boxplot comparisons of UPDRS III change post-DBS vs race, symptom side, and psychiatric status. All three African American patients showed weak responses to DBS. A two-sample t-test allowing unequal variances found a statistically significant difference in mean UPDRS III improvement for white and black patients (p<0.01). From this test we are 95% confidence that the true difference in mean UPDRS III improvement between these groups lays between 3.9 and 9.9 (white group with greater improvement).

Patients with left-sided symptoms averaged higher score improvements than those with right sided symptoms. A two-sample t-test allowing unequal variances found a statistically significant difference in mean UPDRS III improvement for these groups (p<0.02). From this test we are 95% confidence that the true difference in mean UPDRS III improvement between these groups lays between 2.9 and 20.0 (left-sided group with greater improvement).

### Table 3: Comparison of medians and interquartile ranges (IQR) of select features relative to strong and weak response groups. P values were obtained from two-sample t tests allowing unequal variances. Strong response is defined as a negative change (improvement) in UPDRS III score post-DBS. Weak response is defined as a positive or no change (worsening) in UPDRS III score post-DBS.

**Table 3**: Comparison of medians and interquartile ranges (IQR) of select features relative to strong and weak response groups. P values were obtained from two-sample t tests allowing unequal variances. Strong response is defined as a negative change (improvement) in UPDRS III score post-DBS. Weak response is defined as a positive or no change (worsening) in UPDRS III score post-DBS.

**Figure 2**: Boxplot of DBS outcome vs size of left putamen area in brain. Strong response is UPDRS III improvement (score decrease). Weak response is UPDRS III worsening (score increase).

**Figure 3**: Comparison of UPDRS III score improvement after DBS, grouped by race, symptom side, and psychiatric status. Positive improvements indicate strong DBS response. Negative improvements indicate weak DBS response.
Patients with untreated psychiatric conditions averaged lower improvements in UPDRS III score than those with treated psychiatric conditions. From our two-sample t-test we are 95% confident that the true difference in mean UPDRS III improvement between these groups lays between 1.1 and 10.6. However, we did not find sufficient evidence that there is a difference between these groups (p<0.2).

**Classification Results**

Table 4 shows the cross-validated performance metrics for our best optimized binary and multicategory models. The highest AUC binary model was a supervised support vector classifier (AUC 0.90). The multicategory model with the highest performance was a logistic regression with pseudo-labeling (f1-macro: 50.9, MSE: 0.68). Table 4 also compares our best performing models against the performance of the neurologists. The binary and multicategory models both outperformed the neurologists and neurologists-best-case (best-neurologist AUC: 0.560, best-neurologist f1-macro: 0.264). Table 5 compares the Cohen kappa agreement scores between the best binary model, neurologist A, neurologist B, and neurologist-best-case.

**Discussion**

In this study, we built, optimized, and analyzed eight machine learning models. Logistic regression and support vector classifiers seemed to produce the best fits to our data. Our models outperformed the clinical experts in a variety of performance metrics, suggesting that there may be a viable future for this type of tool in the clinic. The addition of imaging features in our analysis may have produced a significant performance improvement over similar studies which did not include them. In addition, we found several interesting outcome-correlations, including race, symptom-sidedness, psychiatric status, and putamen volume.
Our strongest binary classification model outperformed the trained neurologists. The strongest multiclassification classification model achieved lower performance, yet still outperformed the neurologists. In both cases, the neurologists achieved high recall scores, but low AUC and f1 scores, suggesting a tendency to overpredict strong DBS response (predicting ‘strong response’ for every patient in the binary case yields 100% recall). The low kappa interrater agreement scores between neurologists underscore the clinical difficulty in predicting DBS response. One possible explanation for the discrepancies between the neurologists is that they would not typically make predictions based on a binary indication of change in UPDRS III. Rather, neurologists consider a host of factors around motor fluctuations, medication responsiveness, and quality of life. Our study used a best-case agreement scheme to generate a set of the strongest predictions from our two board-certified neurologist-reviewers. Future analyses may benefit from an additional expert reviewer, as an odd number of reviewers would permit a majority-voting scheme to generate the best-case predictions.

Our best-fit binary model’s results rival those of previous ML studies in this arena. One major difference in our approach is the inclusion of imaging data into our predictor. Despite the performance improvement, imaging features are more difficult to obtain, and future end-users may prefer a tool which does not require them. These findings highlight the challenge of balancing performance with user-friendliness.

This study found a significant positive correlation between larger left putamen volumes and positive DBS response. Interestingly, other studies have noted decreased size and grey matter volume of the putamen in Parkinson’s and other neurodegenerative disorders. Further, research has shown that targeting the putamen with DBS improves motor fluctuations. It is possible that a larger putamen is easier to target with DBS, or that patients with larger putamen regions have less severe symptoms. The exact link is between DBS, tremor, and the putamen, is unknown but the limited research available suggests that a connection is probable. The differences observed in left and right putamen size significances may be due to differences in symptom-sidedness and/or surgical implant sidedness.

There was a strong correlation between race and DBS response. All three African American patients in this study experienced worsened motor symptoms. Additionally, one out of one Asian participant experienced worsened tremors. The small number of nonwhites in the study (5) makes it challenging to accurately analyze the impact of race on DBS response. Other research has indicated a lower prevalence of PD in African-Americans and Latinos, as compared with whites. These differences are believed not to be related to age, sex, income, insurance, or healthcare utilization, but rather biological or other differences. More longitudinal data are needed to thoroughly explore the interesting relationships between race and DBS response.

The difference in symptom sidedness and outcome may be related to differences observed in PD progression between symptom sidedness groups. Many studies have noted less severe cognitive symptoms in patients with right-sided symptoms and less severe motor symptoms in patients with left-sided symptoms. Our study noted motor outcome favorability for left-sided patients, which is consistent with the general observation of less severe motor outcomes in left-sided PD patients.

One limitation of our study is that we only included motor symptom scores (UPDRS III) as success benchmarks, while other studies have included broader features related to quality of life. For example, Habets et al. defined strong response relative to changes in UPDRS II, III, and IV. UPDRS II measures PD difficulties in daily life and UPDRS IV measures complications of therapy, while UPDRS III only measures motor fluctuation severity. Management of motor fluctuations is a major motivating factor in choosing to undergo DBS, so changes in their severity are a reasonable benchmark for DBS response. Further, we were able to gather a larger training cohort by only requiring UPDRS III measurements, which are more regularly recorded in our database. If we had access to more data, we would have liked to have included benchmarks from the PD-Q-39, UPDRS II, or UPDRS IV, which measure factors beyond motor symptoms in PD patients.
Another limitation of this study is the lack of an external validation test set. We chose not to withhold a final test set due to the small size of our dataset (N=105) which could easily become overfit if the sample size were further reduced. We validated our results with 10-fold stratified cross validation, providing an optimistic estimate of our model’s fit.

Conclusion

Our predictive model produced a clinically significant performance improvement. These results are very promising for the future of DBS candidate evaluation, counselling, and expectation-setting. More work is necessary to validate these findings in a larger cohort and taking into consideration broader quality of life outcome measures. However, if these models can be further refined and validated in larger cohorts, it may be possible to deploy such a tool in the clinical setting to better support DBS candidate counselling, evaluation, and expectation setting.

Trust and credibility of information sources related to COVID-19 among high-risk ethnically diverse adults at the onset of the New York City outbreak: A cross-sectional survey conducted via a community health portal

Abstract

In March 2020, days after New York shut down to mitigate the spread of COVID-19, we developed a cross-sectional, participant-administered electronic survey to explore how New Yorkers were impacted by and were responding to the ongoing crisis. A critical component of the survey was to assess how credible and trustworthy respondents found various information sources. To advertise and distribute the survey, we embedded an invitation to participate using a popup on the GetHealthyHeights.org website. GetHealthyHeights was designed using community-based participatory research for the medically-underserved, urban, and largely Latinx community of Washington Heights-Inwood, New York City. We received 321 responses from April through July 2020. Participant ages ranged from 25 to 87, and 25% were Latinx. Results showed that the choice of and trust in different COVID-19 information sources were observed to be significantly different across demographic variables, including gender, age, race, and chronic health conditions. In the domains of trust and information source credibility, designers should account for perspectives of diverse subgroups.

Introduction

Beginning in late 2019, a severe acute respiratory syndrome (COVID-19) began to rapidly spread across the globe, becoming an unprecedented public health crisis. While the COVID-19 impact was global, New York City (NYC) quickly became the pandemic’s epicenter. By mid-March, infection rates were five times higher than the rest of the county, with cases one-third of total confirmed US cases.¹ In an effort to contain the spread of COVID-19, the governor's office implemented extraordinary restrictions on businesses, schools, social gatherings, and use of public transportation. These restrictions were fundamentally the same behaviorally focused non-pharmaceutical interventions (NPIs) put into place during the 1918 pandemic ² ³, but unprecedented for the ethnic and diverse populations living and working in the NYC area with access to a multitude of information sources, the Internet and social media.

The novel COVID-19 pandemic has shone a spotlight on the importance of communication and, in particular the critical importance of citizen trust in the communicator. A review of 26 papers found that having a high level of trust in authorities and with communications received about the disease is associated with adherence to behaviors that could not be explained in terms of perceptions of risk, disease severity or coping appraisals.⁴ The uncertainty and constantly evolving science on COVID-19 has made health communication during the pandemic difficult, as it has resulted not only in a massive flow of health information, but also in rapidly changing, mixed and inconsistent messages.⁵ Trust in information sources has been shown to influence perceived severity, increase willingness to adopt behaviors such as physical distancing, and information seeking.⁶ ⁵, ⁷-⁹ Lack of trust in information sources has also been related to increased COVID-19 mortality.¹⁰ Patterns of anxiety resulting in compulsive behaviors such as binge shopping and hoarding have also been associated with lack of trust in information sources.¹¹

In this paper, we describe insights from a time sensitive cross-sectional survey conducted in April 2020 among high-risk ethnically diverse adults in NYC. A critical component of the survey was to assess how credibility and trustworthy respondents found various information sources of information. We present these findings here, as well as how credibility and trust were perceived differently by varying socio-demographic population characteristics.
Methods

Design and setting

In March 2020, days after New York shut down to mitigate the spread of COVID-19, we developed a cross-sectional, participant-administered electronic survey to explore how New Yorkers were impacted by and were responding to the ongoing crisis. Because the survey was intended to capture participants’ perceptions and experiences during the rapidly evolving emergency, we employed an open, voluntary-response sampling frame, which allowed us to administer the survey as quickly as possible. To advertise and distribute the survey, we embedded an invitation to participate on the GetHealthyHeights.org website. GetHealthyHeights was designed using community-based participatory research for the medically underserved, urban, and largely Latinx community of Washington Heights-Inwood, New York City (WAHI).12, 13 A pop-up on the website was added on April 9th, 2020, inviting respondents to share how the outbreak has affected their health and well-being. In addition, we emailed participants engaged in three community-based research studies on breast cancer prevention and the Database Shared Resource at Columbia University Irving Medical Center (CUIMC), inviting them to participate in the survey. This solicitation to CUIMC research participants was conducted to gain survey responses from community members at higher risk for COVID-19 complications due to co-morbidities compared to the general population. Finally, we emailed the listserv of the Columbia Community Partnership for Health, Columbia University’s community outreach organization that connects members of the WAHI community to health resources and research, with an invitation to participate in the survey. The survey took approximately fifteen minutes to complete, and respondents were not compensated for participating. The CUIMC Institutional Review Board approved the study procedures. Data were collected from April through July 2020.

Questionnaire

Sociocultural, healthcare utilization and demographic factors

We selected questions from the validated Flu Telephone Survey Template (FluTEST), which was designed to assess perceptions and behavior during an influenza pandemic.14 Information collected on demographics and background included age, sex, gender, racial/ethnic background, employment, and current medical conditions that could increase risk for susceptibility to and/or complications from COVID-19. In addition, we asked whether participants had been tested, were told by a healthcare provider or believed they had been infected with COVID-19, whether access to healthcare was interrupted, and whether they lost a job due to the pandemic.

Trust in information sources

We assessed credibility of information sources and trust in official agencies with 16 items. Participants were instructed to ‘indicate how credible you believe the below communicators are by selecting the options that best reflect your opinions’ about sources coming from the Federal Government (like the president or vice president), information coming from your governor (for example, Andrew Cuomo (New York) or Phil Murphy (New Jersey)), information coming from your mayor (for example, Bill de Blasio (New York City)) and information coming from scientists. For each source, participants were asked to indicate the degree to which the information source could be trusted, is accurate, tells the whole story, and is biased or one-sided. The responses included probably true, probably false, not sure and no opinion. Participants were also asked their opinions on the various sources from which they received information on COVID-19, including people they speak to daily, healthcare professionals (for example, your doctor, nurse, or pharmacist), official websites (like the Centers for Disease Control or the health department), other websites, social media, and television. Participants rated these sources with response options that included very helpful, somewhat helpful, somewhat unhelpful, very unhelpful and not sure.
Statistical Methods

Chi square tests (and fisher’s exact tests where appropriate) and students t-tests (or non-parametric alternatives such as the Wilcoxon rank-sum test where appropriate) were performed to test for any differences by co-morbidities, age, race, ethnicity and employment status. A p-value of less than 0.05 was considered to indicate statistical significance. Data analyses were performed using SAS 9.4 (SAS Institute).

Results

Participant Characteristics

Between April and July 2020, 321 people responded to the survey. Table 1 summarizes participant characteristics.

*To explore the impact of minority status in subsequent analyses, we dichotomized these variables into White/non-Hispanic (N=182, 66.91%) and Other to include other than White/non-Hispanic minority groups (N=90, 33.09%). Missing=49
Respondents ranged in age from 25 to 87 years old, with a mean age of 62. Twenty-five percent (25%) were Hispanic or Latino, and 82% were female. Around thirteen percent (13.5%) were not working and 36% were retired. Ninety one percent (91%) of lived in NYC or in areas commutable to NYC. All respondents reported having at least one chronic condition: 29% reported having cancer, 18% reporting mental illness and 17% reporting breathing disorders. Given that COVID-19 testing was mostly unavailable early in the pandemic, only 10% report that they were tested.

Sociodemographic Factors and Co-morbid Conditions Associated with Sources of COVID-19 Information Sources

Perceived helpfulness of information sources by sociodemographic and chronic health conditions is shown in Table 2. White/non-Hispanic participants were significantly more likely to rank ‘people I speak to daily’ as helpful compared to others. Younger participants, aged 18-45, ranked social media significantly more useful compared with older participants, whereas participants >65 ranked television as more useful compared with younger participants. Females were significantly more likely than males to rank social media and official websites and social media as helpful. With respect to chronic health conditions, respondents reporting conditions other than cancer, mental illness, breathing disorders or diabetes were significantly more likely to rank official websites more useful, and also more likely to be unsure of the usefulness of websites compared with respondents not reporting in this category.

Sociodemographic Factors and Co-morbid Conditions Associated with Trust of Information Sources of COVID-19

Participants’ perceptions of the credibility of information coming from the federal government and scientists are shown in tables 3 and 4. White/non-Hispanic participants valued information coming from the federal government and scientists differently than minority respondents. Few among both White/non-Hispanic and minority respondents responded true when asked if information coming from the federal government can be trusted (14.92% and 16.67% respectively). White/non-Hispanic respondents were significantly more likely to respond false when asked if information coming from the federal government can be trusted compared with minority groups (72.93% vs. 47.78% respectively). White/non-Hispanic respondents were also more likely to indicate that information coming from the federal government is inaccurate, biased, and does not tell the whole story. Minority groups were more likely to be unsure or have no opinion about the trustworthiness, accuracy, bias, and completeness of information from the federal government.

**Other Chronic Condition**

| Yes            | Prob True: 17  |
|                | Prob False: 15 | 0.005**    | 17 (20.00%)            | 17 (20.00%)            |  
| No             | Prob True: 20  |
|                | Prob False: 17 |             | 30 (47.00%)            |                        |  

This pattern held true for information coming from scientists, reflecting an overall level of uncertainty about information from both the federal government and scientists among minority groups compared with White/non-Hispanics. Overall, both groups rated the credibility of information coming from the federal government lower compared with information from scientists. Only 14.97% of White/non-Hispanics and 16.67% of minority participants responded that information from the federal government can be trusted, while 93% of White/non-Hispanics and 77% of minority respondents believed that information from scientists can be trusted. Respondents reporting chronic health conditions, particularly diabetes, were significantly more likely to rate information from the federal government as likely to be false, inaccurate, and not telling the whole story compared with respondents not reporting diabetes as a condition. Males were more likely than females to trust information coming from the federal government, and to rate this information as likely to be true. Respondents who reported losing a job due to COVID-19 were less trusting of information coming from the federal government and less likely to believe this information was accurate than respondents not reporting a job loss. Those who lost a job also rated information coming from scientists as less trustworthy and accurate compared with respondents who did not lose a job.

Abstract

Selecting radiology examination protocol is a repetitive, and time-consuming process. In this paper, we present a deep learning approach to automatically assign protocols to computed tomography examinations, by pre-training a domain-specific BERT model (BERT\textsubscript{md}). To handle the high data imbalance across exam protocols, we used a knowledge distillation approach that up-sampled the minority classes through data augmentation. We compared classification performance of the described approach with n-gram models using Support Vector Machine (SVM), Gradient Boosting Machine (GBM), and Random Forest (RF) classifiers, as well as the BERT\textsubscript{base} model. SVM, GBM and RF achieved macro-averaged F1 scores of 0.45, 0.45, and 0.6 while BERT\textsubscript{base} and BERT\textsubscript{md} achieved 0.61 and 0.63. Knowledge distillation boosted performance on the minority classes and achieved an F1 score of 0.66.

Introduction

When an advanced imaging order is placed, e.g. for computed tomography (CT) or magnetic resonance imaging (MRI), a radiologist often has to select the most applicable imaging protocol for the imaging technologist to perform the examination. The imaging protocol contains the technical parameters for CT or MRI image acquisition. For CTs and MRIs, this includes the number of sequences, use of intravenous or oral contrast, scanning planes and other technical parameters to ensure that the image acquisition is best suited to answer the clinical question being asked by the ordering provider. The radiologist gives the protocol decision based on the free-text clinical information in the electronic order and the suggested examination by the ordering physician. This manual protocoling process can be time-consuming, may delay performing timely imaging, and result in unnecessary variability in the techniques used for image acquisition\textsuperscript{1}.

Radiologists are one of the highest paid medical specialties, with an average salary of USD $485,000 in 2020, according to the 2020 physician compensation report published by Doximity. Radiologists’ primary clinical and revenue generating task is image interpretation, but their time is often spent performing ‘non-interpretive tasks’, which are non-revenue generating and often can distract them from performing quality image interpretations. Radiologists may spend 37-44\% of their typical workday performing non-interpretive tasks, and 3.5-6.2\% of their time protocoling\textsuperscript{2,3}. For clinically urgent studies, radiologists may be interrupted to protocol non-urgent examinations, which reduces productivity, potentially impairs interpretive accuracy and lengthens report turnaround time (a radiology service quality metric)\textsuperscript{4,5}.

Radiology exam protocoling is a repetitive and fairly simple classification task. It is therefore a strong candidate for automation. By applying machine learning techniques to protocoling, radiologists could spend a greater proportion of their time performing interpretive tasks, thereby improving the cost-effectiveness of a radiology practice, reducing interruptions for protocoling, improve interpretation accuracy and shorten report turnaround time. Integration of a ML protocoling pipeline into the protocoling software that radiologists use (usually the radiology information system) would permit radiologists to obviate the need to protocol examinations altogether or, in some cases, reduce the number of protocoling steps by suggesting the correct protocol or simply flagging more complex protocols for a radiologist to ‘manually’ protocol.

In this paper, we defined the task of protocol assignment as a classification task. We used structured radiology exam meta-data (exam name and code provided by referring physician) and patient demographics (age and gender) as well as free text diagnoses and history information to automatically assign a radiology protocol. Table 1 presents an example of the radiology examination data from our dataset. Information listed in Table 1 is available to radiologists when they assign protocols manually. In our experiments, we (1) compared different statistical ML models to the state-of-the-art BERT\textsuperscript{6} model for radiology protocol classification task, (2) evaluated the BERT model pre-trained on
general domain ($BERT_{base}$) in comparison to a BERT model pre-trained on our radiology corpus ($BERT_{rad}$), and (3) applied deep learning knowledge distillation approach to tackle high data imbalance in our dataset.

Related Work

Automating radiology protocol selection has been investigated in previous studies. Brown et al. compared three different ML models, including support vector machine (SVM), gradient boosting machine (GBM), and random forest (RF), to classify MRI protocol selection. They used bag-of-words approach with unigrams to represent features for the text data and combined them with the structured variables (age, sex, location and ordering service). The dataset consisted of 7487 observations. Since each protocol can consist of a sequence of procedures, it is considered a multi-label classification task. They trained 41 binary classifiers for each model to predict each procedure in a sequence. The three ML algorithms included in this study demonstrated similar performance. GBM achieved 86% precision and 80% recall. SVM achieved 83% precision and 82% recall, followed by RF with 85% precision and 80% recall. In another study, the same authors employed similar ML approaches to protocol and prioritize MRI brain examinations. Their best classifier using RF achieved 82% precision and 83% recall. In this paper, we used SVM, GBM, and RF as baselines to compare the performance of our proposed classification approach.

Trivedi et al. used IBM Watson to determine the use of intravenous contrast for musculoskeletal MRI protocols by analyzing only clinical texts. The task was to classify a free-text clinical indication into one of the two labels “with contrast” or “non-contrast”. The dataset consisted of 650 positive and 870 negative labels. Watson achieved over 90% precision and 74% recall. The overall performance is similar to their ensemble model comprising 8 traditional statistical models (SVM, scaled linear discriminant analysis, boosting, bagging, classification and regression tree, RF, Lasso and elastic-net regularized generalized linear model, maximum entropy). Although they claimed that Watson’s classifier was based on deep learning, no specific details about the model architecture and hyperparameters were provided by IBM.

One research conducted by Kalra et al. is the most similar to our study. They developed two statistical ML models and one deep learning model to automate CT and MRI protocol assignment. The dataset contained 18000 CT and MRI examinations in 108 unique protocols. Similar to our dataset, their protocol frequency distribution is highly imbalanced with the 5 most commonly assigned protocols making up 49% of the entire dataset. They trained a k-nearest neighbor and a random forest classifier using TF-IDF feature vectors on unigrams from clinical texts. Interestingly, they excluded structured data elements such as age and gender, which could be strong predictor variables. The performance results from the top two classifiers, RF (80% precision, 82% recall) and DNN (82% precision, 84% recall), were comparable. However, they only reported weighted micro-averages and did not report performance metrics per protocol. Hence, we do not know how the model performed on the minority classes.

Our main contribution in this paper is the feasibility analysis of applying transfer learning using pre-trained language models for protocol classification task. In our experiments, we first evaluated the three ML approaches (SVM, GBM, and RF) presented in previous studies, and observed similar micro-averaged classification performance. Compared to other published datasets, our dataset is relatively larger in which 57% of the data fall into two specific protocol groups. To handle such high data imbalance, we presented a knowledge distillation approach by up sampling the minority classes through data augmentation. We presented the classification result for each protocol group and showed the performance gain for the minority classes.

Methods

Dataset:

Our dataset included 35085 radiology body CT examinations performed at 7 hospital-based and clinic-based imaging sites between January 2018 and June 2019. The data was extracted from the University of Washington radiology
information system. As demonstrated in Table 1, each exam is represented with 4 structured data fields including exam meta-data (exam code, protocol code) and patient demographics (age, gender) as well as 2 unstructured fields to capture patient history (history, diagnosis). Table 2 describes the word level statistics on the two unstructured fields. In our initial analysis of the dataset, we observed that the lengths of the unstructured data are relatively short (average numbers of words for history and diagnosis fields were 8 and 10 with standard deviations 6.57 and 8.6 respectively). 4759 (13.6%) examinations contained no history data and 3 (0.01%) examinations contained no diagnosis data.

**Table 2.** Word statistics on unstructured fields.

In addition, we observed that some of the same protocols had multiple protocol codes, reflecting different codes for the identical protocols performed at different imaging sites. To remove this inconsistency, we manually categorized the protocol codes into 27 unique “protocol groups”; each group unified identical protocols with different codes. We excluded 2 groups that had less than 20 examinations in our experiments (CT CA Oral Only and CT Abdomen IV Only). Table 3 shows the examination frequency with percentages for each protocol group. As can be observed from Table 3, the dataset is highly imbalanced, with the first two protocol groups constituting 57% of the entire dataset. The distribution of examination frequency among the groups has a mean of 1299, median of 200 and standard deviation of 2706.

**Table 3.** Distribution of examinations across protocols.

**Approach:**

We trained a deep learning classifier using the state-of-the-art neural language model, BERT® to automatically assign protocols to computer tomography (CT) examinations. Specifically, we fine-tuned the Google pre-trained model BERTbase with a linear layer on top using cross-entropy loss. We formulated the task as a single-sequence classification task by first transforming the structured and unstructured data into the following template: “Exam is <exam code>. Sex is <gender>. Age at Exam <age>. History: <history>. Diagnosis: <diagnosis>” and subsequently classifying it into one of 25 protocol groups listed in Table 3. We observed that the mean and median of number of characters in the templated data are 192 and 178. In order to capture context presented in the training instances, we set the maximum
sequence length parameter of the BERT model to be 200 with a batch size of 48. We followed the suggestions described in the BERT paper and used the Adam optimizer with a learning rate of 2-e5. We fine-tuned the BERT model for 4 epochs.

Conceptually, BERT learns the relations between words by randomly masking words in a sequence with a [MASK] token and then trains itself to predict them from the context of the unmasked ones. Additionally, it learns the sentence relationships by training itself to predict if the second sentence in a pair is truly following the first sentence in the corpus. These two learning tasks allow BERT to self-train and capture the context of language used in an unlabeled corpus before transferring all parameters to downstream applications. Previous studies showed promising results of using BERT in clinical applications. Examples include chest x-ray reports classification\textsuperscript{11}, and relation extraction in clinical and biomedical domain\textsuperscript{12,13}. Since BERT\textsubscript{base} was originally pre-trained on BookCorpus and English Wikipedia, to fully encode the semantic context in clinical and biomedical text, it has been shown that further training BERT\textsubscript{base} on MIMIC and PubMed data can boost the performance of named entity recognition in the biomedical domain\textsuperscript{14,15}. Inspired by these studies, we further pre-trained BERT\textsubscript{base} on our radiology protocol corpus and named it BERT\textsubscript{rad}. We repeated the same experiment with BERT\textsubscript{rad} using the same hyperparameters listed above. All BERT experiments were implemented with Huggingface’s transformer library\textsuperscript{16}.

Knowledge distillation:

Imbalanced class distribution usually leads to poor classification results on the minority classes\textsuperscript{17}. When dealing with imbalanced datasets, a popular approach is to use the Synthetic Minority Oversample Technique (SMOTE)\textsuperscript{18} which generates new artificial samples for the minority classes by interpolating the nearest neighbors of the existing samples. This method reduces the likelihood of overfitting minority classes commonly observed in random over sampling approach. However, because the inputs of the BERT model include positional embeddings and WordPiece tokenization with special classifier token [CLS] and separator token [SEP], synthesizing these input values in vector space using interpolation will lose the context of the tokens in the samples.

Recent studies have successfully demonstrated the possibility to transfer task specific knowledge from the large BERT model to a smaller neural architecture without significant performance degradation\textsuperscript{19-21}, using a technique called knowledge distillation. The process involves training a second model (student) to match the predictions from the first model (teacher). We hypothesized that by transferring knowledge specific to the minority classes from the BERT\textsubscript{rad} model to a second BERT model, we could improve the classification performance on the minority classes. In particular, we aimed to train a student model that could outperform the teacher with identical neural architecture. Furlanello et al. referred to this approach as Born-Again Neural Network (BAN)\textsuperscript{22}, which has been shown to produce better results in both single and multi-task settings\textsuperscript{23}. During the knowledge distillation process, the raw predictions from the teacher model, known as logits, are being used as “soft labels” for training the student model. As Hinton et al. suggest, the distribution in the logits, even among incorrect predictions, contains information about how the teacher model is generalizing, thereby offering more training signals than one-hot categorical labels\textsuperscript{19}.

To effectively transfer knowledge about the minority classes to a student model, a large unlabeled dataset is needed to generate enough soft labels from the teacher model. In this study, we applied Tang et al.’s data augmentation techniques to synthesize masked data in order to allow the teacher to fully express its knowledge\textsuperscript{24}. To augment a given training instance, we randomly sampled a number $P$ from the uniform distribution $[0,1]$. If $P < 0.1$, we randomly replaced a word in the history and diagnosis section with the [MASK] token. If $P$ is between 0.1 and 0.2, we randomly replaced a word with another word in the training set that has the same POS tag. Finally, we randomly replaced an n-gram ($n \in [1,3]$) in the training instance with the [MASK] token. This technique is similar to the masking procedure employed in BERT’s masked language model. We repeated this augmentation process to generate 30 new instances, without duplication, for each training instance. We evaluated different numbers of augmented instances (25, 30, 35, 40, 50) by running 5-fold cross validation with the augmented data. Our evaluation showed that the experiment with 30 augmented instances achieved the best result. In addition, we wanted to limit the augmented sample size of the dominant classes and therefore set a maximum sampling limit of 12000, such that the final sample size of each class after augmentation could not exceed 12000. We then ran inferencing on the augmented dataset using the teacher model BERT\textsubscript{rad} to generate soft labels for distillation. Finally, we initialized a student BERT\textsubscript{rad} model with a different random seed and trained it to imitate the teacher by minimizing the mean squared error (MSE) between the student’s logits and teacher’s logits. At the same time, we allowed the student model to surpass the teacher by training with the true labels by minimizing the cross-entropy loss against the one-hot multi-class labels:

$$L_{distill} = \alpha \cdot L_{cross-entropy} + (1 - \alpha) \cdot L_{MSE}$$
where \( \alpha \) is the ratio of true labels within a single batch of training samples. After each iteration of knowledge distillation, the student model became the teacher for next generation.

Baselines: For our prediction task, we trained three separate ML models with Support Vector Machine (SVM), Gradient Boosting Machine (GBM) and Random Forest (RF) as baselines and compared their performance against our proposed deep learning classifier. To train the baselines, we transformed the unigrams and bigrams of the history and diagnosis notes into feature space using TF-IDF before combining with the numeric values in the structured data. The baselines were trained with the same features. All statistical classification modelling was implemented using the Scikit-learn machine learning python package\(^2\).

Results

We used 5-fold cross validation to evaluate the general performance of the models. For each fold, the models were trained on the same training data and evaluated on the same held-out test data. We used precision, recall, and F1-score as metrics to measure the performance. The overall macro-average and weighted micro-average results are presented in Table 4. To generate macro-averaged results, we first calculated the metrics for each class and calculated the average of them giving each class equal weight. To generate weighted micro-averaged metrics, we calculated the metric averages weighted by the number of true labels in each class. As can be observed, the micro-average results are largely similar due to the bias towards the majority classes. In the macro-average results, among the baselines, RF performed the best with 0.60 F1-Score. Both SVM and GBM produced 0.45 F1-score. The SVM in general produced higher precision and lower recall, when compared to GBM. The classifiers based on BERT models performed better than the SVM, GBM and RF baselines. Furthermore, the in-domain BERT\(_{rad}\) produced 0.2 higher macro F1 score than the out-of-domain BERT\(_{base}\) model (0.63 versus 0.61).

To mitigate the high data imbalance, two resampling experiments were performed with the BERT\(_{rad}\) model. The resampling was performed only on the training data while the validation data were kept the same. First, we undersampled the 2 majority classes by randomly removing some training instances such that their sample sizes matched the size of the third largest protocol group (#3). The result shows that the macro-average F1 dropped 0.24 and the weighted micro-average F1 dropped 0.2 due to the misclassification of the majority classes given their smaller sample sizes. In the over-sampling experiment, the training instances in the minority classes were randomly replicated so that their sample sizes matched the size of the second largest protocol group (#2). The result shows no performance improvement in the macro-average F1 but degradation in the weighted micro-average. This can be caused by overfitting the large number of duplicate training samples in the minority classes\(^18\). The results also show that the BAN models \{2,3\} achieved better macro-average performance than BERT\(_{base}\) and BERT\(_{rad}\), without any degradation in micro-average performance. More specifically, the macro-average F1 in generations of student models (BAN\{1,2,3\}) improved, suggesting that the classifiers achieved better performance in predicting the minority classes through knowledge distillation. We also observed that the performance saturated after training the second generation of BAN student model. This finding is similar to the one reported by Furlanello et al\(^22\).

Table 4. Comparison of model results. BAN\{1,2,3\} denotes the 1st, 2nd and 3rd generation of knowledge distillation.
Table 6 presents performance results at the protocol level. Our results showed that the BERT models generally outperformed statistical baselines among the protocol groups. From the protocol group #2 to #9, the difference in F1 scores between the best performing statistical model and the best performing BERT model is between 1% to 5%. In some specific groups, such as “CT CAP No Contrast” (#10) and “CT Abd Pel Enterography” (#11), we observed much larger improvement. Overall, we did not observe a substantial improvement in BERT_rad compared to BERT_base. The small size of the dataset and sparseness of the unstructured data fields resulted this outcome. Nonetheless, BERT_rad was able to outperform BERT_base in some protocol groups by capturing the context of words that are not common in general domain. For example, in the protocol group “CT Abd Pel Enterography” (#11), the word hernia, which describes the symptom that a tissue pushes through the abdominal opening, appeared in over 79% of the diagnosis fields, while another word CREATININE, a compound that indicates the level of kidney function, appeared in over 73% of the history fields. These two medical terms are not commonly seen in the general corpora. By pre-training on the radiology corpus, BERT_rad was able to learn better contextual representation of these medical terms and outperformed BERT_base by 0.07 F1 in that protocol group. We observed similar improvement in protocol groups “CT Abdomen IV and Oral” (#19) and “CT Abdomen Pelvis w Oral only” (#21).

One interesting observation was BERT_base model’s substantially low F1-score of 0.16 for group “CT IVP < 50” (#14) when compared to the F1-scores (SVM: 0.61, GBM: 0.73, RF: 0.88) of statistical baselines. Further investigation showed that 87% of the false negatives for “CT IVP < 50” (#14) were misclassified to “CT IVP 50 yrs +” (#8) by BERT_base. Because the main difference between these two protocol groups is age of patient, the age feature by itself offered high information gain to allow RF to learn a more robust model. On the other hand, deep learning models require considerably large volume of data to extract patterns from high-dimensional data points. The smaller sample size of protocol group #14 limited the BERT_base model to learn to differentiate from protocol group #8. However, data augmentation in the knowledge distillation process eventually supplied additional training signals for the model to generalize, leading to the similar performance levels as RF.

Although knowledge distillation enabled the BERT models to improve overall performance on the minority classes, one particular protocol group that was not correctly classified by any models was “CT Liver 2 Phase” (#24). Our error analysis showed that the models misclassified some #24 cases to “CT Liver 3 Phase” (#6) because of similar patient diagnosis and history. Table 5 presents one of these cases.

Table 5. Examinations in two different protocol groups with similar history and diagnosis.

While these were the correct protocol assignments in clinical practice, because #24 only constituted 0.15% of the training data and was 30 times less than #6, there were not enough data to train the models to differentiate #24 from #6. Additionally, we found that some #24 cases were misclassified to “CT CAP IV and Oral” (#1) because of the exact same history and diagnosis found in #24. For instance, there were 6 cases with history of “ORAL and IV Contrast” and diagnosis of “2 Phase Liver, PNET Metastatic” assigned to protocol #1 and 1 case with the same history and diagnosis assigned to #24. Without any additional clinical information to help differentiate the two protocol assignments, the models simply inferred to the group that was more dominant in the training data.
source codes will be shared with radiologist workflow and used on biomedical datasets are intrinsically imbalanced (e.g. the prevalence of certain diseases). Improved overall classification performance of models assigned protocols based on patient demographic and history data. The results showed that overall pre-trained language models performed better than traditional n-gram models. Additionally, we demonstrated that knowledge distillation improved overall classification performance for the majority of under-represented groups. Since many real-world biomedical datasets are intrinsically imbalanced (e.g. the prevalence of certain uncommon cancer types or chronic diseases), we think that this technique could be useful in many classification problems involving clinical text using pre-trained language models. In future studies, we plan to integrate the machine learning models into actual radiologist workflow and compare the agreement between radiologists and models. The dataset and experimentation source codes will be shared with the research community.

Conclusion

In this study, we presented a novel ML approach using pre-trained language models to help radiologists automatically assign protocols based on patient demographic and history data. The results showed that overall pre-trained language models performed better than traditional n-gram models. Additionally, we demonstrated that knowledge distillation improved overall classification performance for the majority of under-represented groups. Since many real-world biomedical datasets are intrinsically imbalanced (e.g. the prevalence of certain uncommon cancer types or chronic diseases), we think that this technique could be useful in many classification problems involving clinical text using pre-trained language models. In future studies, we plan to integrate the machine learning models into actual radiologist workflow and compare the agreement between radiologists and models. The dataset and experimentation source codes will be shared with the research community.

Abstract

Sentence boundary detection (SBD) is a fundamental building block in the Natural Language Processing (NLP) pipeline. Incorrect SBD may impact subsequent processing stages resulting in decreased performance. In well-behaved corpora, a few simple rules based on punctuation and capitalization are sufficient for successfully detecting sentence boundaries. However, a corpus like MEDLINE citations presents challenges for SBD due to several syntactic ambiguities, e.g., abbreviation-periods, capital letters in first words of sentences, etc. In this manuscript we present an algorithm to address these challenges based on majority voting among three SBD engines (Python NLTK, pySBD, and Syntok) followed by custom post-processing algorithms that rely on NLP spaCy part-of-speech, abbreviation and capital letter detection, and computing general sentence statistics. Experiments on several thousand MEDLINE citations show that our proposed approach for combining multiple SBD engines and post-processing rules performs better than each individual engine.

Introduction

This paper describes an ongoing effort at the National Library of Medicine (NLM) related to the detection of sentence boundaries of MEDLINE documents where a document refers to a MEDLINE citation which contains a title and may contain an abstract.

Sentence boundary detection (SBD) is an important pre-processing step in many Natural Language Processing (NLP) applications, such as sentence embedding, part-of-speech taggers, document indexing, and question answering. Several techniques for detecting sentence boundaries have been reported in the NLP literature covering a variety of text domains including general text (WSJ text and the Brown corpus [1,2]), biomedical text (the GENIA corpus [3] of biomedical abstracts), clinical text (the i2b2 corpus [4]), and legal text (the United States Courts decisions dataset [5]).

As pointed out in reviews by Griffis [6] and Read [7], the performance of the reviewed SBD techniques is domain dependent. Most do well in general text domains that “conform to formal English” but perform poorly in certain domains, like biomedicine and legal text, where customized algorithms tend to perform better. A specialized corpus like MEDLINE containing journal citations, titles and abstracts presents challenges for SBD due to the difficulties in recognizing uppercase letters belonging to domain-specific (genetic, biological, and chemical) terms, and disambiguating abbreviation-periods among journal abbreviations and medical terms.

In the domain of general text SBD, Riley [8] used a decision tree classifier while Gillick [9] used a supervised approach with Naïve Bayes and Support Vector Machine (SVM). Kiss [10] proposed an unsupervised abbreviation detection algorithm with the Punkt model that “can detect abbreviations based on collocation between periods and truncated words”. Palmer [11] used a neural network with inputs as vectors of binary values representing contextual words surrounding punctuation marks. These techniques reported high accuracies of over 98.00% on both WSJ and the Brown corpus.

Savelka [5] and Sanchez [12] suggested methods to detect sentence boundaries in legal text domains “using customized Punkt tokenizer and Conditional Random Field (CRF) algorithms”. Both systems reported accuracies in the range from 75.00% to 90.00%. Buyko [13] recommended a new approach by retraining the OpenNLP software application on specific biology domains, including the GENIA and PennBioIE25 corpora, and the system reported accuracies of 99.00% and 97.40%, respectively. This experiment was applied on the GENIA corpus [3], a collection with 1,999 abstracts from the MEDLINE database. Kreuzthaler [14] suggested a system using two SVM binary classifiers for abbreviation and sentence detection to detect sentence boundaries in German clinical narratives. The system reported an F-measure of 95.00% for abbreviation detection and 94.00% for sentence delineation.

In this paper, we describe our hybrid-ensemble approach to detect sentence boundaries to address and resolve identified SBD challenges. The algorithm is based on majority voting among three SBD engines (Python NLTK [15], pySBD [16], and Syntok [17]) followed by custom post-processing rule-based algorithms to detect sentence
boundaries that rely on NLP spaCy part-of-speech (POS) [18] tokenization library, abbreviation, and capital letter detection, and computing general sentence statistics. The performance of the proposed SBD algorithm has been evaluated using two data sets of approximately three thousand MEDLINE citations. The evaluation results show that our hybrid-ensemble approach performs better than each individual engine in terms of improving the detection accuracy of correct sentence boundaries.

**Methods**

**Data sets**

The training data set consists of 1,514,446 citations randomly selected from the 30-million citations in the 2020 MEDLINE Baseline data set [19] and is used for observations and for developing features and rules for the proposed SBD algorithm. There are two ground-truth data sets that we used to evaluate the system performance of the proposed SBD algorithm: the GENIA corpus [3] ground-truth data set and the 2021 SBD ground-truth data set.

The GENIA corpus [3] ground-truth data set consists of 18,541 sentences segmented from 1,999 citations from MEDLINE database. It was created from the Genome Informatics Extraction (GENIA) project to provide the gold standard for the evaluation of text mining systems. For the 2021 SBD ground-truth data set, we downloaded approximately 32-million citations from the 2021 MEDLINE Baseline data set [19] in XML file format. We then randomly selected 1,020 citations that were not in the 2020 MEDLINE Baseline data set and extracted titles and abstracts from the XML. For any “structured abstracts” citations, we kept only the label followed by a colon space and filtered out “NlmCategory” and their XML tag “AbstractText” [20]. For example, the XML text “<AbstractText Label="abstracts" citations, we kept only the label followed by a colon space and filtered out

**Basic definitions**

Definitions of the basic features used in our system are given here.

1. A “regular” capital word versus a “special” capital word: In our system, words that begin a sentence could be considered as “regular” or “special” capital words. A “regular” capital word has its first character as an uppercase letter (e.g. “National”) while a “special” capital word includes a lowercase letter after its first character (e.g. “20-Hydroxycholesterol”).

2. **VERB-Phrase sentences and NOUN-Phrase sentences**: POS tagging is a technique to map words as nouns, verbs, adjectives, adverbs, etc. In our system, NLP spaCy POS tagging library [18] is used to generate two lists of attributes of the tokenization outputs for any sentence: a POS list and a TAG list. A POS list shows the coarse-grained part of speech, and its associated TAG list shows the fine-grained part of speech, as shown in the following example.

   Sentence: “This method shows advantages in two aspects.”

A complete list of POS and associated TAG list are available [18]. Based on these lists, a “VERB-Phrase sentence” and a “NOUN-Phrase sentence” are defined as follows:

A sentence is considered a “VERB-Phrase sentence” if it satisfies one of the following two cases:

- Case 1: POS = AUX and TAG = VB or VBD or VBP or VBZ
- Case 2: POS = VERB and TAG = VBD or VBP or VBZ or VBN or MD

A sentence is considered a “NOUN-Phrase sentence” if it satisfies one of the following three cases:

- Case 1: POS = NOUN or PROPN
- Case 2: POS = PRON and TAG = EX or PRP or WP
- Case 3: POS = DET and TAG = WPS

As a result, we define the “five-sentence-based POS tagging types” as follows:

<table>
<thead>
<tr>
<th>Type</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>NP:</td>
<td>A sentence with only a “NOUN-Phrase sentence”, e.g., “Level of evidence : Level II.”</td>
</tr>
<tr>
<td>VP:</td>
<td>A sentence with only a “VERB-Phrase sentence”, e.g., “were investigated.”</td>
</tr>
<tr>
<td>NP+VP:</td>
<td>A sentence with a “NOUN-Phrase sentence” followed by a “VERB-Phrase sentence”, e.g., “Fast and scalable tools are hence needed”</td>
</tr>
<tr>
<td>VP+NP:</td>
<td>A sentence with a “VERB-Phrase sentence” followed by a “NOUN-Phrase sentence”, e.g., “Excluded were 139 Web sites.”</td>
</tr>
<tr>
<td>NP+VP+NP:</td>
<td>A sentence with a “NOUN-Phrase sentence” followed by a “VERB-Phrase” and a “NOUN-Phrase” e.g., “Costs were estimated in US dollars.”</td>
</tr>
</tbody>
</table>
3. Normal POS versus Special POS: Based on our observations, we recognized two POS terms that play an important role in helping to make the connection decisions between consecutive sentences: “PROPN” and “INTJ”. They are defined in this paper as special-POS and the remaining terms are normal-POS (“ADJ”, “ADP”, “ADV”, “AUX”, “CCONJ”, “DET”, “NOUN”, “NUM”, “PART”, “PRON”, “PUNCT”, “SCONJ”, “SYM”, “VERB”, and “X”). The following show examples of broken sentences that could be connected through the help of special-POS.

<table>
<thead>
<tr>
<th>By contrast, cyto.</th>
<th>o, i.e., the ... tension.</th>
</tr>
</thead>
<tbody>
<tr>

### Algorithms to Handle Sentence Boundaries Challenges in MEDLINE

We used two algorithms to address the above-mentioned challenges: the “special” capital word detection algorithm and the abbreviations detection algorithm.

1. The “special” capital word detection algorithm: A sentence usually starts with a word in which its first character is an uppercase letter. However, this condition might not hold true for some genetic, biological, and chemical terms where digits, punctuation, lowercase letters, and symbols (such as “12α-Hydroxyl”, “(-)-Deprenyl”, “•Lichen”) might start a sentence. For these terms, we observed some special patterns from characters before their first uppercase letter (such as “digits, Greek letters, punctuations” for “12α-Hydroxyl”, “punctuations” for “(-)-Deprenyl”, “symbols” for “•Lichen”). Therefore, in order to address such variants, we built a predefined list of “special” capital word patterns and developed an algorithm using this list to detect whether the first word of a sentence is a “special” capital word.

To build a predefined list of capital word patterns, we collected only sentences of which the first word has at least one uppercase letter, but its first character is not an uppercase letter. In addition, we limited the sentence length to be greater or equal to the average sentence length which is 110 characters to reduce the number of collected samples.

Note that a common plain English guideline says that an average sentence length is about 15–20 words [21] and the average word length is about 4.7 characters [22]. In this paper, the average sentence length (AVGSL) is calculated based on 5 characters per word, an average of 18 words, and 17 spaces per sentence as follows:

\[
\text{AVGSL} = 18 \text{ words} \times 5 \text{ characters} + 17 \text{ spaces} \approx 110 \text{ characters.}
\]

To build a predefined list of capital word patterns, we first collected all “special” capital word patterns that are generated by (a) taking the sentences’ first words and truncate them at their uppercase letter. For example, the first word “12α-Hydroxyl” is truncated into “12α”-, (b) building lists of Unicode names associated with characters of the truncated words. For the truncated word “12α-”, the list of Unicode names is: “DIGIT ONE”, “DIGIT TWO”, “GREEK SMALL LETTER ALPHA”, “HYPHEN-MINUS”, (c) replacing Unicode names based on their type by their predefined “replacement” symbols using the replacement table (Table 1). For the list of Unicode names in b), the replacement symbols are 00XH, (d) replacing consecutive similar “replacement” symbols by a single “replacement” symbol to build “special” capital word patterns for the truncated words. For the above replacement symbols in c), the “special” capital word pattern is 0XH. We then tabulated and sorted the collection of the “special” capital word patterns based on their pattern occurrence frequency and selected the topmost patterns as the predefined list of “special” capital word patterns.

### Table 1. Replacement symbols

<table>
<thead>
<tr>
<th>Type of Unicode Name</th>
<th>Replacement</th>
</tr>
</thead>
<tbody>
<tr>
<td>Greek alphabet</td>
<td>X</td>
</tr>
<tr>
<td>Hyphen</td>
<td>H</td>
</tr>
<tr>
<td>Punctuation</td>
<td>P</td>
</tr>
<tr>
<td>Digit or Number</td>
<td>0</td>
</tr>
<tr>
<td>Superscript</td>
<td>S</td>
</tr>
<tr>
<td>Roman numeral</td>
<td>R</td>
</tr>
<tr>
<td>Small letter</td>
<td>Y</td>
</tr>
<tr>
<td>Bullet</td>
<td>B</td>
</tr>
<tr>
<td>Inverted question</td>
<td>I</td>
</tr>
<tr>
<td>Symbols</td>
<td>Z</td>
</tr>
<tr>
<td>Special space</td>
<td>*</td>
</tr>
<tr>
<td>No replacement</td>
<td>?</td>
</tr>
</tbody>
</table>

We applied the above procedure on the training data set described in the Methods section and came up with a predefined list of “special” capital word patterns (Table 2).

A first word in a sentence could be classified as a “special” capital word or not by first represent it as a symbol-based
word using the replacement table (Table 1) and then compare the symbol-based word with the predefined list of “special” capital word patterns (Table 2).

The algorithm to detect a “special” capital word for the first word in a sentence starts by truncating the given word at its first uppercase letter and then represents the truncated word as a list of Unicode names where each Unicode name is associated with each character of the truncated word. Next, it converts a list of Unicode names into a symbol-based word using the replacement table (Table 1). Finally, it checks the symbol-based word against the predefined list of “special” capital word patterns (Table 2) to determine whether or not the given word is a “special” capital word.

</tbody>
</table>

2. The abbreviations detection algorithm: Based on our observations of MEDLINE citations in our training data set, we have found that one of the ways sentences are incorrectly segmented is due to the failure of recognizing abbreviations between consecutive sentences. To minimize the impact of this problem, we build a predefined list of abbreviations (Figures 1 and 2) from last words of sentences and develop a simple abbreviations detection algorithm using it.

Abbreviations could connect to sentences that have the first character of their first word as either a lowercase or uppercase letter; however, we limit the algorithm’s attention to just lowercase letters and consider only abbreviations having 8 characters or less to reduce the number of collected samples.

To build a list of abbreviations, we collected all words that (a) have 8 characters or less, (b) are ended with a period, and (c) are followed with a word starting with a lowercase letter. We then tabulated the collection of the collected words into two groups: 1-period group (e.g., “approx.”, “Corp.”, etc.) and 2-period group (e.g., “i.e.”, “Ph.D.”, etc.) and filtered out words with a frequency of less than 100 to build the predefined list of abbreviations.

We applied the above procedure on the training data set and came up with the following list of abbreviations for the 1-period group (Figure 1) and the 2-period group (Figure 2).

Figure 1: The “general” 1-period abbreviation group

Figure 2: The “general” 2-period abbreviation group

The simple abbreviations detection algorithm could be implemented by checking the sentence last word. If the sentence last word without trailing whitespace characters is found in the above 1-period or 2-period abbreviation group, then it is an abbreviation.

**System Overview**

The algorithm starts with segmenting a document into sentences with each SBD engine, followed by a majority voting to build a list of most voted sentence “proposals” for the document. After this, the content-based features and the grammar-based features are computed using the five sentence-based POS tagging types, the abbreviation detection algorithm, the capital word detection algorithm, and computing general sentence statistics. These features are then used to determine whether to connect consecutive sentences. The algorithm ends with splitting sentences with specific patterns.

To decide on the connection among segmented sentences, the algorithmic approach is to look for complete and incomplete sentences. Incomplete sentences could be the results of SBD engines that failed to recognize sentence delimiters, identify capital words, detect abbreviations, etc. Further, incomplete sentences should connect to other sentences.
We used sentence attributes, the number of votes on each sentence, sentence structure, and POS to evaluate the completeness of each segmented sentence. There are two sets of features for each sentence: content-based and grammar-based. Content-based features are based on character statistics, abbreviations, majority voting, and five sentence-based POS tagging types. Grammar-based features are based on the POS tags for the first and last two terms in a sentence. These two sets of features complement each other to help in making connection decisions between consecutive segmented sentences. Figure 3 shows the workflow of the MEDLINE SBD system to process a MEDLINE citation and each step of this process is described in detail in the next section.

Figure 3: MEDLINE Sentence Boundary Detection Diagram

**MEDLINE Sentence Boundary Detection Process**

The MEDLINE SBD process consists of six steps: (1) segment a document into sentences by each SBD engine, (2) build voted sentences among SBD engines using a majority voting algorithm, (3) generate the content-based features for voted sentences, (4) generate the grammar-based features for voted sentences, (5) apply the rules-based SBD algorithm to decide on connection between consecutive sentences, and (6) split sentences with specific patterns.

1. **Segment a document into sentences:** Each SBD engine segments the document into sentences and each sentence is recorded with a starting index and a stopping index relative to the start of the document and its voting SBD engine.

2. **Build voted sentences using a majority voting algorithm:** The majority voting algorithm groups sentences from SBD engines together and assigns the number of votes for each sentence to build the voted sentences for the document. For the three SBD engines, the algorithm collects sentences into three groups: 3-vote group, 2-vote group, and 1-vote group. First, sentences with 3 votes are collected into the 3-vote group. Next, sentences with 2 votes that are not in the 3-vote group are collected into the 2-vote group. Finally, sentences with 1 vote that are not in the 3-vote and 2-vote groups are collected into the 1-vote group.

Note that only one SBD engine will be selected for the last group with one vote to avoid overlapping among selected
3. Generate the sentence content-based features: The content-based features consist of structure information and character statistics of a sentence, and they are used to justify if a sentence is complete or incomplete for the purpose of connecting consecutive sentences. There are six sentence content-based features: “GRAMMAR”, “STYLE”, “ABBREVIATION”, “LENGTH”, “LOCATION”, and “CATEGORY”, and they are defined and explained next.

A sentence is complete when it begins with a capital letter (a regular/special capital word), ends with a punctuation mark (period, question mark, or exclamation point), and has both a subject and a verb. A subject may be a noun (a person, place, or thing) or a pronoun. For example, a sentence that starts with a capital word and consists of one or several combinations of “NOUN-Phrase sentence” and “VERB-Phrase sentence” has a high chance to be a complete sentence. As a result, we used the five sentence-based POS tagging types and the “special” capital word detection algorithm defined in the Methods section (Basic definitions and Algorithms to Handle Sentence Boundaries Challenges in MEDLINE) to generate the “GRAMMAR” feature and the “STYLE” feature, respectively.

| **GRAMMAR** = “Grammatical Complete” | If the POS tagging type = NP+VP+NP or NP+VP or VP+NP |
| **GRAMMAR** = “Grammatical Incomplete” | If the POS tagging type = NP or VP or Unknown |

| **STYLE** = “Upper-case Sentence” | If a sentence has a “regular” or “special” capital word |
| **STYLE** = “Lower-case Sentence” | Otherwise |

Next, we apply the abbreviations detection algorithm defined in the Methods section (Algorithms to Handle Sentence Boundaries Challenges in MEDLINE) on the last word of the sentence to build the “ABBREVIATION” feature.

| **ABBREVIATION** = “Yes” | If an abbreviation is found at the end of the sentence |
| **ABBREVIATION** = “No” | Otherwise |

Based on our observations, a sentence with an average sentence length (AVGSL ≈ 110 characters) or higher is most likely to be a complete sentence. In addition, the higher number of votes assigned on a sentence from three SBD engines gives more confidence that it is a complete sentence. Therefore, the number of characters and the number of votes are used to define a sentence content-based feature called “LENGTH” as follows:

| **LENGTH** = “Medium-or-Long Sentence” | If (votes <= 2 and number of characters >= ¼ of AVGSL) or (votes > 2 and number of characters >= ½ of AVGSL) |
| **LENGTH** = “Short Sentence” | Otherwise |

The location of a sentence is another feature, and its values include below:

| **LOCATION** = “First” | If the sentence is the first sentence |
| **LOCATION** = “Last” | If the sentence is the last sentence |
| **LOCATION** = “Middle” | Otherwise |

In addition, the punctuations are used to define one more feature: “CATEGORY”.

| **CATEGORY** = “Punctuations-Only-Sentence” | If the sentence consists of punctuations only |
| **CATEGORY** = “Regular” | Otherwise |

4. Generate the sentence grammar-based features: POS categorizes words by type, such as nouns, verbs, adjectives, and each sentence is associated with a POS list that is used to build the grammar-based features. As shown in the Methods section (Basic definitions), some combinations between the ending POS terms of the current sentence and the beginning POS terms of the next sentence could help to connect them together. Therefore, we define two grammar-based features for each sentence: “BEGINNING POST TERMS (BPT)” and “ENDING POST TERMS (EPT)”. The first feature is based on the first one or two POS terms of the sentence while the second one is based on the last one or two POS terms of the sentence.

The four values of the BPT are “normal-POS”, “PUNCT+normal-POS”, “special-POS”, and “PUNCT+special-POS”. 

| **normal-POS** | The POS list starts with a normal-POS |
| **PUNCT+normal-POS** | The POS list starts with a PUNCT followed with a normal-POS |
| **special-POS** | The POS list starts with a special-POS (“PROPN” or “INTJ”) |
| **PUNCT+special-POS** | The POS list starts with a PUNCT followed with a special-POS |
The four values of the EPT are “normal-POS”, “normal-POS+PUNCT”, “special-POS”, and “special-POS+PUNCT”.

<table>
<thead>
<tr>
<th>Feature</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>normal-POS</td>
<td>The POS list ends with a normal-POS</td>
</tr>
<tr>
<td>normal-POS+PUNCT</td>
<td>The POS list ends with a normal-POS followed with a PUNCT</td>
</tr>
<tr>
<td>special-POS</td>
<td>The POS list ends with a special-POS</td>
</tr>
<tr>
<td>special-POS+PUNCT</td>
<td>The POS list ends with a special-POS followed with a PUNCT</td>
</tr>
</tbody>
</table>

For example, consider the following sentence with its POS list:

Sentence: “This method shows advantages in two aspects.”
POS list: ['DET', 'NOUN', 'VERB', 'NOUN', 'ADP', 'NUM', 'NOUN', 'PUNCT']

The BPT feature is “normal-POS” because its POS list starts with a normal-POS (DET) and the EPT feature is “normal-POS+PUNCT” because its POS list ends with a normal-POS and a PUNCT (NOUN, PUNCT).

5. Apply the rules-based SBD algorithm: We apply the rules-based SBD algorithm to connect or separate segmented sentences and the following statements are used in the algorithm.

- Set the sentence “START” or “STOP” means it is the start sentence or the end sentence, respectively.
- Set the sentence “RIGHT CONNECT” means it connects to the next sentence on its right.
- Set the sentence “LEFT CONNECT” means it connects to the previous sentence on its left.

There are heuristic rules and three parts of observation rules, and they are executed in this order. In addition, there are synchronization rules to synchronize connections.

5a) Heuristic Rules: There are eight straightforward heuristic rules, and they are created to handle common-sense cases. For example, sentences ended with abbreviations should be “RIGHT CONNECT” to the next sentence.

<table>
<thead>
<tr>
<th>Rule</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>If sentence CATEGORY = “Punctuations-Only-Sentence” then If sentence LOCATION = “First” then set the sentence to “RIGHT CONNECT” Else if sentence LOCATION = “Last” then set the sentence to “LEFT CONNECT” and “STOP”</td>
</tr>
<tr>
<td>2</td>
<td>If sentence LOCATION = “First” then set the sentence to “START”</td>
</tr>
<tr>
<td>3</td>
<td>If sentence LOCATION = “Last” then set the sentence to “STOP”</td>
</tr>
<tr>
<td>4</td>
<td>If sentence LENGTH = “Medium-or-Long Sentence” then set the sentence to “START”</td>
</tr>
<tr>
<td>5</td>
<td>If sentence ABBREVIATION = “Yes” If sentence LOCATION = “First” or “Middle” then set the sentence to “RIGHT CONNECT”</td>
</tr>
<tr>
<td>6</td>
<td>If the sentence starts with a case-insensitive “Copyright” or a symbol® then If the sentence contains a year between 1900 and 2200 then set the sentence to “START”</td>
</tr>
<tr>
<td>7</td>
<td>If sentence LENGTH = “Short Sentence” and GRAMMAR = “Grammatical Complete” then If sentence STYLE = “Uppercase Sentence” then set the sentence to “START”</td>
</tr>
<tr>
<td>8</td>
<td>If sentence LENGTH = “Short Sentence” and GRAMMAR = “Grammatical Incomplete” and If number of words &lt;= 1 or number of words without stop words &lt;= 1 or number of characters &lt;= 5 then If sentence LOCATION = “First” then set the sentence to “RIGHT CONNECT” Else if sentence LOCATION = “Last” then set the sentence to “LEFT CONNECT”</td>
</tr>
</tbody>
</table>

5b) Synchronization rules: These rules are straightforward rules, and they are required to synchronize connections among surrounding sentences when there is a new connection between sentences.

<table>
<thead>
<tr>
<th>Rule</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>If the current sentence is not the first sentence: If it is set to “LEFT CONNECT” then set the previous sentence to “RIGHT CONNECT” Else if it is set to “START” then set the previous sentence to “STOP”</td>
</tr>
<tr>
<td>2</td>
<td>If the current sentence is not the last sentence: If it is set to “RIGHT CONNECT” then set the next sentence to “LEFT CONNECT” Else if it is set to “STOP” then set the next sentence to “START”</td>
</tr>
</tbody>
</table>
5c) Observation rules - Part 1: When a sentence is a short sentence and does not start with a capital word, it should connect to its preceding sentence as described in the following two rules.

Rule 1: If the current sentence GRAMMAR = “Grammatical Incomplete” and STYLE = “Lowercase Sentence” and LENGTH = “Short Sentence” then
Set the current to “LEFT CONNECT” and the preceding to “RIGHT CONNECT”

Rule 2: If the current sentence GRAMMAR = “Grammatical Complete” and STYLE = “Lowercase Sentence” and LENGTH = “Short Sentence” then
If the preceding sentence GRAMMAR = “Grammatical Incomplete” and LENGTH = “Short Sentence” then
Set the current to “LEFT CONNECT” and the preceding to “RIGHT CONNECT”

5d) Observation rules - Part 2: Rules developed in this section are more complicated than the rest since both content-based features and grammar-based features of the current and next sentences are involved to make the connection decisions. There are many cases where sentences are broken into pieces due to errors in recognizing sentence delimiters, capital words, and abbreviations; most of these sentences are incomplete. There are twelve rules shown in Figure 4 that are created based on the combinations between sentence content-based features GRAMMAR, STYLE, LENGTH, and sentence grammar-based features EPT and BPT and they are applicable only to “Short” sentences.

<table>
<thead>
<tr>
<th>RULE</th>
<th>CURRENT SENTENCE</th>
<th>NEXT SENTENCE</th>
<th>ACTIONS</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Grammatical Incomplete</td>
<td>Uppercase</td>
<td>normal-POS or normal-POS+PUNCT or special-POS or special-POS+PUNCT</td>
</tr>
<tr>
<td>2</td>
<td>Lowercase</td>
<td>Short</td>
<td>normal-POS or normal-POS+PUNCT or special-POS or special-POS+PUNCT</td>
</tr>
<tr>
<td>3</td>
<td>Grammatical Incomplete</td>
<td>Uppercase</td>
<td>Short</td>
</tr>
<tr>
<td>4</td>
<td>Grammatical Incomplete</td>
<td>Uppercase</td>
<td>Short</td>
</tr>
<tr>
<td>5</td>
<td>Grammatical Incomplete</td>
<td>Uppercase</td>
<td>Short</td>
</tr>
<tr>
<td>6</td>
<td>Grammatical Incomplete</td>
<td>Lowercase</td>
<td>Short</td>
</tr>
<tr>
<td>7</td>
<td>Grammatical Incomplete</td>
<td>Lowercase</td>
<td>Short</td>
</tr>
<tr>
<td>8</td>
<td>Grammatical Incomplete</td>
<td>Lowercase</td>
<td>Short</td>
</tr>
<tr>
<td>9</td>
<td>Grammatical Incomplete</td>
<td>Lowercase</td>
<td>Short</td>
</tr>
<tr>
<td>10</td>
<td>Grammatical Incomplete</td>
<td>Lowercase</td>
<td>Short</td>
</tr>
<tr>
<td>11</td>
<td>Grammatical Incomplete</td>
<td>Lowercase</td>
<td>Short</td>
</tr>
<tr>
<td>12</td>
<td>Grammatical Incomplete</td>
<td>Lowercase</td>
<td>Short</td>
</tr>
</tbody>
</table>

Figure 4: Observation rules - Part 2

5e) Observation rules - Part 3: The following rule is applicable to short and incomplete sentences and the connection decision is based solely on the sentence grammar-based feature BPT of the next sentence.

Rule 1: If the current sentence GRAMMAR = “Grammatical Incomplete” and STYLE = “Lowercase Sentence” and LENGTH = “Short Sentence” then
If the next sentence GRAMMAR = “Grammatical Incomplete” and LENGTH = “Short Sentence” then
If the next sentence BPT = “normal-POS, PUNCT+normal-POS, special-POS, or PUNCT+special-POS” then
Set the current to “RIGHT CONNECT” and the next to “LEFT CONNECT”

684
6. Split sentences with specific patterns: Through our observations, we identified some specific patterns that SBD engines failed to recognize, and they are as follows:

<table>
<thead>
<tr>
<th>Pattern #1</th>
<th>Pattern #2</th>
</tr>
</thead>
<tbody>
<tr>
<td>It starts with a space, an uppercase letter, a period, a space, and a capital word such as “B. The” or “A. In”</td>
<td>It starts with a word, a period, and a capital word such as “test. The” or “station. That”</td>
</tr>
</tbody>
</table>

For both patterns, we observed that when sentences in the left and right of the period are grammatically complete (GRAMMAR = “Grammatical Complete”) and the POS term of the first word followed the period is ‘DET’, ‘ADV’, ‘ADJ’, ‘VERB’, ‘PRON’ or ‘NUM’, sentences could be split at the period.

Therefore, the method to split sentences with specific patterns could start with the detection of the pattern #1 or #2 in a sentence and follow by splitting the sentence into the left sentence and the right sentence at the period. When both sentences are grammatically complete and the POS term of the first word of the right sentence belongs to the above-mentioned POS list, the sentence splitting is acceptable.

Discussion

We implemented the SBD algorithm and conducted experiments on MEDLINE citations randomly selected from several different biomedical journals. The algorithm is a combination between a majority voting among three SBD engines and rule-based post-processing algorithms. Some rules are heuristic, while others are derived from observations and from processing the collected training data set. The SBD algorithm is trained from the 2020 MEDLINE training data set and evaluated from two ground-truth data sets and these data sets are described in detail in the Methods section.

For the evaluation, we measure the SBD performance in terms of accuracy using two criteria: sentence-based and citation-based. For the sentence-based, the accuracy is based on the number of sentences detected by an SBD engine that are found in the ground-truth data set (Tables 3A and 3B). For the citation-based, the accuracy is relied on the number of citations having all their sentences found in the ground-truth data set (Tables 4A and 4B).

The average time in milliseconds to process a citation on a “DELL Intel(R) Core(TM)i7-8700 CPU @ 3.20GHz with 64.0 GB running 64-bit OS Windows 10 Enterprise” are: 1.21 ms, 2.22 ms, 1.36 ms, and 6.27 ms for Python NLTK, pySBD, Syntok, and MEDLINE SBD, respectively.

The results show that the combined MEDLINE SBD engine offers the best sentence boundary detection accuracy on the ground-truth data sets compared to the other three single SBD engines.
Conclusion

We developed the MEDLINE SBD algorithm using majority voting among multiple SBD engines and post-processing rules derived from content-based and grammar-based sentence features. Evaluation results show that our proposed SBD algorithm yielded good performance in terms of accuracy when compared to each single SBD. Therefore, we conclude that the MEDLINE SBD algorithm provides an improved approach to sentence segmentation for MEDLINE citations. However, we identified two shortcomings that should be resolved to further improve the detection results. First, the algorithm starts with a voting from sentences segmented by each SBD engine and follows with rules to decide whether to connect consecutive sentences. Even though there were some brute-force parsing operations in the last step of the MEDLINE SBD process to split segmented sentences with certain specific patterns, these operations actually just help to minimize the impact of the problem by handling obvious cases, but the problem still remained to be solved. Additionally, when all SBD engines do not agree on detected sentence boundaries, a predefined single engine is selected for the task and the algorithm cannot select other engines that might have better sentence boundaries. As a result, we plan to expand the current approach by including sophisticated methods to split segmented sentences as well as techniques to dynamically select an appropriate single engine when none of the engines agree on detected sentence boundaries.

Abstract

In this study, we describe the development and use of a biological-behavior-intervention computational informatics framework that combines disease modelling for infectious virus with stratifications for social behavior and employment, and resource logistics. The framework incorporates heterogeneous group behavior and interaction dynamics, and optimizes intervention and resources for effective containment. We demonstrate its usage by analyzing and optimizing containment strategies for the 2014-2016 West Africa Ebola outbreak, and its implementation for responses to the 2020 COVID-19 pandemic in the United States. Our analysis shows that timely action within 1.5 months from the onset of confirmed cases can cut down 90% of overall infections and bring rapid containment within 6-8 months. The additional medical resources required are minor and would ensure proper treatment and quarantine of patients while reducing the risk of infections among healthcare workers. The benefits of infection control (e.g., infection control / death control) would be reduced by 10 to over 100 fold and time to containment would increase by 2-4 fold when intervention and medical resources are injected within 5 months. In contrast, the additional resources needed to bring down the overall infection in a delayed intervention are significant, with inferior results. The disease module can be tailored for different pathogens. It expands the well-used SEIR model to include social and intervention activities, asymptomatic and post-recovery transmission, hospitalization, outcome of recovery, and funeral events. The model also examines the transmission rate of healthcare workers and allows for heterogenous infection factors among different groups. It also captures time-variant human behavior during the horizon of an outbreak. The framework optimizes the intervention timeline and resource allocation during an infectious disease outbreak and offers insights into resource availability in time and quantity can affect the disease trends and containment significantly. This can inform policy, disease management and resource allocation. While focusing on bed availability for quarantine and treatment appears to be simplistic, their necessity for Ebola responses cannot be overemphasized. We link these insights to a web-based tool to provide quick and intuitive observations for decision making and investigation of the disease outbreak situation. Subsequent use of the system to determine the optimal timing and effectiveness and tradeoffs analysis of various non-pharmaceutical intervention strategies for COVID-19 provide a foundation for policy makers to execute the first-step response. These results have been implemented on the ground since March 2020. The web-based tool pinpoints accurately the import of disease from global travels and associated disease spread and health burdens. This prospectively affirms the importance of such a real-time computational system, and its availability before onset of a pandemic.

1. Introduction

SARs, bird flu, H1N1, Ebola, Zika and the current SARS-CoV-2 outbreaks underscore the critical importance of emergency response and medical preparedness. Such needs are widespread as globalization and air transportation facilitate rapid disease spread across the world. For the past two decades, as the public health community worked to strengthen national systems to avoid international spread of disease, governing bodies increasingly recognized that biological threats not only have global health impacts but also wide-ranging socioeconomic disruptions.

Mathematical models of dynamic systems and their interactions are powerful tools for analyzing disease outbreaks and supporting real-time decision-making. Computational tools of infectious disease outbreaks and epidemics offer insights in propagation patterns and help policy makers to synthesize potential interventions. This facilitates strategic planning and establishment of guidelines to prevent further disease spread. These models focus on describing the mechanism of disease propagation and model it as processes that result in the transition of individuals of the population between different disease stages or compartments. While many existing models incorporate contact tracing to predict spread pattern, key elements on optimal usage of scarce resources and effective and efficient process performance (e.g., diagnostics and screening, non-pharmaceutical interventions (NPIs), trained personnel/robots and medical resources for treatment, decontamination, vaccination) have not been integrated.

Since Kermack and McKendrick (1) established the theory of the SIR models and other corresponding compartmental models in the 1920s and 1930s, ordinary-differential-equation based compartmental models are among the most popular methods. Researchers continue to expand and employ them in modeling numerous infectious diseases.

2 Methods and Design
Over the last two decades, our team has worked with thousands of public health leaders and frontline emergency responders, providing them with decision support tools and analytic-informatics expertise as they respond to numerous domestic and global public health crises, and establish state and federal guidelines. Specifically, we have developed
specialized mathematical theory and computational systems for numerous infectious diseases including smallpox, hepatitis A, H1N1, Ebola, Zika, MERS, avian flu, and COVID-19 (17,19,20,21,24-28) and have the honor to assist on-the-ground operations with great success (16,18). Our experiences and lessons learnt reveal the challenge and urgency to derive a unified mathematical theory that is applicable to any type of infectious disease (29) and develop a holistic biological-behavior-intervention computational framework that allows for in-depth validation and adoption.

In this study, we design a biological-behavior-intervention system computational decision modeling framework that simultaneously (i) captures disease spread characteristics, (ii) models social, human behavior and dynamic environment, (iii) incorporates resource usage and intervention logistics, and (iv) allows for system optimization to minimize infection and mortality under time and resource constraints. We first test our model using the 2014-2016 real data from Guinea, Sierra Leone, and Liberia and compare the optimal resource and predicted trend of the outbreak against the actual reported cases. Our result suggests that timely and optimal allocation of limited medical resources during pandemics is crucial to minimize the cumulative infections and achieve early containment. Using these historical data, the system predicts with promising results the recent 2018-2020 Ebola outbreak in DRC. We link these insights and design a web-based tool for public health and policy makers to investigate the disease transmission outbreak and intervention impact. The web-application is universal and practical and can be generalized to other infectious diseases.

Since December 2019, the system has been used for COVID-19 response. Using early results from Germany and China, we established human-to-human transmission and asymptomatic transmission in January 2020. In February 2020, we employed the system to optimize the timing and impact of non-pharmaceutical intervention (NPI) of school closure, business telework, facemask and social distancing. Our findings echo the Ebola results, and underscore the importance of early NPI implementation that can significantly reduce deaths and overall infections, and facilitate early containment. Our recommendations to local and state officials triggered the initial school closures. It also facilitated adoption of telework by a major private organization. Furthermore, the prospective prediction of confirmed cases and deaths for a collection of cities and counties prove to be very accurate. Currently, we continue to support safe re-opening, mass vaccination and evidence-based and personalized treatment.

2 Methods and Design
Our informatics framework combines disease modelling for infectious virus with stratifications for social behavior and employment, and resource logistics (Figure 1). The framework accounts for disease progression and transmission (light blue) that vary according to the specific pathogen. It incorporates human behavior, social and environmental influences, and risk factors (light beige) to model heterogeneous transmission dynamics on how disease spread takes hold. Interventions, pharmaceutical or non-pharmaceutical, in combination or alone, play crucial roles in containing the disease. For example, for Ebola, safe funerals offer a venue to minimize disease spread that would otherwise
occur during traditional funeral ceremonies. This is both human/social behavior change as well as a means of non-pharmaceutical intervention. Other behavioral changes such as handwashing and use of face masks can have significant positive impact in combating contagious infectious disease, as evidenced by the current COVID-19 pandemic (26-28).

2.1 Compartmental Model for Disease Propagation and Dynamic Heterogeneous Interaction

Our disease module employs an ordinary differential equation-based disease propagation model and generalizes the SEIR model to the specific pathogens. For Ebola, due to the high possibility of transmission during traditional funerals without protection, deceased patients who do not receive cremation will stay infectious. A new stage \( F \) for the funeral is added to model the transmission happens during funerals. If a deceased patient is buried instead of cremated, it is not removed from the system immediately; instead, it stays in stage \( F \) for a period of time before being removed. Another stage introduced to the model is \( H \) for hospitalization. Depending on available medical resource, infectious individuals can be hospitalized, and are quarantined from outside civilians. Therefore, patients in stage \( H \) are not infectious to civilians but are infectious to healthcare workers who have direct contact with them. Similar to stage \( I \), a patient in stage \( H \) can either recover (\( R \)) or die, and the deceased hospitalized patients can either be buried or cremated. Thus, the disease transmission system for civilians contains seven stages: \( S \) (susceptible), \( E \) (exposed), \( I \) (infectious), \( R \) (recovered), \( H \) (hospitalized), \( F \) (funeral), and \( D \) (deceased; removed from the system), as depicted in Figure 2a.

Healthcare workers are also in danger of getting infected and they face different situations than local civilians. Although they have proper protection within the hospital, there is still a possibility of getting infected. There are resources such that healthcare workers are dealt with caution to minimize cross infection to others, i.e., there is no funeral stage (of potential infection) for healthcare workers. Let \( HS, HE, HI, HH, HR, \) and \( HD \) denote the 6 stages for healthcare workers (Figure 2b).

These two groups are not isolated: Healthcare workers get exposed (\( HE \)) because of their close physical contact with patients who are hospitalized (\( H \)) as well as with infectious healthcare workers (\( HI \)). For brevity, in the results, healthcare workers are assumed to be better informed and protected than outside civilians, and hence do not get infected by contacting infectious civilians (\( I \)). Furthermore, if healthcare workers are infected (\( HI \)) they do not infect healthy civilians (\( S \)) as they take extra precautions. In section Discussion, we describe time-variant parameters that are introduced to handle varying transmission factors among heterogeneous groups.

The final component is the integration of the two compartmental models above with interrelation. We define the disease stage space \( \Phi = (S, E, I, R, H, F, D, HS, HE, HI, HH, HR, HD) \). Let the civilian population in the system who are not hospitalized be \( N = S + E + I + R + F \), and let the total number of healthcare workers be \( HN = HS + HE + HI + HR + HD \). Let \( \mu_s \) denote the average number of infectious contacts each individual makes in a unit time, i.e., the baseline contact rate; \( \mu_F \) is the transition rate from exposed stage to the infectious stage and it is characterized by the incubation period of the virus; \( \mu_I \) is the baseline transition rate from infectious stage to stage \( R, F, \) or \( D \) and it is determined by the duration of the infection; \( \mu_H \) is the transition rate from infectious stage to hospitalized or the inverse of the time between infection to admission to healthcare facility; \( \mu_H \) is the transition rate from stage \( H \) to stage \( R, F, \) or \( D \), or the inverse of the duration of hospitalization; \( \mu_F \) is the transition rate from stage \( F \) to stage \( D \) and it is characterized by the duration of the funeral.

Other parameters in the model include \( H_m \), the total number of beds available. Although Ebola is a severe, often fatal disease, getting medical care early can make a significant difference. This reflects the availability of healthcare resource in the West African countries during the outbreak: \( p_{HD} \) and \( p_D \) are the death rate due to infections with and without hospitalization, respectively. \( p_{HF} \) and \( p_F \) are the percentages of deceased patients who will go through traditional burial (non-cremation) with and without hospitalization, respectively. \( p_{SF} \) is the adjusted factor of baseline contact rate for funerals/unsafe burials, and \( f \) is the adjusted factor of healthcare worker transmission rate, reflecting their proper protection.

The following system represents the dynamics of their heterogeneous interaction:

\[
\begin{align*}
\frac{d}{dt} S &= -\mu_s S \left( 1 + p_{SF} F \right) \\
\frac{d}{dt} E &= \mu_s S \left( 1 + p_{SF} F \right) - \mu_E E \\
\frac{d}{dt} I &= \mu_E E - \mu_I I - \mu_I I \\
\frac{d}{dt} H &= \mu_I I - \mu_H H \\
\frac{d}{dt} HS &= -\mu_{HF} \frac{HS}{HN + HH} \left( H + HI + HH \right) \\
\frac{d}{dt} HE &= \mu_{HF} \frac{HS}{HN + HH} \left( H + HI + HH \right) - \mu_E HE \\
\frac{d}{dt} HI &= \mu_E HE - \mu_H HI \\
\frac{d}{dt} HH &= \mu_H HI - \mu_H HH
\end{align*}
\]
The model divides the disease spread into two categories: (i) disease propagation outside healthcare facilities that infects civilians, and (ii) disease propagation within healthcare facilities that infects healthcare workers. In addition, the heterogeneous infectivity among civilians and healthcare workers is characterized by factor \( f \) to capture the proper knowledge and protections of healthcare workers. Numerous risk groups can be expanded based on different disease vulnerabilities and transmission vectors / factors (19,40). The modeling framework is not limited to Ebola outbreaks or hospital beds; by setting proper parameters and types of intervention, it can be used to estimate and predict the potential disease trend of outbreaks of other infectious diseases and strategize the best intervention options. The Results section includes tailored model for SARS-CoV-2 analyses.

2.2 Optimization Framework for Intervention, Resource Allocation, and Disease Containment

One major challenge faced by resource-constrained countries is the lack of healthcare facilities and infrastructures. The current COVID-19 pandemic clearly underscores the devastation and the intense healthcare and resource burden. This is sorely felt in developing countries. During the 2014 Ebola outbreak, Guinea did not have enough hospital beds or healthcare facilities, thus not all patients could be properly quarantined or receive medical care. Without available beds, patients could only be treated at home, which brought risks to their relatives and neighbors. The parameter \( p_H \) in the model can be used to capture the available beds (yes, or no): if there are beds available at hospitals or healthcare facilities, then \( p_H = 1 \), i.e., infectious patients will be admitted to quarantine; otherwise \( p_H = 0 \). Essentially, \( p_H \) can be seen as an indicator of whether there are vacancies for quarantine and treatment. Therefore, \( p_H = \{ H < H_m \} \), where \( I \) is the indicator function. Thus \( p_H \) denotes if an infected patient receives the needed medical resources. We use the number of beds available in each affected location as the main factor in controlling the spread of the virus and investigate the impact of availability and delayed supply of beds; and determine the number of beds required to contain the outbreak. We estimate total infections and the timeline of the outbreak, including those for healthcare workers. These additional beds and the associated resources and healthcare workers are from international assistance. However, international assistance is limited, and devoting too many resources to an infected area does not necessarily accelerate the containment, rather it may increase risk of infections among healthcare workers. Therefore, we design an optimization framework to minimize the number of beds required and the associated medical resources subject to the constraints on the total infections among civilians and healthcare workers at containment and the time needed to achieve containment. In particular, the following constrained optimization problem will be solved numerically:

\[
\min_{H_m} \quad I \leq I_0, H \leq H_0, T \leq T_0
\]

such that:

\[
\frac{d}{dt} R = (1 - p_D) \mu I + (1 - p_H) \mu_H
\]

\[
\frac{d}{dt} F = \mu_H \mu I + \mu_F F
\]

\[
\frac{d}{dt} D = (1 - p_F) \mu I + (1 - p_H) \mu_H F + \mu_F F
\]

\[
\frac{d}{dt} HR = (1 - p_H) \mu_H HH
\]

\[
\frac{d}{dt} HD = p_H \mu_H HH
\]

\[
\frac{d}{dt} H = p_H \mu_H HH - \mu_F F
\]

\[
\frac{d}{dt} I = \mu_H F - \mu I - (1 - p_F) \mu I - (1 - p_H) \mu_H I
\]

\[
\frac{d}{dt} F = \mu_F F - \mu_F F
\]

\[
\frac{d}{dt} D = (1 - p_F) \mu I + (1 - p_H) \mu_H D + \mu_F F
\]

\[
\frac{d}{dt} H = p_H \mu_H HH - \mu_F F
\]

where \( I \) and \( H \) are the numbers of infections among civilians and healthcare workers by the end of outbreak, respectively, while \( I_0 \) and \( H_0 \) being the target number of infections among civilians and healthcare workers at the end of the outbreak. Here, \( T_0 \) is the target time of containment, and \( T \) is the actual time of containment, and defined as \( T = \min \{ t : \frac{1}{I_0} t e^{-\ln 2} \leq \delta \} \), i.e., the earliest time such that the change rate of infections is controlled by a certain level \( \delta \). Other constraints can also be introduced to obtain the optimal allocation of healthcare resources under different scenarios (e.g., labor, protective gears, ventilators etc). The variables in this optimization framework are the output of the system of ordinary differential equations of the disease module, thus searching for optimal solutions is computationally expensive. We apply a line search algorithm for a given structure of parameters and search for the optimal setting iteratively on the surface generated by the solution to the differential equations. To avoid local minima, the line search is conducted on multiple starting points. Each iteration requires about 10 CPU minutes to solve.

3. Results

3.1 2014-2016 Ebola Numerical experiments are first performed for the 2014-2016 outbreak in Guinea, Sierra Leone, and Liberia to validate the model and predict the trend of disease spread. Table 1 summarizes the common parameters used by the experiments. Other parameters are country-specific, in particular the basic reproduction number is estimated using the CDC historical statistics (30). Table 2 summarizes the individualized parameters. For each country, we use the first five months for training and parameter estimates, and then we predict the disease trends. We optimize the timing and resource needs to achieve disease containment within 6 months and contrast the outcome against several scenarios.

WHO report, Guinea had 160 beds by October 250 total infections (blue curve). According to the 200 additional beds were made available by disease outbreak. The optimal (minimum) resource requirements for containment within 6 months occurs when 50 beds observed starting from April 15, 2014. The basic reproduction number by mid 2015 with approximately 3,800 infections 2014. With 160 beds, the epidemic was contained by the end of 2015 (red solid curve). This reflects closely the real situation (orange dotted curve). If the intervention reflect ing the change of human behavior and the effort of interventions with public awareness of the disease outbreak. The optimal (minimum) resource requirements for containment within 6 months occurs when 50 beds are available within a month. The epidemic could have been rapidly contained with no more than 250 total infections (blue curve). According to the WHO report, Guinea had 160 beds by October 2014. With 160 beds, the epidemic was contained by mid 2015 with approximately 3,800 infections by the end of 2015 (red solid curve). This reflects closely the real situation (orange dotted curve). If 200 additional beds were made available by November 2014, the outbreak would have been contained by the end of 2015 with roughly 3,500 cumulative infections (yellow curve). We observe that timing is critical. Rapid containment can be achieved with minimal extra resources if they become available early on. Late availability of beds only marginally reduces the overall infections.

The analyses for Sierra Leone and Liberia bear similar patterns. Figure 4 shows the performance of the 3 countries under different resources and response timelines evaluated under six metrics: time to containment, resource needs, total infections and deaths, healthcare workers (HCW) infections and deaths. We normalize the results with respect to the real data. Hence, a value 1 means it performs the same as the real situation, < 1 is an improvement, and > 1 is a degradation. The brown curve uses the resources reported by WHO. Our model results in metrics all within the interval (0.95, 1.06), indicating that the model predicts well. Uniformly, the results show that timely action within 1.5 months (optimal: blue curves) from the onset of confirmed cases can cut down 90% of overall infections and bring rapid containment within 6-8 months. The optimal medical resources (beds) required are minor (16.6% to 31.3% with respect to the real-world situation) and would ensure proper treatment and quarantine of patients while reducing the risk of infections among healthcare workers. If intervention of medical resources are injected within 5 months (non-optimal), infections will be reduced by over 50% with containment achieved within 12 months. However, when compared to the optimal solution, its benefit (in infection/death control) would be reduced by 10 to over 100 fold and time to containment would increase by 2-4 fold when intervention and medical resources are delayed. We illustrate one such non-optimal solution (Liberia, deep blue curves) that uses 10 times the bed resources, and results in 24-fold

Table 2. Parameters Specific for Each Country

Figure 3 shows the number of predicted infections in Guinea under different scenarios. The intervention effect was observed starting from April 15, 2014. The basic reproduction number $R_0$ changes twice (1.45 to 0.9, then to 1.3) during the intervention reflecting the change of human behavior and the effort of interventions with public awareness of the disease outbreak. The optimal (minimum) resource requirements for containment within 6 months occurs when 50 beds are available within a month. The epidemic could have been rapidly contained with no more than 250 total infections (blue curve). According to the WHO report, Guinea had 160 beds by October 2014. Late availability of beds only marginally reduces the overall infections.

The analyses for Sierra Leone and Liberia bear similar patterns. Figure 4 shows the performance of the 3 countries under different resources and response timelines evaluated under six metrics: time to containment, resource needs, total infections and deaths, healthcare workers (HCW) infections and deaths. We normalize the results with respect to the real data. Hence, a value 1 means it performs the same as the real situation, < 1 is an improvement, and > 1 is a degradation. The brown curve uses the resources reported by WHO. Our model results in metrics all within the interval (0.95, 1.06), indicating that the model predicts well. Uniformly, the results show that timely action within 1.5 months (optimal: blue curves) from the onset of confirmed cases can cut down 90% of overall infections and bring rapid containment within 6-8 months. The optimal medical resources (beds) required are minor (16.6% to 31.3% with respect to the real-world situation) and would ensure proper treatment and quarantine of patients while reducing the risk of infections among healthcare workers. If intervention of medical resources are injected within 5 months (non-optimal), infections will be reduced by over 50% with containment achieved within 12 months. However, when compared to the optimal solution, its benefit (in infection/death control) would be reduced by 10 to over 100 fold and time to containment would increase by 2-4 fold when intervention and medical resources are delayed. We illustrate one such non-optimal solution (Liberia, deep blue curves) that uses 10 times the bed resources, and results in 24-fold
total infection and 2.2-fold in time to containment with respect to the optimal solution. However, it still outperforms the real situation: using 80% of the resources, reducing 25% of the time to containment and 41%-55% infection and deaths. The orange curves correspond to delayed interventions that use excess amounts of medical resources, yet the results are inferior to the optimal solution, and a marginal improvement over the real-world situation. These findings reaffirm that with delayed intervention, the extra resources needed to bring down the overall infections are significant.

At the onset of disease, the spread appears to be extremely sensitive to timing of available beds. The red curve on Liberia shows that even with the same resources (as the brown curve), a mere delay of 2 days in receiving half of the resources would result in 23% increase in infections and deaths Bed resources available at the fast-spreading phase of the outbreak has a huge impact on its propagation. Policy makers must act decisively, and the impact can be very significant.

Our analyses also reveal that early intervention has critical impact on healthcare workers. Although protected by protective gear against the virus, healthcare workers are still at high risk of infection due to their close contact with infected patients. At the initial phase of the pandemic, i.e., the second half of 2014, the number of infections among healthcare workers increased drastically. For example, according to our model, under the real-world bed availability, the infections among healthcare workers in Liberia reached 250 after 6 months of the initial outbreak and 368 at disease containment. There are several reasons to explain this phenomenon: insufficient personal protective gear before international intervention, improper use of protective gear, and severe shortage of medical staff among these resource-constrained countries to combat a relatively large outbreak. We note that the loss of medical staff including experienced doctors and nurses made it increasingly difficult to control the outbreak. This triggered the necessary assistance by foreign countries, including sending in healthcare workers who could provide intensive patient care.

3.2 COVID-19 In January 2020, we expanded our 6-stage SEPAIR model (17) that incorporates pre-symptomatic infectious (P) and asymptomatic infectious (A) to include post-recovery infectious (Q), recovered-immune (R), and recovered-not-immune (T) to model the SARS-CoV-2 virus (Figure 5). Below, we briefly present our findings regarding timing and effectiveness of NPI during the early stage of the pandemic.

Based on public data from China and Germany, we established the first analytic results of SARS-CoV-2 virus and the resulting 2019 coronavirus disease. Specifically, our analyses reveal the index case in China must have begun no later than November 15, 2019; and that asymptomatic spread contributes substantially (at least 1/3 to ½) to the disease propagation. These critical insights set a tone of urgency as we discussed our findings to state and local public health emergency leaders. Subsequent analysis in February 2020 confirmed the effectiveness of NPI in Singapore and Hong Kong. This along with public data from Diamond Princess, allowed us to model NPI interventions in dozens of cities and counties in the United States in February 2020, including New York City, King County Seattle, Santa Clara and San Diego California, Washington DC, Atlanta Georgia, and Montgomery, Baltimore counties in Maryland (26-28).

Table 3 summarizes the parameters used in the SARS-CoV-2 analyses. Other parameters are region-specific, including population, total number of students, workforce / labor statistics, and travel patterns. Figure 6 shows that uniformly across the U.S., timely school closure (upon confirmed onset of infected cases) can potentially reduce 32%-77% of the total infection within 4 weeks, and 98% within 12 weeks. A delay of two weeks would render only 1-27% reduction in the initial month, and 94% by 14 weeks. Adding 50% of tele-work workforce can reduce infection over 77% within 4 weeks and 97% within 8 weeks. Without NPI, and with the current bed availability, about 48% - 85% of population will be infected before herd immunity can be achieved. It also shows that with a compliance of 90%, facemasks can reduce 35%-57% of infection. It illustrates timing of implementation is of paramount importance, and that without these interventions, our healthcare system will be overwhelmed.

3.3 A web-based tool for investigating disease transmission, intervention strategies, and aiding decision-making We design a web-based tool, RealOpt-Ebola©, on top of our existing CDC emergency response decision support system RealOpt-Regional© \((14-16,18,20)\) (Figure 7). RealOpt-Ebola links to our computational framework and is tailored to help public health and policy makers investigate the transmission of a disease outbreak (both regionally and internationally). The system translates user input into backend mathematical models. Users can analyze scenarios and strategize interventions to control the outbreak. Since solving the ODE disease module is computationally expensive on the client side, we design a modified fast algorithm of the inclined decay with an exponential adjustment model \((5)\). The fast heuristics returns solution rapidly with minimal difference in solution quality. Different scenarios analysis can be performed by specifying different model parameters (e.g., the average number of contacts per infected individual each day, risk factor, and the distribution of incubation period, etc.). Users can also introduce disease control by adjusting the control effectiveness. The system then simulates the interventions being implemented and returns the containment curves showing how the disease spread would have changed as a result.

RealOpt-Ebola© includes all recorded Ebola cases occurring since 2014. Users can select any month and view the number and geographic distribution of the cases, and perform disease spread and predictive analysis. Besides modeling and visualizing the Ebola outbreak (e.g., in West Africa, DRC), the interactive map tool in RealOpt-Ebola can model the influence of the outbreak to other countries (e.g., infected patients arrived via international flights). Specifically, when performing the predicted infection trend in a country, e.g., Africa, some infected individuals may travel to other countries outside by air. In this case, users can initialize a new scenario analysis in the destination of that flight and evaluate the impact of the traveling patients. A new disease model will be initialized which simulates the disease spread scenario at the destination. If there are no travel restrictions, infectious travelers can lead to disastrous consequences. RealOpt-Ebola’s surveillance and simulation modules enable emergency planners to analyze the future trend of the outbreak with an up-to-date information feed and evaluate the strategies for containment and the severity of disease spread due to the infectious travelers. Supported by proper model parameters (from historical data or estimates), this tool can also be used to monitor other regional disease outbreaks.
Since 2016, we have disseminated RealOpt-Ebola on the ground in Africa, assisting in biosurveillance, monitoring, and tracking of risk and potential spread, and rapid response actions. Policy makers use the predicted outcome to produce actionable policies regarding preparedness timeline and expected risks. The system is also adapted to RealOpt-COVID to help predict and evaluate impacts of global travel restrictions in the early stage of the COVID-19 outbreak.

4. Discussion
This work focuses on designing a holistic biological-behavior-intervention system computational decision modeling framework that simultaneously (i) captures disease spread characteristics, (ii) models social, human behavior and dynamic environment, (iii) incorporates resource usage and intervention logistics, and (iv) allows for system optimization to minimize infection and mortality under time and resource constraints. To the best of our knowledge, the modeling framework is the first that incorporates biology of the virus, human and social behavior and available resources, and intervention and operations logistics into a single computational framework. The system allows population-based analysis as well as county-level local studies.

Analysis and modeling provide important tools to understanding the usefulness of timely interventions and risks associated with delays. The outcomes presented herein offer an argument for having capacity for timely interventions.

The disease module adapts to different pathogens and disease pathways. It allows heterogeneous compartmental modules for different (risk) groups and with dynamic contact environments. Human behaviors that can be modelled include those that reduce disease spread such as self-protection, and those that fuel spread such as crowded dwellings and work environments, and certain social events or religious / cultural beliefs. All these play key roles in the disease dynamic. Resource needs arise naturally -- beds, providers, personal protective equipment, drugs, medical and life-support devices, vaccines, etc. These interlay with operations processes and supply-and-demand logistics. Smart and rapid resource allocation must be carried out under limited time and resources when minutes mean life-and-death.

The informatics framework allows one to focus on the problem at hand and analyze optimal strategies, whether it is to optimize timing and bed allocations for the treatment of patients, or optimal timing in rolling out combinations of NPIs. All these decisions require actions by policy makers. The informatics framework empowers policy makers to take decisive actions with informed risks and tradeoffs and understanding of the look-ahead situations.

During a pandemic or any critical mission, time, labor, and resources are essential yet are limited. Policy makers face tough decisions on actions, when and how to carry out, and allocate optimally what types of resources, how many and to whom, with the goals to protect the population and save as many lives as possible. The optimization module can accommodate various objectives. In this paper, we demonstrate its usage in optimizing the timing for intervention and (minimizing) the resources needed to contain the Ebola crisis; and the timing of combination strategies of non-pharmaceutical interventions that minimizes total infections and deaths for COVID-19. The system considers individual behavior, personal actions, and social influence. It can also be used, among a wealth of applications, to optimize resource allocation in vaccine prioritization, mass diagnostic testing, and vaccination events (14,15,16,18,19,40). The interlace of optimization within simulation and ODE systems is novel and useful yet computationally challenging.

For the 2014-2016 Ebola outbreak in Guinea, Sierra Leone, and Liberia, using the initial infection on the ground and the initial 5 months as training, our model predicts the subsequent disease trends given the available medical resources. The optimal timing and resource needs to ensure rapid disease containment within 6 – 8 months can be achieved through early intervention (within 1.5 months of onset of confirmed cases). In this case, a relatively small resource investment yields over 90% reduction in overall infections and deaths. Our Ebola predictions, reported first in November 2014 (24) and January 2015 (25) to the State Department and the United Nations, was promising and rather accurate in reflecting the on-the-ground situations. In 2016, the team was in W. Africa training local healthcare and emergency responders in using the early version of the RealOpt-Ebola webtool for monitoring and optimizing their resources. Predictions for the 2018-2020 DRC Ebola outbreak showcase that historical data can be highly informative in predicting future trends, empowering policy makers to take timely risk-informed actions.

Since December 2019, our system has been used for modeling and evaluating effectiveness and timing of intervention strategies for COVID-19, with some results implemented on the ground in the United States since March 2020 (26-28,40). Using data from other countries, the predictions for the US offer insightful risks and tradeoffs. The NPI intervention and case/death prediction was accurate and was adopted by policymakers during the initial stage of the
pandemic. Our analysis shows that early NPI intervention can save lives (98%) and achieve disease containment within 6-9 months. Delaying actions add significant disease and resource burden while producing inferior overall outcome. The web-based tool pinpoints accurately the import of disease from global travels and associated disease spread and health burdens. This prospectively affirms the importance of such a real-time computational system, and its availability before onset of a pandemic.

COVID-19 has revealed major challenges in science-based recommendations. The rippling and interdepending downstream impacts of NPI create social, economic, and political implications that prove to be extremely controversial for timely decisions. Nonetheless, analytic results offer actionable steps and opportunities for valuable discussion by policy makers. Our theoretical and computational framework continues to facilitate states and local jurisdictions, including determining optimal diagnostic and pooling strategies, vaccination prioritization, mass vaccination, variant effects on herd immunity, and the after-COVID next generation health systems delivery.

The model can handle heterogeneous transmission and risk factors. If the transition rate from stage $I$ to stage $H$ is faster, which requires rapid diagnosis of infectious patients and immediate transition to hospitalization, the outbreak would also be contained much faster. The infections among healthcare workers in affected populations are also estimated. Healthcare workers remain at high risk of getting infected due to lack of training, insufficient protective equipment and working in highly contagious and stressed conditions.

The informatics framework is general-purpose and allows analyses of complicated scenarios, such as multiple groups with different parameters. In this paper, the baseline contact rate between civilians is treated as a linear relationship. Since virus can spread via different means and contacts, the possibility of infection rate of individuals in stage $S$ may be nonlinear depending on how they interact with the infected ones, or whether they make direct contact, and under what environment. Figure 8 shows types of contacts of different risk groups and environments. Under this setup, the civilians, healthcare workers, event handlers, etc. can be further divided into groups with different parameters associated with different contacts. Similarly, as more organizations get involved in the outbreak, other groups such as volunteers and military forces can be added to the model with their own compartments and model parameters. This enables us to predict the number of infections among different groups and evaluates their risk to mount respective mitigation strategies, respectively. In our vaccine prioritization and mass vaccination work, populations are divided into different risk-groups according to age, health conditions and employment nature, and vaccine allocation and timing are optimized. The model simultaneously tracks infections/deaths and optimizes overall disease spread for both intra-facility and various indoor activities, and outside in the public, where dynamic transmission patterns are incorporated (19,40).

The equation captures the behavior of healthcare workers during different times of the day. Other equations in the system parameter a constant value, we set the parameters as functions of time. During different times of a day (different social events, or different phases of the pandemic), people interact differently, and this affects the spread of the virus. For example, healthcare workers have different infection rates depending on if they are inside their work facilities or at home or in social settings. If a healthcare worker is infected but not hospitalized yet, civilians may get infected if their social contact with infected civilians, or attend an unsafe funeral, or social events. Then

\[
\frac{d}{dt} S = -\mu_S \left( I + p_F S + \eta(t) p_H I \right)
\]

where $\eta(t)$ is a time-variant parameter indicating if the healthcare workers are outside the healthcare facilities at time $t$, and $p_D$ is the proportion of these off-duty healthcare workers. Similarly, off-duty healthcare workers may come into contact with infected civilians, or attend an unsafe funeral, or social events. Then

\[
\frac{d}{dt} HS = -\left( 1 - \eta(t) \right) \mu_F \frac{HS}{HN + HH} (H + H + HH) - \eta(t) \mu_F \frac{HS}{(1 - p_D)HN + HH} (H + (1 - p_D)H + HH) + \frac{p_D HS}{p_D HN + N} (I + p_F S + p_H I)
\]

This equation captures the behavior of healthcare workers during different times of the day. Other equations in the system can be updated accordingly. Parameters such as the basic reproduction rate can also be defined as functions of time to
accommodate the changes in policy or environment during the outbreak. This enables the modeling and analysis of complicated situations.

In our recent work, we apply these heterogeneous risk factors and dynamic transmissions to optimize vaccine prioritization and mass vaccination strategies. Our findings show that it is of paramount importance to split available vaccines optimally among the high-risk groups and the general public (40). The reduction in total infections and deaths, as shown in Figure 9, is significant.

The biological-behavior intervention modeling and optimization framework developed herein can be adapted to other kinds of epidemics. With proper set up of the compartmental model and parameters, as well as the definition of interventions, and medical / resources and the role they play in mitigating the spread of the disease, one can utilize the system and analysis procedure to predict the future development of an outbreak and optimize the timing, and types (and combinations) of interventions and optimal allocation of resources to contain it. This will be of great significance in the current and future global pandemic preparedness.

Abstract

Audio is increasingly used to communicate health information. Initial evaluations have shown it to be an effective means with many features that can be optimized. This study focuses on missing functional elements: words that relate concepts in a sentence but are often excluded for brevity. They are not easily recognizable without linguistics expertise but can be detected algorithmically. Two studies showed that they are common and affect comprehension. A corpus statistics study with medical (Cochrane sentences, N=44,488) and general text (English and Simple English Wikipedia sentences, N=318,056 each) showed that functional elements were missing in 20-30\% of sentences. A user study with Cochrane (N=50) and Wikipedia (N=50) paragraphs in text and audio format showed that more missing functional elements increased perceived difficulty of reading text, with the effect less pronounced with audio, and increased actual difficulty of both written and audio information with less information recalled with more missing elements.

Introduction

Health literacy is vital for achieving and maintaining good health. In the previous decade in the US, several national programs have emphasized this goal and its importance. For example, the Affordable Care Act\textsuperscript{(1)} emphasized patient-centeredness, the National Action Plan to Improve Health Literacy\textsuperscript{(2)} specified national goals, and the Plain Writing Act\textsuperscript{(3)} demanded clarity in government communications\textsuperscript{(4)}. However, these existing guidelines do not focus and have not been validated for new information distribution methods. They focus on text and visual presentation, but to our knowledge, they have not been updated for audio.

As technology evolves, new modes for communication are being created to provide access to health information. Audio is becoming increasingly popular with mobile devices using virtual assistants and smart speakers. Smart speakers are now ubiquitous in US households and are increasingly used for health-related application. By 2020 there were about 87.7M smart speakers used in the US\textsuperscript{(5, 6)} with annual growth of 30-40\%. Hospitals are testing the use of smart speakers\textsuperscript{(7, 8)} and in 2019, about 16\% of all questions asked of a smart speaker were health and wellness questions\textsuperscript{(6)}. There are few studies and little existing expertise on how to create audio or to combine audio with text. For example, the Plain Language Summit in 2019\textsuperscript{(9)}, described plain language as “language that people can understand the first time they read or hear it,” but audio was not covered during the summit.

With the increasing popularity of audio as an information source, research is needed to design the best strategies for using this resource as a medium for disseminating health information. In our early work, we focused on discovering lexical, semantic, syntactic, and composition features in text with demonstrated impact on comprehension. We are expanding this work to audio to discover how best to create content for audio consumption. We have already established that health information consumers can learn from audio information as well as from text information\textsuperscript{(10)}. Critically, unlike previous work that only focused on text, we now examine both text and audio to see how text features affect comprehension in the different presentation formats.

Sentences in English rely upon syntactic structure to convey the meaning of a sentence. The structure of a sentence dictates the order of words in a sentence, but also relies on function words that help join different phrases and clauses in a sentence. These function words tell us about the relationships between content words, but often carry little content themselves. For example, the word ‘that’ in a phrase such as ‘parasites that impact’, relates the two content words. Often, these function words are left out in spoken language or in complex written language for various reasons. When these words are left out, i.e., missing functional elements, the person reading the sentence has less information available to decode the meaning of the sentences than if all of these words were included.

We hypothesize that when there are missing functional elements in a sentence, the sentence will be more difficult to readers than if these functional elements were included because explicit connections between content-bearing terms are omitted. We developed an algorithm to detect missing functional elements in text. Using this algorithm, we examine the frequency of missing function elements in two corpora (medical and general) and evaluated the effect of missing elements on comprehension with both text and audio. Missing elements are a very frequent phenomenon,
occurring in almost a third of the sentences in our corpora. We found that there is a subtle effect of missing functional elements on comprehension and we found differences between the text and audio presentation. Even though the effects are subtle, because missing elements occur so frequently, the effect is important.

The current work brings two contributions. The first is a demonstration that some text features, not easily recognize by non-experts, are frequently found in text, hence the usefulness of algorithmically identifying them. The second contribution is in showing how such features affect comprehension and how this differs depending on the mode of interaction with the information (text vs audio). For brevity, we will use the phrase ‘missing elements’.

**Background**

**Content Simplification.** Most literacy research has focused on text as the mode of distribution and examined how to make that text as accessible as possible. Given some existing text, the goal of text simplification is to transform that text into a variant that is more understandable. In the healthcare community, the majority of work has used readability formulas to aid content creators (e.g., medical writers) in simplifying text. A variety of different metrics have been proposed, e.g., Flesh-Kincaid and Reading Ease, and Simple Measure of Gobbledygook (SMOG), and some more comprehensive tools, e.g., Coh-Metrix, have been created. The scores assigned by these metrics and tools indicate the difficulty level of a text and there are agreed upon limits for text intended for use by non-experts. For example, the advice is to write at 6th to 8th grade level. This approach suffers from three main problems. First, there is a single score assigned to an entire text; unless a writer is very familiar with the inner workings of the formula, adjusting the text to improve the score is difficult. Second, these formulas rely on simple text statistics that tend to correlate with text readability, e.g., word length, but often don’t accurately measure, on a per instance case, the actual text difficulty. Well written, understandable text tends to have better readability score, however, simply manipulating the components of the readability metrics does not create text that is more readable or easier to understand. The following examples were evaluated using the built-in Flesh-Kincaid formulas in Microsoft Word:

- Eating fruit is a healthy habit and enjoyable too. (7.5 Grade Level)
- Eating fruit is. A healthy habit and enjoyable too. (5.8 Grade Level)
- Eating fruit is. A healthy habit. And enjoyable too. (5.2 Grade Level)

Our own work and that of others have shown that there is no relationship between these scores and reader comprehension. Third, as we consider new modes of communication, i.e., audio, these formulas have not been validated and it is not clear how the formulas will translate to this new medium.

On the other end of the spectrum, there has been a lot of work recently that focuses on fully automated approaches to text simplification that do not require any human editing. These approaches usually rely on a sentence-aligned training corpus of difficult sentences aligned to corresponding simple sentences. Most of these approaches have leveraged models that have been successful for machine translation, including phrasal models and syntactic models and, most recently, sequence-to-sequence neural networks. There are two key challenges with applying these models in the health and medical domain. First, the performance of these models, including our own, is still not nearly good enough for practical application, particularly in a domain like health where correctness is critical. Second, currently, there are no good large sentence-aligned corpora of medical text available. While general domain text will provide some guidance, it is important to have domain text to capture both the lexical and syntactic nuances.

In this work, we take a compromise between these two extremes and view the text simplification processes as a semi-automated approach where a human in the loop utilizes a tool to help guide the writing process. Unlike readability formulas that only provide high-level information, the tool provides concrete guidance on which portions of the text are problematic and, critically, also provides concrete suggestions for how these sections can be improved. We have successfully used a range of data sources, corpus statistics, and machine learning to discover many features and develop individual algorithms evaluated through user studies. The algorithms that are shown to impact readability and understandability are integrated in an online text editor. The current version of the tool contains a range of tool components at the word level, sentence level, and corpus level. In this work, we are expanding to focus on features that are useful for audio content.

---

1 http://simple.cs.pomona.edu:3000/
Importance of Audio Information. While text is still a common mode for providing information in medicine, a new approach is emerging fast: audio information presentation. An important contributing factor is the rapidly rising use of virtual assistants and smart speakers. In 2018, 30% of Americans used voice to find and purchase products. Smart speakers have become an increasingly common household item and offer a range of activities with an increasing number of interactions that focus on healthcare. For example, in 2021 there were more than 2,000 skills in the Alexa’s Health and Fitness section, several focus on tracking (medication, menstruation, fertility, calories), finding providers and scheduling, but a large portion is devoted to providing information (e.g., drug information, general health advice, and information on specific conditions and treatments). A 2019 survey found that 52% of those surveyed would welcome using a voice assistant for healthcare and many are already asking information about symptoms (73%), medication (46%), hospitals (38%), research treatment (38%), nutrition (39%) and more. The COVID pandemic has sped up several initiatives using text or audio. For example, Microsoft and the Centers for Disease Control and Prevention (CDC) collaborated on a COVID-19 chatbot and the World Health Organization (WHO) released a chatbot using WhatsApp to provide relevant information.

Creating audio information from existing text is straightforward through the use of existing APIs, e.g., the Bing Speech Text-to-Speech API or Google’s Cloud Text-to-Speech API. Using audio itself is not new and has been used with visually impaired audiences. Example research has focused on e.g., effectiveness of audio instructions or dental programs for visually impaired children. Newer studies focusing on virtual assistants are often limited to evaluating the usefulness and correctness of answers in response to queries, e.g., a comparison of virtual assistant and their acceptance at home and usefulness in answering queries such as about gynecologic oncology.

However, there are increasingly more options for more sophisticated information exchanges, for example, Amazon Alexa competitions focusing on Type 2 diabetes support, hospitals providing Alexa skills or adding smart speakers in patient rooms (e.g., Cedars’ Sinai pilot study), and the increasing use of the Internet of Medical Things with voice-activated devices.

Our work differs from others in that we evaluate how to improve content for general, automated audio generation, a feature provided by virtual assistants although currently using existing, and not optimized, content. Since we focus on medical and healthcare content, the standards for accuracy are high and limited information (preferably none) can be omitted.

Methods

Identifying Missing Elements. We algorithmically identify missing elements in text based on the syntactic structure of the sentences. The algorithm does not require any human intervention and can be applied efficiently to text in a wide range of domains. Using this algorithm, we analyzed the frequency of missing elements in two different corpora. Then, we performed a user study to see the impact of missing elements on comprehension in both text and audio presentation.

Missing elements can be introduced into sentences in English in a variety of ways. In this work, we focus on two different ways that can occur in noun phrases. The first is missing elements in complex noun phrases. More specifically, we focus on noun phrases that contain a relative clause or verbal element in a nominal without an overt subordinate clause. For example, in the phrase

“The patients included are tested for ....”

there is syntactic information missing. This is often done in an attempt to be succinct, though it does leave some information implied rather than explicitly stated. A version of the sentence that includes this information could be written as:

“The patients who were included are tested for ...”

These missing elements can be detected using the grammatical structure of the sentence. A missing element occurs if there exists a noun phrase that contains a verb but does not contain a preposition or subordinating conjunction (i.e., a word with part-of-speech ‘IN’). We denote this Rule 1.

Another type of missing element is found in noun phrases that do not contain nouns, more specifically, having a nominal that lacks a determiner. In English, these include deictic determiners: function words that point or refer back to items that are not explicitly stated in the sentence. For example, in the phrase

3 https://cloud.google.com/text-to-speech/
“The patients included are tested for the disease, this indicates that... “

the term ‘this’ refers to a noun that is implied by the content but not stated. It can be made explicit, for example:

“The patients included are tested for the disease, this fact indicates that... “

A missing element of this type occurs if there exists a noun phrase that does not contain a noun or other words that act like nouns, i.e. a preposition, an existential ‘there’, a number, a gerund verb, or a comparative or superlative adjective. We denote this Rule 2.

For both rules, we can determine if a missing element occurs in a sentence, given the syntactic parse of the sentence. To apply the rules, we first preprocess the text with the Stanford CoreNLP toolkit to split the text into sentences and automatically parse the sentences. The rules conditions above are checked based on these automatically generated parse trees. In our case, we implemented the rules in Java. Rule 1 identifies as containing missing element all noun phrases that contain a verb (identified by one of the five verb part of speech tags), but that do not contain a preposition or subordinating conjunction (i.e., does not contain a word with the ‘IN’ part of speech tag). Rule 2 identifies as containing a missing element all noun phrases that do not contain a noun or a noun-like word, specifically, one of ten parts of speech (four noun tags, two adjective tags, a preposition, a number, existential there, or a gerund verb).

Evaluating Occurrence: Corpus Statistics Study. To get an understanding of the impact of these two types of missing elements we completed corpus analyses to evaluate whether these missing elements appear regularly in text and whether they are especially indicative of difficult text. We used two different corpora to measure the impact of missing elements. The first corpus is a medical corpus with abstracts collected from Cochrane articles. Cochrane provides a collection of a wide range of medical articles that are meant to “inform healthcare decision-making”. They represent digests of current research and represent a source where patients can obtain current information on diseases, treatments, and other medically-related information. We queried the database for 15 different illnesses that were the leading causes of death according to the CDC (e.g., heart disease) along with 4 common conditions (e.g., obesity) and collected the abstracts for all of the articles returned. The total dataset contains 44,488 sentences.

For the second corpus, we examined a corpus that contains 318,056 aligned sentence pairs from English Wikipedia and Simple English Wikipedia articles. Wikipedia articles are a common source for people searching for a wide range of topics and are written to be generally accessible. Simple English Wikipedia articles contain similar topics to the normal English Wikipedia articles, but written to be more accessible and broadly digestible. For each English Wikipedia sentence the corpus contains a corresponding sentence in Simple English Wikipedia with roughly equivalent information, though expressed more simply. This parallel corpus allows for a direct comparison of text with varying difficulty levels that is agnostic of topic. The Wikipedia dataset contains a broad range of topics and is an extremely commonly used resource. As noted above, currently no corpus exists of such sentences in the medical domain.

Evaluating Effects on Listeners: User Study. To evaluate the impact on reading and listening, we combined the data from two user studies where comprehension was tested with online consumers using a corpus of text snippets. The difference between the two studies was in how comprehension of the content was measured: with either multiple-choice questions or with free recall of information. These initial studies showed that consumer can learn new information from audio as well as from text which is a requirement before commencing research on optimizing content. The study was reviewed and approved by the Institutional Review Board of the University of Arizona.

The results for the current study are based on an analysis of our consumer comprehension data using the new missing element algorithms. The algorithms to detect missing elements (Rules 1 and 2) as well as the analysis of the relationship between missing elements and comprehension on the text snippets are new for this study and not reported elsewhere.

The goal was to compare user comprehension after being shown medical information two times. This simulates the situation where a patient is presented information after a medical consultation (e.g., orally in the doctor’s office and then again at home with written information). The studies were done in two phases designed to isolate the effect on comprehension of listening to information versus reading the same information. In the text-text variant, the information was presented twice to the participants as text. In the audio-text variant, the information was presented

4 https://www.cochranelibrary.com/
first as audio and then again as text. We used a total of 100 text snippets randomly selected from two medical sources and chosen to be of approximately equal length: Cochrane (N=50) and English Wikipedia snippets for health-related pages (N=50). For this paper, we calculated the number of missing elements based on Rules 1 and 2 in the text snippets to evaluate how the number of missing elements relates to comprehension.

In the first study, we used multiple-choice questions to measure comprehension. The participants were presented with the snippet (in either text form or audio form, depending on the condition) and then answered a multiple-choice question about the content (Multiple-Choice 1). They also scored the perceived difficulty of the snippet using a 5-point Likert scale with a score of 1 indicating ‘Very Easy’ text and 5 indicating ‘Very Difficult’ text. The participants were then shown the information again as text and they were given an opportunity to correct their answer to the same multiple-choice question (Multiple-Choice 2). We included the same question to see how much an individual improved with the second presentation of the information. For each multiple-choice question, there were three answer choices, one of which was correct. We measured comprehension with the percentage correct.

In the second study, we used free recall to measure comprehension; the study was identical to the first except that the first multiple-choice question was replaced with a free recall question where participants were asked to write, in their own words, as many pieces of information that they could remember about the information presented. To evaluate the quality of the free recall answers, we quantified how much of the information they recalled was in the original text that they were presented. To calculate this we first applied an automated spelling checker (to avoid differences due to participants who used a spelling checker and those who did not). Then, we measured the number of words that overlapped between the original text and the information recalled by the study participants.

To better understand the relationship between the information recalled and the original text, we used two measures of recall: exact and semantic. Exact recall was calculated by counting the number of content bearing words (i.e., nouns, verbs, adjectives, and adverbs) in the information recalled that occurred in the original text. This type of exact match can be too strict and does not allow for synonyms or other paraphrasing that participants might do. To capture a broader sense of overlap, we also used semantic recall, which is the number of content bearing words that were either an exact match of or that had a similar meaning to a word in the original text. To calculate if two words were similar, words were first represented by their word embedding. We then used the cosine similarity between word embeddings to identify word with similar semantic meaning. We used Google’s pre-trained 300-dimension word embeddings(37) and a cosine similarity threshold of 0.45 to tag words as semantically similar (this threshold was empirically determined).

Both studies were conducted using Amazon Mechanical Work (AMT) with three workers participating for each text snippet for each condition. Comprehension scores were averaged across the three workers and across the text snippets. We also report here on the time spent on the task, which is provided by AMT. Additional details of the AMT study have been reported in the study which focused on the impact of text-text and audio-text ordering on comprehension (38).

**Results**

**Corpus Statistics Study Results.** Table 1 shows the results of the corpus analysis for the two corpora. For each resource, we counted each occurrence of a missing functional element as well as the number of sentences containing one or more missing element. Since there can be multiple occurrence of missing elements in a single sentence (e.g., in different noun phrases), the number of occurrences can be higher than the number of sentences.

Missing elements occur frequently in medical text. The Cochrane dataset contained 15,734 instances of Rule 1 elements and almost a quarter of all sentences (23.5%) had at least one occurrence. Rule 2 was less frequent with 4,784 instances overall and almost a tenth of the sentences (9.7%) had at least one occurrence. Combining the rules, there was at least one missing element in 29.5% of the sentences.

Missing elements also tended to occur more frequently in difficult text, particularly Rule 1 elements. In the Wikipedia corpus 20.0% (63,737 sentences) of the English Wikipedia sentences contained a missing element versus 18.9% (60,067 sentences) for Simple English Wikipedia. This difference was almost entirely due to Rule 1 occurrences (41,545 sentences vs. 37,427 sentences, English vs. Simple English).

User Study Results. Table 2 provides an overview of the study corpus used to measure user comprehension. Overall, missing elements are common in both types of text. The snippets contained on average 4.5 sentences and most contained one or more missing elements. There were more missing elements identified by Rule 1 (0.82 and 1.16 per snippet for Wikipedia and Cochrane snippets, respectively) than for Rule 2 (0.18 and 0.20 for Wikipedia and Cochrane snippets, respectively). The differences were not statistically significant.

In Table 3, we show the relationship with reading the text and the number of missing elements (text-text condition). We present reading first as it serves as a baseline: reading information is a familiar activity. We conducted
correlation analyses to estimate the impact of missing elements on the difficulty (actual or perceived) of text. We calculated one-tailed Pearson Correlation Coefficients using the average scores of the three AMT participants for each of the snippets (N=100). We chose one-tailed because we hypothesize that an increasing number of missing elements makes the text more difficult. We found that more time is spent on the tasks with more missing elements. The text is also perceived as more difficult when there are more missing elements. The effects are stronger for Rule 1 (which occurs more frequently in the text). There was no significant correlation with actual difficulty as measured here with multiple-choice questions.

Table 3. Results for the multiple-choice questions for the reading (text-text) condition. One-tailed Pearson correlation significant at 0.05 level* or at 0.01 level**.

Table 4 shows the results for listening to the content first and reading afterwards (audio-text condition). When participants have little control over the time spent (they could not pause the recording) there is no relationship with time spent. Interestingly, we found a negative correlation with the perceived difficulty of the audio and the number of missing elements: when listening to the information, more missing elements make the information sound easier. While including functional elements may help make the connections more explicit in the sentences, leaving them out can sometimes help with the fluency of the sentences. Similar to reading text (above), there is no correlation between the actual difficulty, measured with the multiple-choice questions and the number of missing elements.

Our second study repeated this approach but replaced the multiple-choice questions with a free recall measure. This was done to provide a more sensitive measure of information comprehension and retention. Free recall was calculated as the overlap of words between the given content and the participants’ recall. Similar to the analysis above, we calculated the correlations between missing elements and the retention of information.

Table 5 shows the results with the free recall of information and reading text (text-text condition). There is no correlation between time spent and missing elements. While the number of exact or semantically matching words is not correlated to the missing elements (not surprisingly since many AMT workers prefer to work fast and spent a limited amount of time on a task), the overall similarity of the answer to the original information is strongly correlated with more missing elements resulting in a lower overall answer similarity, i.e., a worse answer by the participants. The information is perceived as more difficult when there are more missing elements.

Table 5. Results for the free recall measure for the reading (text-text) condition. One-tailed Pearson correlation significant at 0.05 level* or at 0.01 level**.

Table 6 shows the results for free recall of information after listening to the information first (audio-text condition). As expected, since participants have no control over audio play, there was no correlation between time spent and missing elements. The results are similar to reading of the text. The number of exact or similar words is not correlated with missing elements. However, the overall answer similarity correlates to the number of missing elements with similarity being lower (i.e., worse answer) when there are more missing elements. As with text, the audio is perceived as more difficult when there are more missing elements.

**Discussion**

We presented the discovery and results for missing elements, and its relationship to perceived and actual difficulty of content presented as text or audio. The effect of missing elements on reader comprehension is subtle. We believe that our broad-multiple choice questions were not sufficiently sensitive to capture the impact of missing elements. However, we find that with a more sensitive measure such as free recall, there is a relationship between the number of missing elements in the content and how much was recalled by study participants. The results are similar for audio and text presentation: when the content has more missing elements less is recalled. We believe these results might be an underestimate of the impact because AMT workers tend to work fast with quick and short answers.

Furthermore, there was an interesting but complex relationship between missing elements and perceived difficulty that needs further follow up. In the audio-text condition, having more missing elements was perceived as easier: this was when the participants were listening and only had to answer a multiple-choice question. In the text-text condition, they perceived content as more difficult when there were more missing elements. Our corpus statistics study showed that missing elements are a very frequent occurrence. It is reasonable to assume that people remove functional elements for a purpose, e.g., to make the text flow better. This discrepancy between text and audio in how they are perceived gives some insight into this, but further exploration is required. Additionally, perceived difficulty cannot be ignored since it may impact how consumers process and understand health information. The Health Belief Model (HBM) (39) and the Theory of Planned Behavior (TPB) (40) have shown this impact. In a review of 24 studies, the 4th dimension in the HBM, perceived barriers, was found to be the most significant in explaining health behavior (39). Similarly, in TPB, perceived difficulty, a sub-factor for perceived behavioral control, has been found to be the stronger predictor of intentions and behavior (41). Other work has showed how perceived difficulty correlates with a decrease in the recall of information (42).

**Practical Implications**

Our work has three main practical implications. First, audio is an effective delivery medium for information. This paper represents the second study to support this. Audio as a medium for information dissemination is becoming increasingly important the growing popularity of audio for information access. Second, our combined studies show the need for evidence-based guidance on how to optimize content for text and audio. Ideally, such guidelines will be incorporated into automated or semi-automated tools to allow a broad variety of content providers to optimize their content without requiring them to have a background in linguistics or communications. Finally, in addition to features discovered in previous work, we demonstrated here a new feature and its impact on the actual and perceived difficulty of content in text and audio presentation. This study shows that it is important to specify nouns and verbs when they refer to previously presented information. This makes the content seem easier and also contributes to better recall of the information.

Future work on health literacy for patient or consumer education where there is an information exchange with laypersons utilizing audio for information delivery would benefit from evaluating content, style, and presentation for their impact on perceived and actual difficulty. Beyond these, there are also potential opportunities for examining
other dimensions that are more relevant for audio delivery, e.g., emphasis, persuasion, and bias. With audio information delivery, few evidence-based guidelines are currently available.

**Conclusion**

Our overall goal is to optimize content for delivery both via text and audio. We aim to do this by creating tools that provide evidence-based guidelines on how to change text. In a first study conducted, we found that audio is an effective medium to deliver content, an exciting and promising result particularly given the increasing prevalence of audio devices in our lives\(^{10}\). In the study presented here, we focused on one text feature, missing elements, and found that it affects both perceived difficulty and actual difficulty for both text and audio. Again, this is a promising result since it means that optimizing content will be equally effective for text and audio presentation. While the impact of missing elements may seem small, the feature appears in nearly 30% of sentences used to provide health information; even a small improvement could have a large impact.

Abstract

There is a pressing need to provide health professional learners experiential learning opportunities in health systems science and quality improvement. Moreover, there are several published tools to diagnose and treat health system vulnerabilities and hazards. The Health Care Failure Mode and Effect Analysis™ (HFMEA) is a systems-engineering tool that the military and aerospace industries developed to proactively identify potential errors. While this technique has been used in a range of healthcare settings, there are few reports where health professional educators have used it with learners to teach quality improvement and systems engineering methods. We describe herewith an application of HFMEA in a medical informatics professional student rotation. In this manuscript, we briefly review HFMEA theory and methods, illustrate its application to address a quality improvement initiative, and reflect upon its value – and limitations – when used in an educational context.

Introduction and Background

There is a movement in medical education to teach health systems science – sometimes referred to as the third pillar of medicine – along with the basic and clinical sciences1. Clinical workflow analysis, process redesign, and healthcare quality improvement are foundational topics in health systems science that crosswalk with applied clinical informatics2. Consequently, there is a pressing need for academic informatics departments to provide an educational program for learners to study and apply health systems science. This program should include an experiential component that enriches learning by allowing learners to apply lessons and develop new skills.

At the University of Oklahoma-University of Tulsa School of Community Medicine (OU-TU SCM), the Department of Medical Informatics offers applied informatics and data science rotations to medical residents and health professional students. These rotations include didactics, practicums, and mentored scholarship in the form of a mini-capstone addressing a health systems science topic3. The mini-capstone projects focus on enterprise-level problems. This creates opportunities to teach core informatics topics like computerized decision support (CDS), health information technology (HIT) management, interprofessional collaboration, and quality improvement methodology.

Knowing how to “diagnose” health system failures and “prescribe” implementation science solutions is an important cross-cutting competency within these educational domains. Two systems diagnosis tools useful for evaluating healthcare workflow include root cause analysis (RCA) and Health Care Failure Mode and Effect Analysis (HFMEA)™4. We teach these concepts when students embark on quality improvement or systems engineering projects. In this manuscript, we illustrate the use of HFMEA using a CDS problem, review the benefits and limitations of HFMEA, and explain how we used HFMEA to teach health systems science and quality improvement.

Problem Definition

The OU-TU SCM maintains academic relationships with several community hospitals. One of our affiliate hospitals is part of a hospital network governed by a centralized corporate authority. Corporate leaders partnered with clinical staff to create an electronic medical record (EMR) pain management bundle. The bundle includes new electronic orders and an interdisciplinary workflow. They designed the bundle with the intent to reduce inpatient opioid use and opioid related adverse events. Encouraged by initial piloting success at two network hospitals, corporate leaders approved a “big-bang” implementation across the remaining hospitals in network. At the time of our project, leadership had not yet implemented the bundle at our affiliate hospital. Anticipating a range of implementation challenges (e.g., staff education, workflow re-engineering) and unintended consequences (e.g., under or over-treating patient pain), the clinical champions consulted our medical informatics team to conduct an HFMEA. Our informatics faculty required students to participate in this project as part of the rotation practicum.
Project and Manuscript Goals and Objectives

We identified project goals and objectives based upon stakeholder expectations. Corporate quality and safety officers set a goal to improve opiate prescribing safety. Corporate management set timeline objectives for implementation. Clinical champions (i.e., our customers) set goals to limit systems-based errors, secure clinician buy-in, and increase patient satisfaction. Our medical informatics department sought to provide a prospective risk analysis and actionable recommendations. We knew at the outset that our project had to address clinicians’ goals within management’s timeline. We also needed to provide an educational experience that met course learning objectives.

The focus of this paper is to illustrate how to use the HFMEA within an informatics educational rotation to teach health systems science techniques, satisfy professional school educational program objectives, and provide consultative support to clinicians. We have several objectives with this manuscript. We intend to (1) give a brief review of HFMEA theory and methods; (2) demonstrate use of the HFMEA in a real-world situation; (3) illustrate how to integrate these methods into a professional school rotation; and (4) highlight early lessons learned and limitations. This paper should be of interest to applied informaticians, educators, and quality improvement specialists.

Theoretical Framework and Focused Literature Review

In 2001, the Department of Veterans’ Affairs (VA) adapted HFMEA from methods used by the aerospace and military sectors to identify risks in manufacturing processes. The VA method combined concepts associated with Failure Mode Effect Analysis (FMEA) and Hazard Analysis and Critical Control Point (HACCP) to proactively identify and address health system vulnerabilities. The VA also included the Safety Assessment Code (SAC) Matrix from RCA and a novel decision algorithm to prioritize corrective actions.

The HFMEA is most effective during product design, but practitioners may use it to analyze systems in a mature healthcare enterprise. It consists of five main steps: (1) selecting a process for inspection; (2) recruiting an interdisciplinary team; (3) creating a flow process map; (4) conducting a hazard analysis; and (5) formulating an action plan to address failure modes. Because HFMEA is a proactive “diagnostic tool” to predict failures, it is crucial to assemble an interdisciplinary team of subject matter experts (SMEs). This team can draw upon their collective experience when brainstorming.

![Figure 1](image-url). Sample section of an HFMEA flow process map illustrating processes, sub-process, and hazard analysis.

After identifying all failure modes, the team assigns a SAC score to each failure mode using a 16-point scale that predicts the probability and clinical severity of an event. Once scored, the team uses the HFMEA Decision Tree to prioritize action based upon hazard criticality, absence of effective control measures, and lack of detectability. The interconnectedness and complexity of healthcare systems can make a comprehensive HFMEA cost prohibitive. Therefore, one approach is to focus upon a small section of the workflow.
There are numerous studies demonstrating the value of HFMEA across a range of clinical settings including oncology, surgery, and general inpatient care\textsuperscript{6-13}. Notably, researchers have used HFMEA to diagnosis and manage health-systems pharmacy hazards leading to adverse events\textsuperscript{9,14,15}. For example, Velez-Diaz-Pallares and colleagues used HFMEA to analyze medication management on inpatient wards using computerized physician order entry and unit dose dispensing\textsuperscript{9}. They found that HFMEA helped the quality improvement team reduce inpatient prescribing errors. Anjalee and colleagues conducted a systematic review of published HFMEAs and found it to be an effective tool for reducing medication errors\textsuperscript{10}. Similarly, Faiella and colleagues concluded that HFMEAs are effective for streamlining the evaluation of complex systems, schematizing risk assessment, and selecting safety interventions\textsuperscript{6}.

**Setting**

Our affiliate hospital is an urban tertiary care facility with intensive care, surgical subspecialty services, pediatrics, and obstetrics. The clinical champions charged with implementation included a palliative care physician and two hospitalists with training in pain management and healthcare quality improvement.

The proposed pain management implementation bundle included (1) EMR order menus; (2) CDS; (3) a new interdisciplinary workflow; (3) a staff education campaign; and (4) new hospital policies. The bundle required prescribers to select therapies from a standardized list of orders for non-opioid medications, opioid medications, and non-pharmacologic pain-management alternatives. The orders direct nurses to regularly compare patient functional status to pre-defined therapeutic goals, and administer therapies in an escalating fashion when required. For example, the care team may set a therapeutic activity goal requiring a post-operative patient with a new hip arthroplasty to transfer from bed to bedside commode by the second post-op day. If the patient cannot transfer due to pain, the nurse will begin by administering non-pharmacologic therapies and non-opioid medications. If, upon reassessment, the patient fails to reach this goal, the nurse may administer oral or intravenous opioids.

Developers piloted the bundle at two hospitals and gathered preliminary data showing a reduction in total morphine equivalents (ME) administered, a decrease in the use of opioid reversal agents, and a reduction in opioid prescriptions at discharge. There was no change in patient satisfaction scores related to pain relief. Encouraged by these findings, corporate leadership authorized bundle implementation as part of a national pain management campaign. Management expected our hospital to submit for consideration any local CDS configuration requests, implement the bundle, and remove personalized clinician order sets within 60 days.

The bundle called for a seismic change in prescribing behavior and clinical workflow. Like many real-world health system implementation, the plan had several project management constraints including fixed implementation resources, an ambitious roll-out timeline, and top-down corporate messaging. Therefore, we anticipated numerous challenges and sought to identify as many failure modes as possible. We needed to prioritize failures modes as a function of risk and propose mitigating strategies that could feasibly be implemented within 30 days.

**Methods**

The OU-TU SCM Medical Informatics rotation is a two or four week rotation for medical students, physician assistant students, and residents\textsuperscript{3}. Both formats include didactics, readings, participation in departmental meetings, and a mentored practicum. Typically, the practicum requires the learners to either participate on “in-flight” projects or design a novel project with a focused research question. The rotation culminates with the students delivering a “grand rounds” style presentation on their project to staff and faculty.

For this project, we asked students to conduct an HFMEA of the multi-modal pain order set. Informatics faculty gave several lectures on HFMEA methods and furnished students with readings detailing the theory and steps for analysis. The students then gathered and reviewed data and artifacts related to the protocol. This included preliminary reports from the pilot sites, wireframes of the order menus, written specifications for decision support, and training materials. The students met with local champions to better understand the protocol, the climate of implementation, and how they could apply HFMEA to identify potential implementation barriers.

Faculty supervised students as they conducted semi-structured interviews with SMEs. Interview topics included the current-state workflow and workflow compatibility concerns, perceived usability of the new order sets, perceived usefulness of the new protocol, appropriateness for the patient population, challenges with interdisciplinary
communication, staff training needs, known implementation challenges at other sites, patient or specialty-specific implementation barriers, and the plan for patient education.

We selected a convenience sample of SMEs based upon their clinical domain knowledge and anticipated role in the future-state workflow. The sample included physicians, nurses, physical therapists, and nurse educators employed by the hospital. It was crucial to interview SMEs familiar with inpatient pain management, order entry, and bedside care. We interviewed nurse educators in the hopes of identifying training best-practices.

The students completed a modified HFMEA using the data collected from literature, semi-structured interviews, artifact analysis, and non-participant observation. Given the time constraints, we modified and simplified the HFMEA process so students could complete a preliminary analysis within the student rotation timeline. Rather than focusing on all potential failure modes, the students focused on major themes that emerged during the interviews. Using an apprenticeship model, faculty helped students identify sub-processes, failure modes, and recommendations for corrective action. The students presented their findings to department leadership and project sponsors as part of their rotation and received feedback on their work and presentation.

**Results**

*Graphically describing the process*

From the outset, the steps of our HFMEA deviated from the classic approach described by DeRosier. Typically, the project leader assembles a multidisciplinary team with SMEs and one or more advisors. The SMEs provide insight on how a process works, whereas the advisor helps the leader scope the project and complete tasks. In our case, we had a future-state workflow in hand and needed SMEs to forecast potential problems. Therefore, instead of assembling the team to map workflow, we sought out and interviewed SMEs using the process map as a guide.

We documented the future state workflow using a swim lane diagram labeled with stakeholder roles rather than using a flow process map (*Figure 3*). This is because the workflow was multidisciplinary and included branching logic, and parallel activities. We assigned numbers chronologically to processes. This created a flow map with 22 processes and 22 sub-processes. We found it helpful to cluster related steps and label according to high-level goals. Goals included: (1) initial assessment; (2) order entry; (3) order processing; (4) goal assessment; and (5) administration.

![Figure 3. Simplified flow process map of the future-state workflow. We elected to adapt a swim lane diagram to reflect the non-linear and iterative workflow that crosses multiple stakeholders and clinical settings.](image-url)
Completing the hazard analysis

In one week, the team interviewed two internal medicine residents, five acute care nurses, four maternity care nurses, and two physical therapists. Working iteratively, the faculty and students compared interview notes with the workflow diagram and conducted brainstorming sessions with local champions. The team identified 33 failure modes and four overarching themes (Table 1).

The first theme related to the clinical appropriateness of the order sets. Many clinicians believed the protocol might be inappropriate for some patients’ pain management needs. For example, patients with acute severe post-operative pain, chronic opiate prescriptions, the inability to swallow, or medication allergies may need a bespoke plan.

The second theme related to the delay between clinical assessment and medication administration. Clinicians were concerned that the elapsed time dictated by the protocol to assess analgesic effectiveness before the next medication administration would be unacceptably long. They feared this delay would negatively affect care quality and erode trust between patient and care team.

The third theme related to efficiency. Clinicians were apprehensive about the additional time required to complete tasks. Physicians believed order set complexity would increase order entry times. Nurses were equally concerned about the additional time invested in patient education, pain management counselling, and activity assessments.

The fourth theme highlighted workflow compatibility mismatches between the current-state and future-state. For example, med/surg ward nurses did not know how to reconcile discordant patient-reported pain scales with objectively observed functional performance. If a patient rated their pain 10 on a 10-point pain scale, but met a priori activity goals, should nurses administer or withhold the next analgesic dose? In a separate example, some surgical specialties, including obstetrics, use standardized pain management strategies that did not align with the new workflow. Anesthesiologists oversee patient pain management requirements following caesarean delivery and favor ketorolac, a parenteral drug used to treat moderately severe pain. The EMR order bundle did not include ketorolac.

For several reasons, the team did not use the HFMEA Hazard Scoring matrix or the HFMEA Decision Tree™. This process is time consuming and resource intensive. However, the clinical champions requested a fast turnaround. Furthermore, new clinical management policies restricted the range of potential corrective actions. Per customer request, we prioritized corrective actions based upon logistics and feasibility. We did not prioritize recommendations requiring major technology modifications, major informatics resource investments, or hospital policy revisions.

Corrective Actions and Recommendations

Given the project constraints and customer request, we assembled recommendations that clinical champions or local informaticians could implement within 60 days (Table 1). Our recommendations took one of the following forms: (1) order set configurations to improve usability; (2) patient communication and education materials; (3) local executive messaging; (4) patient inclusion/exclusion decision support; and (5) workflow modifications.

Placing orders for the pain management protocol entails choosing from a lengthy list of activity goals and selecting non-pharmacologic, non-narcotic, and narcotic medication orders. The prescriber must also place several corollary orders including nursing instructions and allied care consults. While the number of options affords a high degree of flexibility, this flexibility carries both learnability and complexity costs. Therefore, we proposed offering some pre-selected options to satisfy the most commonly encountered use-cases.

Nurses expressed concerns about patient reactions to the new pain protocols, hypothesizing that patients will become frustrated if new practices deviate from prior experience or fail to meet expectations. To defuse tension, improve health literacy, and direct culpability away from nurses, we suggested developing institution-branded resources for nurses to furnish to patients describing the pain management goals, program, and rationale.

The SMEs we spoke with expressed dismay over the corporate implementation strategy, arguing that the approach disenfranchised front-line clinicians. We believe the inability to participate in decision-making created a problematic climate of implementation. We recommended that local management and executive leadership conduct a series of “safety rounds” to support and reward adoption and identify and remove barriers to use.

Recognizing that some patients may not be suitable for the multi-modal pain orders, we recommended defining patient inclusion and exclusion criteria. The organization could communicate these criteria through in-person and online trainings, published materials, and point-of-care decision support. We also recommended developing alternative order pathways to accommodate patients that were not suitable for the standard orders.

Finally, we outlined several solutions to handle common workflow exceptions. For example, it may be necessary to include a protocol for patients arriving on high-dose narcotic analgesia. These patients may need a different nursing assessment strategy and an analgesic de-escalation protocol. Also, providers may need to quickly enter pain management orders for patients at hospital admission, before the inter-disciplinary team can assess the patient’s functional status. We recommended including order sets that “release” when allied team members complete the functional assessment. We also recommended using temporary pain management holding orders as a bridge until the provider can enter the multi-modal pain protocol.

Educational Impact

Students shared with faculty several valuable insights about their educational experience. The students received formal instruction and practical experience on many core informatics topics including CDS, workflow analysis, process

---
One weakness the students reported was the lack of prior informatics training which created a steep learning curve. They also noted that the short rotation timeline made it challenging to complete larger projects. Because most operational informatics projects continue longer than an educational rotation, it is crucial that faculty build in mechanisms to teach and support project handoffs. The lack of an established handoff format in medical informatics posed a formidable challenge.

We pragmatically adapted the situation-background-assessment-recommendations (SBAR) framework used in healthcare for patient care handoffs. The students and faculty integrated SBAR information into the final presentation. For “Situation,” students provided a concise summary of the project and relevant informatics domains. For “Background,” the students described our adaptation of the HFMEA and a brief description of the pain management protocol. For “Assessment,” the students reviewed the flow diagram, failure modes, and preliminary recommendations to the customer. For “Recommendations,” outgoing students outlined future strategies for incoming students. Students then exchanged all materials, artifacts, and data.

Discussion

Principle findings

The HFMEA is a robust systems analysis method that is ideally suited for healthcare settings where interdisciplinary teams need a structured approach to unpack, understand, and predict the behavior of complex adaptive systems. It is an effective tool for targeting workflow vulnerabilities, estimating patient safety risks, and prioritizing solutions in resource constrained settings. We found that applying the HFMEA framework to an implementation initiative offered several practical advantages. It increased awareness among stakeholders and fostered interdisciplinary engagement. It generated recommendations for order sets, educational materials, communication strategies, and special-case workflows. The HFMEA also provided a framework for stakeholder discussions and a way to track and finalize recommendations.

While healthcare organizations need competent clinical professionals applying these methods, training programs rarely teach HFMEA. We believe HFMEA is a practical and teachable method that educators can incorporate into undergraduate and graduate medical education. The informatics teaching faculty found it provided a novel and dynamic way to teach systems-based practice to health professional students. By applying HFMEA concepts to a real-world setting, students gained practical experience with quality improvement methods and adapted methods to suit the clinical and business context. Moreover, the experiential nature of the program enabled the faculty to observe and evaluate entrustable professional activities.

It is critical to point out that HFMEA can be time consuming and resource intensive. DeRosier and colleagues noted that a single HFMEA can require large interdisciplinary teams and 10 or more meetings. For this reason, they suggested only examining one facet of a process so as not to overwhelm the participants. Our project was characterized by (1) a rigid, prescriptive future-state workflow; (2) top down implementation without stakeholder input; and (3) significant time and resource constraints. Therefore, we modified the HFMEA steps and streamlined the approach to meet leadership’s deadline, identify nimble solutions, and engage novice learners. We still believe the standard HFMEA framework is an excellent method for analyzing a system; practitioners should complete each step if time and resources permit. However, healthcare executives often demand quick and decisive action. In our experience, it is important to teach students how to keep pace with business operations by adapting to the use-case and available resources.

Relevance to current literature and future steps

There are many published descriptions using HFMEA; our recent literature search using PubMed and Google Scholar, identified 131 monographs describing application in specific disciplines (e.g., radiation oncology) or processes (e.g., inpatient supply chain management). However, we found only one report describing the use of HFMEA to teach health professionals. Schuller and colleagues sent department faculty to a continuing medical education conference offered by the American Association of Physicists in Medicine (AAPM) and then gave a condensed version to department personnel in a series of lunch seminars. The seminars used a combination of didactics and use-cases.
to teach flow process mapping, failure mode analysis, and fault tree analysis. However, they did not describe the training methods, strengths, or limitations.

For several reasons, we believe HFMEA is a teachable, feasible, and generalizable systems diagnosis strategy that academic programs should include in their health systems science curriculum for health professional students, residents, and fellows. First, HFMEA is a useful technique in quality improvement work to analyze systems. Teaching this method to health professional students provides future practitioners with a practical and adaptable skill they can use to diagnosis system stress points and explore a range of solutions. Second, HFMEA provides a framework for students from different programs to leverage their unique skills and knowledge on interprofessional teams. Third, curricular modules incorporating HFMEA can be used by professional programs to meet health systems science learning objectives required by accreditation bodies.

**Strengths and limitations**

Despite the role of HFMEA in health systems science and patient safety, researchers have highlighted important methodologic limitations that could bias findings and outputs. First, identification of failure modes relies heavily upon facilitated brainstorming sessions with interdisciplinary groups. Therefore, participants are vulnerable to anchoring bias, availability bias, and group-think. For this reason, it may be useful to combine HFMEA methods with human factors research methods such as user simulations, cognitive step-throughs, or non-participant ethnography. Second, risk scoring and decision analysis have validity issues. Scoring risk based upon perceived probability and severity requires a considerable amount of guesswork. Finally, decision analysis methods in the HFMEA process do not quantify the reliability or effectiveness of system controls, backups, or fail-safe measures.

Faiella and colleagues theorized that HFMEA may miss certain classes of failure modes and recommended examining human-computer interaction errors using Systematic Human Error Reduction and Prediction Analysis (SHERPA). They also recommended analyzing the interconnectedness of complex adaptive systems using Systems Theoretic Accident Model and Processes and System Theoretic Process Analysis (STAMP-STPA). Similarly, Abrahamsen and colleagues suggested combining HFMEA with other systems engineering methods such as incident learning and Structured What If Technique (SWIFT). Kricke and colleagues recommended using EMR data and big-data analytic methods to identify sub-processes and workflow variations overlooked during process mapping.

This background literature provides insights into limitations in our work. First, the rotation schedule and management objectives created an aggressive project timeline; students had very little time to brainstorm with frontline workers. This created an inherent selection bias. We could address this risk in the future by surging resources and assigning more students to the process workflow. Second, to improve and measure the validity and completeness of HFMEAs, we need to concurrently assign several groups of learners to independently complete an HFMEA on the same system and then compare outputs. Third, we hope to add human factors methods to our analysis protocol. Fourth and finally, adding a health data science module using EMR data to identify systems issues and errors might provide an important dimension to an overall safety appraisal.

**Conclusions**

In summary, we believe that the HFMEA is an important tool for health systems diagnosis and a powerful educational lever to improve the informatics and quality improvement competencies of health professional learners. However, traditional HFMEA methods can be quite time intensive and often demand full engagement of an interdisciplinary clinical team. This can erode stakeholder enthusiasm and limit practicality. Through this use-case, we demonstrated how to adapt methods to align with the pace of business operations and offered strategies to teach HFMEA to learners.

Validation of Real-World Data-based Endpoint Measures of Cancer Treatment Outcomes

Qian Li, MS¹, Hansi Zhang, MS¹, Zhaoyi Chen, PhD¹, Yi Guo, PhD¹, Thomas J George Jr, MD, FACP¹, Yong Chen, PhD², Fei Wang, PhD³, Jiang Bian, PhD¹

¹University of Florida, Gainesville, FL, USA; ²University of Pennsylvania, Philadelphia, PA; ³Weill Cornell Medicine, New York, NY, USA

Abstract

Recently, there has been a growing interest in using real-world data (RWD) to generate real-world evidence that complements clinical trials. To quantify treatment effects, it is important to develop meaningful RWD-based endpoints. In cancer trials, two real-world endpoints are of particular interest: real-world overall survival (rwOS) and real-world time to next treatment (rwTTNT). In this work, we identified ways to calculate these real-world endpoints with structured electronic health record (EHR) data and validate these endpoints against the gold-standard measurements of these endpoints derived from linked EHR and tumor registry (TR) data. In addition, we examined and reported data quality issues, especially inconsistencies between the EHR and TR data. Using a survival model, we show that the presence of next treatment was not significantly associated with rwOS, but patients who had longer rwTTNT had longer rwOS, validating the use of rwTTNT as a real-world surrogate marker for measuring cancer endpoints.

Introduction

In clinical trials, an endpoint is a “precisely defined variable intended to reflect an outcome of interest that is statistically analyzed to address a particular research question,”¹¹ and is usually characterized by the type of research questions or outcomes the trials aim to assess. In cancer trials, the most common outcome-based endpoints are overall survival and measurements of tumor burden, such as tumor response rate and progression-free survival,²,³ that are normally used to measure how well a treatment has worked. A number of endpoints have emerged that can be used as surrogate markers for “duration of clinical benefit,”⁴,⁵ such as time to next treatment (TTNT). Although clinical trials, especially randomized clinical trials, are considered the gold standard for generating clinical evidence about a treatment and its outcomes, they are expensive, time-consuming, and require the recruitment of sufficient participants, which is often difficult⁶,⁷. Further, trial results are often not generalizable to patients treated in real-world settings due to issues such as overly restrictive eligibility criteria⁸. These issues are especially prevalent in cancer trials,⁶,⁷ and approximately 97% of oncology trials ultimately fail⁹.

Recently, there has been a growing interest in using real-world data (RWD) to generate real-world evidence (RWE) that complements the results of clinical trials. The term RWD, widely promoted by the U.S. Food and Drug Administration (FDA), refers to data collected from sources outside of conventional research settings, including electronic health records (EHRs), administrative claims, disease registries, and billing data, among others.¹⁰,¹¹. These RWD sources contain detailed, longitudinally tracked patient information such as disease status, treatment, comorbidities, and concurrent treatments. The information generated from RWD can provide valuable RWE about how patients are treated in real-world clinical settings that can inform therapeutic development, outcomes research, patient care, safety surveillance, and comparative effectiveness studies.¹² In order to quantify the treatment effects, however, it is necessary to develop meaningful RWD-based endpoints.

Another important RWD source in cancer research is tumor registry (TR) data, which is often manually extracted from cancer patients’ medical charts (i.e., EHRs). Variables related to endpoints such as overall survival (OS), cause of death, and the date when the first line of treatment was begun can be reliably obtained from TR data. However, there are a number of gaps in TR data: it lacks detailed information about patients’ other characteristics (e.g., comorbidities) and longitudinal information about patients’ cancer treatment trajectories,¹³ and it does not capture all the cancer patients in the health system, for various practical reasons (e.g., state or national TR reporting requirements and reporting delays due to the labor-intensive manual abstraction process).¹⁴. Patient data missing from the TR leads to

* Corresponding: Jiang Bian; bianjiang@ufl.edu
various issues for research studies (e.g., reduced sample size leading to reduced power of the estimates). For RWD-based research studies, therefore, using linked raw EHR and TR data is ideal.

Literature on real-world endpoints is emerging and a number of endpoints have been proposed, including real-world overall survival (rwOS), real-world time to next treatment (rwTTNT), and real-world progression-free survival (rwPFS)\(^{15-17}\). Nevertheless, the ability of researchers to use RWD to extract these endpoints remains an area of active discussion. For example, rwTTNT can be calculated based on structured EHR data alone, using the dates of various procedures and diagnoses, while rwPFS requires information on the tumor itself, which is often only available in unstructured clinical text (e.g., pathology reports).

Two real-world endpoints are particularly of interest. The first is rwOS, the time from the date of cancer diagnosis or treatment initiation (depending on the type of cancer or the study aims) to the date of death, end of follow-up, or last contact; the second is rwTTNT, the time from the initiation of the first course of cancer-directed treatment to the initiation of the next line of therapy (i.e., “subsequent treatment” in the case of recurrence or progression)\(^{15,16}\). Although rwTTNT derived from RWD sources has not been examined extensively, it can provide critical insight on the real-world performance of cancer treatments\(^{16,19}\). For example, rwTTNT can be used to estimate progression-free survival and the effectiveness of cancer treatment\(^{5}\).

In this work, we aimed to identify ways to calculate real-world endpoints with structured EHR data and validate these endpoints against the gold-standard measurements of these endpoints derived from linked EHR and TR data. We focused on two real-world endpoints, rwOS and rwTTNT, in stage I–III colon cancer patients. We used RWD from the OneFlorida Clinical Research Consortium, a Patient-Centered Outcomes Research Institute (PCORI)-funded clinical data research network contributing to the national Patient-Centered Clinical Research Network (PCORnet).

**Methods**

**Overview.** Our primary analysis goals were to assess the alignment between EHR and TR data, describe the data gaps between the two, and assess the validity of real-world endpoints derived from EHR and TR data. To achieve these objectives, we first needed to understand colon cancer patients’ cancer care pathways using RWD. A conceptual stage I–III colon cancer patient timeline is shown in Figure 1.

![Figure 1. Stage I-III Colon cancer patient treatment timeline.](image)

Our analysis involved five major parts: We (1) identified the events and associated dates of colon cancer diagnoses, death or last contact, and colon cancer treatments from both EHR and TR data; (2) explored the discrepancies between the events and event dates recorded in the EHR and TR data (e.g., patients identified as dead in the EHR but not in the TR, or vice versa); (3) computed the rwOS; (4) identified the starting points of patients’ first course of cancer treatments and subsequent treatments and computed the rwTTNT; and (5) examined the associations between the rwOS and (i) the presence of a subsequent treatment and (ii) rwTTNT. We hypothesized that patients who had a subsequent treatment would have shorter rwOS compared to those who did not and that among patients who had subsequent treatment, those who had a longer rwTTNT would have a longer rwOS than those who had a shorter rwTTNT. The typical first course of cancer treatment and subsequent treatment choices include surgery, radiation therapy, and chemotherapy. As we focused on stage I–III colon cancer patients, we only focused on systemic chemotherapy as depicted in clinical guidelines (see section below for details), and the next line of treatment refer to the intervention with a new regimen after initial chemotherapy\(^{20}\).

**Data source and study population.** We used the linked EHR and TR data from the OneFlorida network. The OneFlorida network contains linked, robust, longitudinal, patient-level RWD from approximately 15 million Floridians, including data from Medicaid claims, TR, vital statistics, and EHRs from its clinical partners. As one of the clinical research networks contributing to PCORnet, OneFlorida includes 12 healthcare organizations that provide care through 4,100 physicians, 914 clinical practices, and 22 hospitals covering all 67 Florida counties. The OneFlorida data follows the PCORnet Common Data Model (CDM) and includes patient demographics, enrollment...
status, vital signs, conditions, encounters, diagnoses, procedures, prescribing and dispensing records, lab results, etc. We extended the CDM to incorporate TR data, which follows the North American Association of Central Cancer Registries (NAACCR) standards\textsuperscript{21}. Currently, OneFlorida includes TR data from three partners that maintain records of documented neoplasms (typically malignant) in their local hospital TRs. The TR records are linked with patients’ EHRs in the OneFlorida data.

The selection of the study cohort is illustrated in Figure 2. We first identified patients diagnosed with colon cancer in both EHR or TR data. Patients were grouped into (A) patients with colon cancer diagnoses in both EHR and TR data, (B) patients with colon cancer diagnoses only in the EHR data, and (C) patients with colon cancer diagnoses only in the TR data. To ensure data quality, and because the stage information was only available discretely in the TR data, we restricted our analyses to Group A. As stage 0 patients need more information to confirm their cancer diagnoses and treatment plans for stage IV patients are more complex, we further restricted the study cohort to patients with stage I–III colon cancer. We also excluded patients with unknown or missing stage information and patients who were diagnosed with colon cancer before 2012 in TR, since our EHR data only included records dating after 2012.

**Determination of cancer cases.** To extract colon cancer patients, we used the International Classification of Disease, Ninth/Tenth Revision, Clinical Modification (ICD-9/10-CM) codes 153.* and C18.* for the EHR data and the International Classification of Disease for Oncology, 3rd Edition (ICD-O-3) codes C18.0 through C18.9 for the TR data. In the EHR data, a colon cancer patient’s onset date was defined as the earliest encounter date with the colon cancer diagnosis.

**Determination of patients’ last contact or death dates to calculate rwOS.** We calculated rwOS as the length of the period from the date of the first colon cancer diagnosis to the death or last contact date. In OneFlorida, the death records in the EHR data come from two sources: The deaths are either recorded directly in the EHR by the health system (e.g., inpatient deaths or deaths reported to the health system by relatives) or are extracted from the Social Security Administration (SSA)'s Death Master File (DMF) and third party data from public and private obituaries through a privacy-preserving record linkage process by a third-party vendor, Datavant\textsuperscript{22}. The death dates in the Datavant’s death data only contain the month and year to protect privacy; thus, we imputed the death date to the first day of the month. If a patient did not have a death record, we assumed the patient to be alive. We then used the last encounter date of the patient in the EHR system as the last contact date.

TRs typically contain a cancer patient’s vital status (i.e., alive or dead) and the death date (if dead) or the last contact date (if alive). However, in our TR data, the last contact date information was missing. To determine patients’ death or last contact date, we combined EHR and TR vital status and event dates as follows: If patients were indicated to be dead in any of the data, we treated them as dead; if they had death dates in both the EHR and TR data, we used the one from the TR data. If patients were indicated to be alive in both datasets, we treated them as alive and used the last contact date from the EHR data.

**Summarization of colon cancer treatments to determine rwTTNT.** We computed rwTTNT as the length of the period between the beginning of the first course of treatment to the beginning of subsequent treatment. To identify the colon cancer treatment, we used the EHR data, as TR data does not contain patients’ longitudinal treatment records. We reviewed the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology\textsuperscript{23} and found
that treatments for stage I–III colon cancer include surgery, chemotherapy, and radiation therapy. For surgery, we identified the Current Procedural Terminology (CPT) and Healthcare Common Procedure Coding System (HCPCS) codes and extracted surgery-related procedures from the EHR data. To identify chemo- and radiation therapies, we used the Cancer Therapy Look-up Tables developed by the Cancer Research Network (CRN)\textsuperscript{24}. As we focused on chemotherapy after surgery, we first identified all chemotherapy occurrences in the EHR data and further distinguished between the first course of treatment and subsequent treatments. We defined the beginning of the first course of treatment as the earliest chemotherapy record in the EHR after the patient’s colon cancer diagnosis date. We implemented two rules for identifying subsequent treatments: (1) if two adjacent chemotherapy occurrences had a gap between them of over 90 days, we considered the former occurrence as the end of the first course of treatment, and the latter occurrence as the beginning of subsequent treatment; and (2) if the patient switched to a new colon cancer treatment regimen, we considered the onset of the new regimen as the beginning of the subsequent treatment. If a patient had multiple subsequent treatments, we considered only the first occurrence in our analysis.

**Statistical analyses.** We first computed the confusion matrices for events (i.e., presence of colon cancer diagnosis and vital status) obtained from the EHR data vs. the TR data. We computed kappa coefficients for each event from the EHR and the TR data. We also compared the dates of these events between the EHR and TR data.

Further, to assess the validity of rwTTNT, we built two Cox proportional hazards models to examine the association between subsequent treatment and overall survival, one that considered whether the patients had subsequent treatments or not, and a second that considered the rwTTNT. For both models, the outcome was the rwOS determined by both the EHR and the TR data. We controlled for age at diagnosis, sex, race/ethnicity, cancer stage at diagnosis, Charlson Comorbidity Index (CCI) (based on diagnosis records from EHR data\textsuperscript{25}), and smoking status.

All data processing procedures were conducted using Python and statistical analyses were performed with SAS, version 9.4 (SAS, Cary, NC, USA).

**Results**

**Demographic characteristics.** Our final study cohort (Group A) included 1,372 stage I–III colon cancer patients. The patients’ characteristics are summarized in Table 1. The mean age at colon cancer diagnosis was 65.2 years old. Men and women were represented approximately equally (50.7% and 49.3%, respectively). The majority of the patients were non-Hispanic Whites (NHW). There were more stage III patients (42.6%) than stage II (33.7%) or stage I (23.7%). Most of the patients (81.0%) had no comorbidities defined by CCI. At baseline, 41.4% of the patients had never smoked, and 58.6% were current or previous smokers.

Cancer diagnosis comparison. Although all 1,372 patients had records of colon cancer diagnosis in both the EHR and the TR data, there were discrepancies in the diagnosis dates between the EHR and the TR data as shown in Table 2. The majority of the discrepancies (73.4%) were of less than 1 month. The TR diagnosis dates tended to be earlier than the EHR dates: 16.2% of patients had a TR date that was 1 to 3 months earlier than their EHR date, and 9.0% had a TR date that was more than 3 months earlier. There were very few patients whose diagnoses were recorded earlier in the EHR than the TR: 0.9% were 1 to 3 months earlier and 0.5% were more than 3 months earlier.

Although our statistical analyses focused on Group A patients, we further explored Group B and Group C patients’ cancer diagnosis records, as shown in Table 3. For patients in Group B (i.e., patients who had colon cancer diagnoses only in the EHR data), more than 50% (N = 1,051) of the patients were diagnosed with rectal cancer. For patients in Group C (i.e., patients who had colon cancer diagnoses only in the TR data), 75% (N = 602) of the patients’ first cancer diagnoses were before 2012, which would not have been captured in our EHR data. Among the remaining 25% (N = 195) of patients, many of their first cancer diagnoses were secondary malignancies.

Vital status and death date comparison. In Group A, there were 248 (18.08%) patients with death information in the EHR data, while 272 (19.83%) patients were deceased according to the TR data. The confusion matrix is shown in Table 4. The Kappa coefficient was 0.66 (95% CI: 0.61–0.71). Both datasets agreed that 75.8% of patients were alive and 13.7% of patients were dead; among patients with inconsistent vital status, 4.37% were alive in the TR but deceased in the EHR and 6.12% were deceased in the TR but alive in the EHR.

We compared the death dates for those recorded as deceased in both EHR and TR data. Among those 188 patients, only one patient had a death date that differed between the TR and the EHR data by over 1 month.

Figure 3 shows the distribution of rwOS in months. There were five patients with death or last contact dates that were
earlier than their colon cancer diagnosis dates; this was likely due to data entry errors or other data quality-related issues. We removed these patients for the statistical modeling. The maximum rwOS time was 101 months and the median was 22.6 months.

Using the EHR data, we identified 174 (12.68%) patients who had subsequent treatments. Table 5 shows the presence of subsequent treatment across different cancer stages. Among stage I patients, 5.85% had subsequent treatments. For the stage II and stage III patients, the percentages were 10.82% and 17.95%, respectively. The distribution of rwTTNT is shown in Figure 4. The average time to next treatment was 9.1 months with a standard deviation of 10.6 months and the median was 6.3 months.

**Association between presence of subsequent treatment/rwTTNT and rwOS.** Table 6 shows the estimates of the Cox proportional hazards model for rwOS using the presence of subsequent treatments as a predictor. Age at diagnosis was significantly inversely associated with rwOS, with a hazard ratio (HR) of 1.038. Sex was not a significant predictor for rwOS, but the HR was 1.246, meaning males had shorter rwOS compared to females. Compared to non-Hispanic Whites, non-Hispanic Blacks and Hispanics had lower hazards, with HRs of 0.659 and 0.623, respectively. Cancer stage at diagnosis was significantly associated with rwOS: stage I and II patients had much longer rwOS compared to stage III patients, with HRs of 0.454 and 0.517, respectively. Patients with CCI > 0 had shorter rwOS compared to those with no comorbidities. Smoking status at baseline was not associated with rwOS. The presence of subsequent treatment was not statistically associated with rwOS, where the HR is 1.203 with a p-value of 0.2173.

Figure 6 shows the KM survival plots of rwOS for the patients with subsequent treatment only, stratified by sex, race-ethnicity, stage, and CCI. Because of the small sample size, the difference between the survival curves for each stratum, except the colon cancer stage, are small.

**Discussion and Conclusion**

In this study, we used RWD from linked EHR and TR to identify and validate two real-world endpoints, rwOS and rwTTNT, in stage I–III colon cancer patients. We identified the necessary events on colon cancer patients’ treatment timelines, including date of cancer diagnosis, vital status and last contact date, and presence and dates of cancer treatments, in order to establish the two real-world endpoints. We assessed the discrepancies in these events and related dates between the EHR and the TR data. Using the longitudinal records in the EHR data, we differentiated the
first course of cancer treatment (focusing on chemotherapy) from any subsequent courses of treatment and used the associated dates to compute rwTTNT. We showed that presence of subsequent treatments was not significantly correlate with overall survival. We also showed that longer rwTTNT was significantly associated with longer rwOS.

![Image](image.png)

**Figure 6.** Kaplan–Meier survival plots of real-world overall survival for the patients with subsequent treatment only, stratified by (a) sex, (b) race-ethnicity, (c) colon cancer stage, and (d) Charlson comorbidity index (CCI).

There were discrepancies between our EHR and TR data, revealing various potential data quality issues with RWD. First, the records of colon cancer diagnosis did not always line up between the EHR and TR data; some patients had a colon cancer diagnosis recorded in only the EHR (Group B) or only the TR (Group C). Possible reasons for such discrepancies between the EHR and the TR could be misdiagnosis (e.g., patients with rectal cancer were initially misdiagnosed with colon cancer and then later determined to have rectal cancer, which was reported to the TR); reporting latency (there is typically a delay of more than 6 months in reporting to the TR because of the manual abstraction process); or patient continuity issues that lead to EHR data continuity issues (e.g., patients seeking care across different health systems). The discrepancies between the EHR data and the TR data in the dates of cancer diagnosis were, however, smaller than we expected. For those patients with consistent colon cancer diagnoses in both datasets (Group A, our final study cohort), over 70% had a difference in their diagnosis dates of less than 1 month. The differences between the EHR death dates and the TR death dates was likewise negligible, and only 1 patient had a difference in deceased dates of over 1 month. We did not anticipate that the last date of contact information for surviving patients would be missing from the TR data. Although RWD has data quality issues in completeness and accuracy, linking RWD from multiple sources such as EHRs and TRs could provide a more accurate depiction of patients’ care history and health status.

In terms of real-world endpoints, past studies like Stewart et al. 2019 have only shown a positive correlation (simply Spearman’s rank-order correlation) between rwTTNT and rwOS, without controlling for other covariates. In our study, we built two Cox proportional hazard models for survival analysis and controlled for a number of important risk factors such as age, gender, race-ethnicity, cancer stage, and CCI. In the first model, we dichotomized the rwTTNT as having vs. not having a second course of treatment, which led to a larger sample size. Thus, we had more statistical power to model and examine the relationship between rwTTNT and rwOS. However, in the Cox model, the non-significant hazard ratio of having vs. not having a second course of treatment showed no statistically significant association between presence of next treatment and rwOS. The crossing KM curves for the presence vs. no presence of subsequent treatments showed that the effects of having or not having subsequent treatments vary across time. Further in-depth studies are needed to investigate the association, such as adding interaction between presence of next treatment and cancer stage. In the second Cox model, we modeled the relationship between the actual length of the rwTTNT and patients’ overall survival and yielded a statistically significant result. As the Cox model is commonly
used in modeling clinical trial results, being able to run Cox models with real-world endpoints and RWD is significant in that RWD-based analyses can generate results compatible with clinical trials. The ability to generate valid surrogate markers, such as the rwTTNT that we investigated in this study, provides health outcomes and comparative effectiveness research investigators with a valuable new tool to leverage as large collections of RWD become increasingly available.

Our study is not without limitations. First, our sample size was relatively small, especially for the second Cox model on patients who had subsequent treatments. The cohort may not well represent the stage I-III colon cancer population. This could be a potential reason for the non-Hispanic whites having higher hazard (i.e., shorter OS) compared to non-Hispanic blacks and Hispanics. As additional sites contribute their TR data to OneFlorida, we can expand the study cohort to achieve higher statistical power. Second, cancer stage information is currently only available discretely in our TR data; however, it is also prevalent in unstructured documents stored in EHRs (e.g., pathology reports). If only EHR data are available, we can explore advanced natural language processing (NLP) tools to unlock critical information such as cancer stage and other tumor characteristics. Third, current rules for identifying the first course of treatment and subsequent treatments can be improved. For example, our rule defines a 90-day wash-out period to differentiate the end of the first course of treatment and the beginning of the subsequent treatment. We assumed that the 90-day gap could eliminate the effects of the previous treatment. However, different drugs have different wash-out periods, leading to potential misclassification of the different treatment courses. For example, some trials have defined a one-month wash-out period to eliminate the effects of the previous treatment for colon cancer. We can potentially further decompose the rules for each type of colon cancer chemotherapy. More fine-grained rules or computable phenotypes should be developed and validated for future studies.

In summary, we calculated rwTTNT and rwOS from EHR and TR data. We assessed the agreement between EHR and TR data on the colon cancer diagnosis, treatment, and survival-related events. We showed that rwTTNT is positively correlated with rwOS. Thus, rwTTNT could be an important surrogate marker for studies that utilize RWD and ultimately help to optimize colon cancer treatment to extend overall survival.

Abstract

Diagnosis prediction aims to predict the patient’s future diagnosis based on their Electronic Health Records (EHRs). Most existing works adopt recurrent neural networks (RNNs) to model the sequential EHR data. However, they mainly utilize medical codes and ignore other useful information such as patients’ clinical features and demographics. We proposed a new model called MDP to augment the prediction performance by integrating the multimodal clinical data. MDP learns the clinical feature representation by adjusting the weights of clinical features based on a patient’s current health condition and demographics. Also, the clinical feature representation, diagnosis codes representation and the demographic embedding are integrated to perform the prediction task. Experiments on a real-world dataset demonstrate that MDP outperforms the state-of-the-art methods.

Introduction

Electronic Health Records (EHRs) are digital version of patient’s medical charts, which consist of longitudinal multimodal data including demographics, diagnosis, clinical notes and clinical features. Among predictive modeling tasks utilizing EHRs, diagnosis prediction is one of the most challenging and widely explored tasks, which aims to predict future diagnosis from the patient’s historical diagnosis record. The input to this task consists of a sequence of past patient visits with diagnosis codes (e.g., ICD9 codes) in each visit, and the output of the task should be the diagnosis codes at the next visit. The challenge of diagnosis prediction mainly exist in the following two aspects: (1) EHR data is heterogeneous and noisy. Various types of features (variables) are included in EHR, including categorical variables (e.g., medical codes), numerical variables (e.g., clinical measurements), and textual variables (e.g., clinical notes). Meanwhile, due to patients’ irregular visits and incomplete recording, there may be a lot of missing data. (2) The potential prediction space is very large. The current ICD-9-CM system consists of more than 13,000 codes, and it is difficult to make predictions given the large target space.

Recently, deep learning techniques have been widely adopted for diagnosis prediction tasks. In order to model the sequential EHR data, most approaches use the recurrent neural networks (RNNs) due to its ability of keeping track of sequential information. The key idea is to project the diagnosis codes in the sequence into low-dimensional features (i.e., embeddings) that capture the information that is the most relevant to the prediction task. This embedding learning is enabled by the RNN, and various methods differ in the strategies that are designed to learn such embeddings effectively. Among these methods, Retain and Dipole make predictions based on sequences of medical codes only, and GRAM, KAME and HAP also incorporates the hierarchical structure of the disease taxonomy. Despite these successes, existing diagnosis prediction methods still have the following limitations.

1) Most of the existing methods only use medical codes as input and ignore other useful information such as clinical features and demographics. Clinical features include vital signs and lab test results, which contain plenty of details about the patient’s symptoms and are considered as a significant complement of diagnosis codes. Similarly, patient demographics record the static information about the patient, including variables such as age, gender and ethnicity. Combining clinical features and demographics with diagnosis codes can greatly boost the prediction performance.

2) Recently, a method called MHM is developed to integrate the clinical features into the diagnosis prediction task. However, this approach simply concatenates the diagnosis codes representation and the clinical feature representation, and learns a representation for every layer of the disease taxonomy. In fact, the importance of clinical features varies enormously for different diseases. In addition, it is essential to assign different weights to clinical features based on current health condition of the patient, which can be derived based on patients’ clinical features and demographics information. This weighted mechanism helps to learn the clinical feature representation that better depicts the clinical symptoms.
(3) The granularity of time stamps when clinical features are recorded fluctuates and there may be a lot of missing data. Clinical features are recorded during a hospital stay. For different visits, the length of hospital stay varies. Meanwhile, in a hospital stay, vital signs and lab test results may not be recorded regularly, and different clinical features may be missing at different time stamps.

Motivated by these observations, we propose a multimodal diagnosis prediction model (MDP) to address these challenges. MDP takes diagnosis codes, disease taxonomy, clinical features and demographics as input, which are all relevant to the prediction task, and then feeds the input to a deep neural networks consisting of the following integral components. As shown in Figure 1, the diagnosis code encoder utilizes the disease taxonomy to learn the diagnosis code representations, and the clinical feature encoder learns the clinical feature representation by integrating the weight adjustment mechanism and the attentive clinical feature aggregation mechanism. The final representation, which combines predictive information obtained from the patient’s demographics, diagnosis codes and clinical features, is used to make the prediction. The proposed model is able to extract the relevant signals from all these valuable information sources, and effectively utilize them for challenging diagnosis prediction tasks with missing data and varied time granularity in the data.

Our main contributions are summarized as follows:

- We propose a novel and effective deep learning framework for diagnosis prediction, a very important task in health informatics. To the best of our knowledge, we are the first to integrate medical codes, clinical features and patient demographics in the diagnosis prediction task.
- We design a clinical feature weight adjustment mechanism which learns the correlation between the patient’s diagnosis codes and the clinical features, and adjusts the weight of clinical features based on the patient’s health condition and demographics.
- We incorporate an attentive clinical feature aggregation mechanism into the framework to deal with the missing data and the varying time granularity of clinical features. The aggregation mechanism assigns lower importance scores to the time stamps with missing data and captures the long-term dependencies by integrating the hidden states of clinical features at different time stamps.
- We empirically show that MDP outperforms existing methods on a real-world EHR data set. We also reveal some important properties of the proposed model that could explain the model superiority by experiments involving a quantitative analysis of clinical feature importance degrees and qualitative analysis based on case studies.

Problem Statement

**EHR Data.** For each patient, the clinical record can be viewed as a sequence of visits $V_1, \ldots, V_T$, where each visit record $V_t$ contains diagnosis information $x_t$ and clinical features $c_t$. The diagnosis information $x_t \in \{0, 1\}^{|D|}$ is a multi-hot binary vector, where $|D|$ is the number of unique diagnosis codes, and $D = \{d_1, d_2, \ldots, d_{|D|}\}$. $x_{t,i} = 1$ indicates that the patient was diagnosed with disease $d_i$ in the $t$-th visit; otherwise 0. For clinical features $c_t \in \mathbb{R}^{N \times T_t}$, $N$ is the number of clinical features that we are interested in, and $T_t$ is the length of the ICU stay in the $t$-th visit. The clinical features include vital signs and some lab test results. Besides, there is a demographic vector $p \in \{0, 1\}^r$ associated with each patient, which includes the patient’s gender, ethnicity, age and other demographic information, and $r$ denotes the number of such information.

**Disease Taxonomy.** Let $G$ denote the disease taxonomy, which contains the hierarchy of disease concepts in the form of a parent-child relationship, and the diagnosis codes in $D$ are the leaf nodes. We define $D’ = \{d_{|D|+1}, d_{|D|+2}, \ldots, d_{|D|+|D’|}\}$ as the set containing the ancestor codes, and all nodes in $G$ form the set $C = D + D’$. We construct $G$ using the multi-level diagnoses CCS categories.\[https://www.hcup-us.ahrq.gov/toolssoftware/ccs/ccs.jsp\]

**Diagnosis Prediction Task.** Based on the above notations, we define our task as follows. Given the patient’s diagnosis information $x_t$, clinical features $c_t$, demographic data $p$, and the disease ontology $G$, the goal of this task is to predict diagnosis codes of the next visit denoted as $\hat{y}_{t+1}$. \[727\]
Methods

Figure 1 shows the overview of the proposed MDP framework, which mainly contains two parts: (1) Diagnosis code encoder that utilizes the patient’s diagnosis codes and Gated Recurrent Unit (GRU) to learn the representations capturing the patient’s health conditions, and (2) clinical feature encoder which adjusts the weights of clinical features based on the current health conditions and demographic information, and finally learns the clinical feature representation during the ICU stay. Next, we describe the two parts separately and show how they can be optimized jointly.

Diagnosis Code Encoder

Diagnosis Code Embedding. In order to learn the robust embeddings of the diagnosis codes in the disease taxonomy $G$, we employ the graph embedding method GRAM. In Figure 1, leaf nodes or solid circles in $G$ represent diagnosis codes in set $D$, while non-leaf nodes or dashed circles represent more general concepts in $D'$. Every node in $G$ has a basic learnable embedding $e_i (1 \leq i \leq |D| + |D'|)$, where $|D'|$ represents the number of intermediate nodes. GRAM learns the final embedding vector of the $i$-th diagnosis code $m_i$ by combining the base embedding $e_i$ and its ancestors’ base embeddings via the graph-based attention mechanism. After concatenating the diagnosis embedding vectors $m_1, m_2, \ldots, m_{|D|}$ of all diagnosis codes, we obtain the diagnosis code embedding matrix $M \in \mathbb{R}^{d_1 \times |D|}$, where $d_1$ is the dimension size of the embedding vector. For the $t$-th visit, given the diagnosis information $x_t$, the vector $v_t$ is computed as $v_t = \text{tanh}(Mx_t)$.

Visit Representation Learning. After obtaining the vector $v_t$ that contains all diagnosis information at the $t$-th visit, we use Recurrent Neural Networks (RNNs) to capture the dependencies among multiple visits. RNN is an efficient method to model sequential data, and it has been widely used on healthcare data [10]. RNNs come in multiple variants, including Long-Short Term Memory (LSTM) and Gated Recurrent Unit (GRU). In this paper, we choose GRU. The hidden state $h_t \in \mathbb{R}^{g_1}$ is calculated recurrently by $h_t = GRU(v_t, h_{t-1}, \Theta_h)$, where $g_1$ is the dimension size of the hidden state, $v_t$ is the diagnosis codes vector, $h_{t-1}$ is the hidden state of the previous visit, and $\Theta_h$ represents all GRU parameters to be learned. We use $h_t$ to denote the representation of the $t$-th visit.

Clinical Feature Encoder

Clinical features include vital signs and lab test results, and they are considered as significant complements of diagnosis codes. During the ICU stay in the $t$-th visit, the vital signs such as heart rate and blood pressure are recorded hourly, and the lab tests such as blood chemistry analysis and urine analysis are performed periodically. We represent the clinical features as $c_t \in \mathbb{R}^{N \times T_t}$, which have two characteristics. (1) The importance of clinical features varies enormously for different diseases. For example, for patients with diabetes, glucose is more important comparing with body temperature, while for patients with fever, the opposite happens. (2) The timescale of clinical features fluctuates.
For different visits, the length of the ICU stay fluctuates from less than 24 hours to more than 500 hours. For visits with long ICU stay, RNNs may fail to capture the long term dependency. To take these unique characteristics into consideration, we design two corresponding modules in MDP, which are clinical feature weight adjustment and attentive clinical feature aggregation.

**Clinical Feature Weight Adjustment.** Given the patient’s current health condition \( h_t \) and demographic data \( p \), the weight adjustment system adjusts the importance of clinical features dynamically, maintaining those features that are highly relevant to the diagnosis codes, and compressing others that are less relevant. Next, we provide the details of adjusting clinical feature weights.

Given the clinical features \( c_t \), we learn the embedding \( c'_t \in \mathbb{R}^{d_2 \times T} \) with \( c'_t = W_c c_t + b_c \), where \( d_2 \) is the dimension size, \( W_c \in \mathbb{R}^{d_2 \times N} \) and \( b_c \in \mathbb{R}^{d_2} \) are the parameters to be learned. The diagnosis codes representation for every time stamp \( t \) contains the clinical information for the \( i \)-th time stamp in the \( t \)-th visit. The clinical embedding \( c'_{t,i} (1 \leq i \leq T_t) \) is fed into the GRU denoted as clinical \( GRU_\alpha \). The hidden state \( g_{t,i} \in \mathbb{R}^{g_2} \) is calculated recurrently by \( g_{t,i} = GRU_\alpha (c'_{t,i}; g_{t,i-1}; \Theta_\alpha) \), where \( g_2 \) is the dimension size, and \( \Theta_\alpha \) is the corresponding parameter.

In order to adjust the importance of clinical features, we need to learn the weights of all clinical features for every time stamp by considering both current health conditions and demographic data. In particular, we first learn a vector \( k \) that encodes the current health condition and demographic data. Given the demographic information \( p \in \{0, 1\}^r \), the embedding \( p' \in \mathbb{R}^{r_1} \) is calculated by \( p' = W_p p + b_p \), where \( r_1 \) is the dimension size, \( W_p \in \mathbb{R}^{r_1 \times r} \) and \( b_p \in \mathbb{R}^{r_1} \) are the parameters to be learned. The diagnosis codes representation \( h_t \) contains the health condition. Then we concatenate \( h_t \) and \( p' \), and compute \( k = W_o [h_t \oplus p'] \), where \( g_2 \) is the dimension size and \( W_o \in \mathbb{R}^{g_2 \times (r_1 + g_1)} \) is the parameter to be learned.

For every time stamp \( t \), we learn a vector \( \alpha_{t,i} \in \mathbb{R}^{g_2} \) with \( \alpha_{t,i} = tanh(k \odot g_{t,i}) \), where \( \odot \) is the Hadamard product. \( \alpha_{t,i} \) contains the correlation between the clinical features and the patient’s health condition at the \( i \)-th visit. Then we map the correlation vector \( \alpha_{t,i} \in \mathbb{R}^{g_2} \) into the clinical embedding space via \( \alpha'_{t,i} = tanh(W_\alpha \alpha_{t,i} + b_\alpha) \), where \( W_\alpha \in \mathbb{R}^{d_2 \times g_2} \) and \( b_\alpha \in \mathbb{R}^{d_2} \) are the parameters to be learned, and \( \alpha'_{t,i} \in \mathbb{R}^{d_2} \). Here \( \alpha'_{t,i} \) is regarded as the weights of clinical features at the \( i \)-th time stamp. We compute the weighted clinical embedding \( c''_{t,i} \in \mathbb{R}^{d_2} \) by multiplying the original clinical embedding \( c'_{t,i} \) by its corresponding weights, which is \( c''_{t,i} = \alpha'_{t,i} \odot c'_{t,i} \). In such a way, \( c''_{t,i} \) assigns more weights to clinical features that are highly related with the patient’s current health condition.

**Attentive Clinical Feature Aggregation.** After we obtain the weighted clinical embedding \( c''_{t,i} (1 \leq i \leq T_t) \), we use another GRU, clinical \( GRU_\beta \), to capture the dependencies among the multiple time stamps. The hidden state \( q_{t,i} \in \mathbb{R}^{g_3} \) is computed with \( q_{t,i} = GRU_\beta (c''_{t,i}; q_{t,i-1}; \Theta_\beta) \), where \( g_3 \) is the dimension size, \( \Theta_\beta \) is the parameter to be learned.

Because some length of the ICU stay may be extremely long, GRU may fail to learn long-range dependencies. Instead of using the hidden state at the last time stamp \( q_{t,T_t} \) as the clinical feature representation, we import the attentive clinical feature aggregation mechanism which combines the hidden states among all time stamps. For time stamp \( i, 1 \leq i \leq T_t \), the aggregation mechanism computes the corresponding attention weight \( \beta'_i \), which is a scalar, and then calculates the weighted sum of the hidden states as the final clinical feature representation \( q'_i \in \mathbb{R}^{g_3} \). The attention weight \( \beta'_i \) is computed as follows:

\[
\beta_i = w_\beta q_{t,i} + b_\beta, \quad \beta'_i, \beta'_2, \cdots, \beta'_{T_t} = softmax(\beta_1, \beta_2, \cdots, \beta_{T_t})
\]

where \( w_\beta \in \mathbb{R}^{g_3} \) and \( b_\beta \in \mathbb{R} \) are the parameters to be learned, \( \beta'_i \) and \( \beta_i \) are scalars. Finally, the clinical feature representation \( q_i \) is calculated by \( q'_i = \sum_{i=1}^{T_t} \beta'_i q_{t,i} \).

**Joint Optimization.**

We concatenate the diagnosis codes representation \( h_t \), the demographic embedding \( p' \), and the clinical feature representation \( q_i \) to obtain the vector \( s_t \) that encodes the overall patient’s health status \( s_t = [h_t \oplus p' \oplus q_i] \), \( s_t \) is then fed into a softmax layer to predict the diagnosis codes in the next visit, which is denoted as \( \hat{y}_{t+1} = Softmax(W_s s_t + b_s) \), where \( W_s \in \mathbb{R}^{P \times (g_1 + r_1 + r_2 + g_3)} \) and \( b_s \in \mathbb{R}^{P} \) are the parameters to be learned.

We compute the cross entropy loss between the ground truth $y_t$ and the predicted $\hat{y}_t$ using

$$
\mathcal{L} = -\frac{1}{T-1} \sum_{t=1}^{T-1} (y_t \log(\hat{y}_t) + (1 - y_t) \log(1 - \hat{y}_t)).
$$

This loss is calculated for a certain patient, and we compute the loss of all patients by averaging $\mathcal{L}$.

Experiments

In this section, we first introduce the experimental settings and then demonstrate the performance of the proposed algorithm on a public EHR dataset MIMIC-III. Moreover, we analyze the importance of clinical feature and visualize the clinical feature importance of three patients with different diseases. Finally, a case study is conducted to illustrate that MDP is able to correctly predict more diagnosis codes comparing with baselines.

Experimental Settings

**Dataset.** MIMIC-III is a publicly available EHR dataset, which consists the admission records of ICU patients over 11 years. EHR data include diagnosis information such as diagnosis codes and procedure codes, clinical features such as vital signs and lab tests results, and clinical notes charted by care providers. We select the patients who made at least two visits. Following the previous work, we only select patients that are older than 18 and have single ICU stay per admission. Table 1 shows the details about the dataset. When performing the diagnosis prediction task, instead of predicting diagnosis categories like most of the previous research, we aim to predict the real diagnosis codes. This means that our task is more difficult since the target space is much larger.

**Baselines.** We select seven baselines that can be divided into three groups. Group 1 contains models that do not use the disease taxonomy information, which includes RNN and Dipole. Group 2 contains models that use the disease taxonomy information, and these models only use patients’ historical diagnosis codes as input, including GRAM, KAME, and HAI. Models in Group 3 use the disease taxonomy information and use the multimodal data as input, including CAMT and MHM.

**Implementation Details.** Following previous work, we extract 17 clinical features, including heart rate, mean blood pressure, glucose and other vital signs. For every clinical feature, we assign a binary variable indicating whether the clinical feature was observed at the current time stamp, and we fill in the missing clinical features with the values in the previous time stamp. For ICU stays with long length, we only use the records in the first 500 hours. The dimension size $N$ of the clinical feature is set to 76. The demographic data is preprocessed as the method used in CAMT, and the dimension size $r$ is 11, which contains 2 genders, 5 age groups and 4 admission types. The clinical embedding size $d_2$ is set to 76, and $d_1$, $g_1$, $g_2$ and $g_3$ are set to 128.
with learning rate 0.001 and weight decay 0.001. For all models, the dimension of the diagnosis code embedding is set to 128, and the corresponding hidden state size $g_1$ is set to 128. We run every experiment ten times, and the average values and standard deviations are reported.

**Evaluation Metric.** Following CAMI[11], we use Recall@$K$ and MAP@$K$ as the evaluation criteria. For every visit $V_t$, we get a 1 if the target diagnosis code appears in the top $k$ predictions and 0 otherwise. Recall@$K$ is defined as the number of diagnosis codes that are predicted correctly in the top $k$ of $\hat{y}_t$ divided by the total number of diagnosis codes in $V_t$. MAP@$K$ refers to mean average precision, and it considers not only the precision and accuracy but also the order of diagnosis codes which are predicted correctly. We vary $K$ from 20 to 60.

**Performance Comparison**

Table 2 shows the performance of MDP comparing with seven baselines. The proposed model MDP outperforms all baselines and achieves 1.2% higher Recall@$K$ and MAP@$K$ over the best baseline. This demonstrates the effectiveness of the clinical features in diagnosis prediction task. Meanwhile, MDP is able to adjust the weights of clinical features according to the patient’s current health condition and the demographics. Among these baselines, methods in Group 1 do not use the disease taxonomy information, and they directly learn the diagnosis code embedding from the input data. The performance of RNN is worse than that of Dipole. It is because Dipole uses the bidirectional RNNs and apply the location-based attention mechanism when it makes predictions, which are able to capture visit dependency even for long sequences.

Three baselines in Group 2 all use the disease taxonomy information, and the inputs are the patient’s diagnosis codes. The performance increases from GRAM to HAP. GRAM only updates the embedding of the leave nodes, and uses the diagnosis code representation to make predictions. KAME is built upon GRAM but learns a knowledge vector that contains the coarse-grained information of ancestor codes. KAME outperforms GRAM, and it suggests that general knowledge of the ancestors helps to represent the patient’s health condition and further boosts the performance of the diagnosis prediction. However, both GRAM and KAME ignore the order among the ancestors. For example, in Figure 1 node $c_0$, $c_1$ and $c_2$ are the ancestors of $c_3$. When learning the diagnosis code embedding, GRAM and KAME treat $c_0$, $c_1$ and $c_2$ equally, without considering their order. HAP fills the gap by designing a two-round attention propagation mechanism, and the embedding of diagnosis code is updated layer by layer. The performance of HAP exceeds GRAM and KAME, which indicates that using the full ontology hierarchy improves the models’ expressibility.

Methods in Group 3 uses the multimodal data as input, and the performance of CAMP and MHM exceeds HAP. CAMP imports a memory network to save the fine-grained patient conditions, and the patient’s demographic data cooperate with the READ/WRITE operations of the memory network. Instead of using the disease hierarchy to learn a more robust embedding, MHM uses the ontology hierarchy in a different way. It models the diagnosis prediction

We randomly split the datasets into the training, validation and testing sets based on the number of patients in a 0.75:0.1:0.15 ratio. For fair comparison, all models are implemented with Pytorch, and we use the Adam optimizer.
task as a hierarchical multi-label classification problem, and clinical features and diagnosis codes are used as inputs. The performance of CAMP is better than MHM because the hierarchical multi-label model generated by MHM can not fully use the ontology hierarchy. The proposed model MDP uses the patient’s diagnosis code, clinical features and demographic data as inputs, and the weights of clinical features are adjusted by the patient health condition and demographic data dynamically. The clinical feature representation learned by MDP is used as a complement of diagnosis code representation, and it contains plenty of details about the patient’s symptoms. Comparing with the best baseline CAMP, MDP gets 1% mean improvement of Recall@K and 1.2% mean improvement of MAP@K.

Clinical Feature Importance Analysis

To demonstrate the benefit of clinical feature weight adjustment and attentive clinical feature aggregation mechanism in diagnosis prediction task, we define a criteria to evaluate the importance of clinical features for every time stamp. For the \( i \)-th time stamp in the \( t \)-th visit, the clinical feature importance \( \omega_i \in \mathbb{R}^N \) is calculated by \( \omega_i = \beta_i \alpha'_{t,i} \), where \( \alpha'_{t,i} \in \mathbb{R}^{d_2} \) is a vector learned in the clinical feature weight adjustment section, and \( \beta_i \) is a scalar learned in attentive clinical feature aggregation section. Since \( \omega_i \) may contain negative numbers, we use the abs function to compute the absolute value, i.e., \( \omega_i = \text{abs}(\beta_i \alpha'_{t,i}) \). Meanwhile, categorical features are encoded into multiple dimensions. In order to fairly evaluate the contributions of all features, we compute the average as the final importance. We concatenate \( \omega_i \) for \( 1 \leq i \leq T_t \) and obtain the importance matrix of clinical features \( \omega \in \mathbb{R}^{T_t \times N} \).

</table>

Figure 2 shows the heatmap of the clinical feature importance matrix for two patients in a visit. In Figure 2, the \( x \) axis is the clinical feature, and the \( y \) axis is the time stamp. The color represents the feature importance, the darker color means the more feature importance. We first analyze the importance of different clinical features. Table 3 lists the corresponding diagnosis codes in the visit. We can observe that patient 1 mainly suffered respiratory diseases, and the heatmap shows that clinical features related with respiratory system obtain more weights. For example, fraction
inspired oxygen, oxygen saturation and respiratory rate have greater weights. Meanwhile, the patient also suffered anemia and hypothyroidism, and both diseases can result in hypoglycemia. We can observe that glucose also has higher weight. Patient 2 suffered heart diseases and cerebrovascular diseases, and MDP assigns high weights to respiratory rate and heart rate. Besides, this patient also suffered diabetes, and glucose is also highly weighted. The above observation shows that clinical feature weight adjustment mechanism can adjust the weights of clinical features based on the patient’s health condition.

We then analyze the importance of different time stamps. We observe that the importance increases as time goes by. In general, MDP assigns more weights to the recent time stamps. It is because clinical features in the latter time stamps can better represent the patient’s symptoms in the current visit, and these time stamps are more helpful to predict the diagnosis codes in the next visit. For patient 2, intermediate time stamps are assigned lower weights comparing with the before and after time stamps. This is because there are lots of missing clinical features in these intermediate time stamps. The above observation shows that the attentive clinical feature aggregation mechanism can assign different weights to different time stamps.

In conclusion, the heatmap of clinical feature importance illustrates that both clinical feature weight adjustment mechanism and the attentive clinical feature aggregation mechanism can coordinate to adjust the importance of clinical features and time stamps, which further helps to learn the clinical feature representations.

### Case Study

Table 4 shows the correctly predicted diagnosis codes of another two patients when $K = 20$. For patient 1, the ground truth contains 14 diagnosis codes. The proposed model MDP correctly predicts 7 diagnosis codes in the top 20 predictions. Dipole achieves the same performance, while other baselines correctly predicted 4-5 diagnosis codes. We can observe that patient 1 mainly suffered from heart diseases, MDP correctly predicts not only the diagnosis codes directly related to heart disease but also the ones describing the details, such as V45.82, which is percutaneous transluminal coronary angioplasty status. This illustrates that the clinical feature can provide more details about the disease and is helpful to make the prediction. Similarly, patient 2 has 5 diagnosis codes, and MDP correctly predicts 3 diagnosis codes in the top 20 predictions, while most baselines only predict 1-2 diagnosis codes. These results show the superiority of the proposed MDP.

### Related Work

Diagnosis prediction, which aims to predict the patient’s future health condition based on their historical EHRs, is an important task in health informatics, and thus has been widely studied. Most of the previous studies investigate how to effectively utilize the patient’s historical diagnosis codes for the prediction. Some representative methods are...
discussed below. RETAIN applies an RNN with reverse time ordered EHR sequences, and designs a two-level neural attention model to provide detailed interpretation of the prediction results. Dipole designs three different attention mechanisms to learn the diagnosis code representations, and feeds the representations into a bidirectional GRU. The hidden state of the GRU is used to predict the potential diagnosis codes in the next visit. Note that diagnosis codes and medical concepts are naturally organized in a hierarchy, and the ancestor node information plays an important role in the prediction of the diagnosis code corresponding to the descendant node. Therefore, several studies exploit this hierarchical structure in diagnosis prediction. GRAM incorporates a graph-based attention mechanism, and computes the embedding of the diagnosis code as the weighted sum of the basic embedding of itself and its ancestors. KAME learns the ancestor representation and concatenates it with the diagnosis code representation. The ancestor representation contains the coarse-grained health condition. HAP proposes a hierarchical attention mechanism in which the attention propagates across the entire hierarchy from layer to layer. The embedding of the node absorbs knowledge from not only its ancestors, but also its descendants, siblings and even some distant nodes. Different from the aforementioned methods that rely on visit sequences of diagnosis codes and their relations only, the proposed MDP model incorporates additional valuable information including patient demographics and clinical features to boost the performance of diagnosis prediction.

Recently, researchers also explore the use of multimodal data to perform the diagnosis prediction task. CAMT incorporates patients’ demographics information in the prediction model. Specifically, it imports an external memory network which saves the fine-grained health condition for every top level categories in the disease taxonomy, and combines the diagnosis codes information with the patient’s demographics to help the READ/WRITE operation of the memory network. Clinical features, which also encodes predictive information for diagnosis prediction and serves as an input to the proposed MDP model, are not considered by the CAMP model. MHM uses the diagnosis codes and clinical features as input. MHM models the diagnosis prediction task as a hierarchical multi-label classification problem, and the disease taxonomy is used to generate the hierarchical label. MHM learns a representation for every layer of the disease taxonomy, and the global representation is the weighted sum of the layer representation. However, MHM neglects the relation between the diagnosis codes and clinical features and ignores the variance in patient groups defined by demographics. The proposed model MDP overcomes this shortcoming by importing a clinical feature weight adjustment mechanism. By this mechanism, the importance of clinical features is adjusted according to the health condition and the demographics.

The proposed MDP and the aforementioned models all aim to tackle the diagnosis prediction task. Existing models utilize one or two sources of information, while the proposed model takes advantage of all the relevant information including diagnosis code sequences, hierarchy, clinical features and patient demographics. Another relevant research topic is the analysis of clinical features, but note that the task tackled by these methods is not diagnosis prediction. Concare learns the inter-dependencies among clinical features, and it improves the multi-head self-attention via the cross-head decorrelation.

Conclusions

In this paper, we propose a novel model MDP to perform the diagnosis prediction task. MDP takes the diagnosis codes, clinical features and demographics as input and consists of integral components that effectively integrates these heterogeneous information sources. The diagnosis code encoder in MDP utilizes the disease taxonomy to learn the diagnosis code representations which capture the patient’s current health condition. The clinical feature encoder learns the clinical feature representations by incorporating a weight adjustment mechanism and an attentive clinical feature aggregation mechanism. The weight adjustment mechanism adjusts the weights of clinical features based on the diagnosis information and demographics, and the attentive clinical feature aggregation mechanism enables the capture of the long term dependencies among the patient’s conditions at multiple time stamps during an ICU stay. By integrating these components, the proposed MDP is able to extract meaningful signals that are relevant to diagnosis prediction from any available source. Experimental results on a real-world EHR dataset show the effectiveness of MDP for diagnosis prediction. To analyze the insights behind the proposed framework, we further demonstrate the assigned weights to various clinical features and time stamps via the clinical feature encoder as well as a comparison with baselines based on the correctly predicted diagnosis codes in the top 20 predictions for some case studies. These results explain how the proposed MDP achieves the superior performance.

Abstract:
Brigham and Women’s Hospital has received funding from the Centers for Medicare and Medicaid Services to develop a novel electronic clinical quality measure to assess the risk-standardized major bleeding and venous thromboembolism (VTE) rate following elective total hip and/or knee arthroplasty. There are currently no existing measures that evaluate both the bleeding and VTE events following joint arthroplasty (TJA). Our novel composite measure was tested within two academic health systems with 17 clinician groups meeting the inclusion criteria.

Following risk adjustment, the overall adjusted bleeding rate was 3.87% and ranged between 1.99% – 5.66%. The unadjusted VTE rate was 0.39% and ranged between 0% – 2.65%. The overall VTE/Bleeding composite score was 2.15 and ranged between 1.15 – 3.19. This measure seeks to provide clinician groups with a tool to assess their patient bleeding and VTE rates and compare them to their peers, ultimately providing an evidence-based quality metric assessing orthopedic practices.

Introduction
Total hip arthroplasty (THA) and total knee arthroplasty (TKA) represent the most common implant surgeries performed on Medicare beneficiaries1 and are increasingly performed for younger and more active recipients2. In 2018, over 650,000 primary TKA and 374,000 THA surgeries were performed in the United States with a projected volume increase of over 100% in the next decade3–5. Patients undergoing these procedures are at risk of developing a venous thromboembolism (VTE), which includes deep vein thrombosis and pulmonary embolism. Studies have estimated that about 4.7% of patients undergoing total joint arthroplasty (TJA) would have symptomatic VTE without prophylaxis6 and that 5-14% of patients diagnosed with a VTE following TJAs are re-admitted to the hospital7. Furthermore, VTE events following TJA are potentially life-threatening and can result in chronic complications with generally poor prognoses, such as thromboembolic pulmonary hypertension8–10. Therefore, there is general agreement that VTE prophylaxis is necessary following TJA11–13. However, orthopedic surgeons face the challenge of balancing VTE prophylaxis against their associated risks which include bleeding, prosthetic joint infections, the need for reoperation, and readmission14,15. A study by Stokes et al indicated that for hip and knee surgeries, bleeding complications increased the average cost and length of stay by 30%16. Thus, it is critical for orthopedic surgeons to strike the proper balance between efficacy and safety when choosing a VTE prophylactic regimen, especially for patients undergoing TJA.

At the time of measure conception, our objective was to develop a novel eCQM (electronic clinical quality measure) to evaluate the rate of major bleeding events following elective primary THA and TKA. Acknowledging the dangers of VTE events on the opposing end of the anticoagulant use spectrum, this measure was later expanded to evaluate both VTE and major bleeding events and seeks to assess the balance between over-prescribing (increasing the risk of bleeding) and under-prescribing anticoagulants (increasing the risk of VTE) following surgery. This eCQM will provide a data driven approach to assist providers in finding the appropriate VTE prophylactic regimen that accounts for both general and patient-specific risks of VTE and major bleeding. Developing an eCQM that relies on routinely captured EHR data ensures that the clinician reporting burden is not increased. This risk adjusted measure seeks to provide clinicians with a unique tool to assess their own performance and compare it to their peers, ultimately encouraging evidence-based quality improvement.
Methods

Patient Population and Data Sources:
Data were collected and analyzed from two geographically distant academic health systems. Site 1 used the EHR vendor Epic, provided data from 2016-2019, and included six clinician groups. Site 2 used the EHR vendor Cerner, provided data from 2017-2019, and included eleven clinician groups. All eligible patients (specifications below) were included in the analysis. Information documented in the EHR (e.g., comorbidities, medication, diagnosis, and procedural information) was used to determine a patient’s eligibility for inclusion.

Based on stakeholder feedback and a review of literature and existing quality measures, the following numerator, denominator, and exclusion statements were used in alpha and beta testing:

Denominator: All patients, aged 18 years or older, who received an elective primary THA and/or TKA procedure and do not meet any exclusion criteria.

Figure 1: Denominator Exclusion Criteria

<table>
<thead>
<tr>
<th>Exclusions: Patients who meet any of the criteria below will be excluded from the measurement population</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Who were discharged against medical advice (AMA)</td>
</tr>
<tr>
<td>• Who had more than two THA/TKA procedure codes during the index hospitalization</td>
</tr>
<tr>
<td>• With diagnosis codes for renal insufficiency within the 365 days prior to the THA/TKA procedure</td>
</tr>
<tr>
<td>• With diagnosis codes for chronic atrial fibrillation within the 365 days prior to the THA/TKA procedure</td>
</tr>
<tr>
<td>• With diagnosis codes for cancer within the 365 days prior to the THA/TKA procedure</td>
</tr>
<tr>
<td>• Who received prescription orders for anticoagulant medications 10-90 Days Prior to Surgery and meets the following criteria:</td>
</tr>
<tr>
<td>o Patient who received an Anticoagulant Injection/Infusion</td>
</tr>
<tr>
<td>o Patient who received a tablet (Oral) Anticoagulant order, Quantity &gt; 1</td>
</tr>
<tr>
<td>• With VTE diagnosis code present on admission for index admission</td>
</tr>
<tr>
<td>• With major bleeding diagnosis code present on admission for index admission</td>
</tr>
<tr>
<td>• With diagnosis code for coagulation disorder within the 365 days prior to the THA/TKA procedure</td>
</tr>
<tr>
<td>• Who had additional surgery within 35 days from the elective primary THA/TKA</td>
</tr>
</tbody>
</table>

Numerator: Patients who develop a major bleeding and/or VTE event occurring from the date of the THA/TKA procedure to 35 days postdate of procedure.

• Diagnosed with a VTE event (Deep Vein Thrombosis or Pulmonary Embolism)
• Presence of ICD 10 diagnosis codes for major bleeding during index admission, inpatient hospital encounters, and/or outpatient physician office visits
• Presence of ICD 10 PCS procedure codes for treatment of hemorrhage or hematoma during the index admission, inpatient hospital encounters, and/or outpatient physician office visits
• If the patient received transfusions of ≥1 unit of whole blood or packed cells

Statistical Testing and Analysis:

Alpha Testing
The development team first performed testing to determine the feasibility of implementing this eCQM into existing EHR systems, focusing on the availability of data elements needed for measurement and risk adjustment. Validity testing was conducted from Site 1 to evaluate the agreement between the eCQM and a manual chart review. Chart reviews were performed on a random sample of 236 patients from Site 1, and 30 patients from Site 2. Separate chart reviews were performed on random samples of both patients who met the inclusion criteria, and random samples of patients who met exclusion criteria, to assess the validity and data agreement between manual review and the eCQM. If disagreements between the manual reviewer and the eCQM were found, the particular disagreement would be documented and explored further by the eCQM development team. In some instances, additional EHR review was required to understand and resolve the disagreement. Multiple rounds of review were conducted as measure specifications were fine tuned to resolve disagreements and/or errors.

Beta Testing
Data were extracted from both sites to analyze the type of surgery performed (THA and/or TKA), patient characteristics, and diagnostic and procedural information. Individual clinician group major bleeding rates were risk adjusted by adapting Yale CORE’s Hospital-Level Risk-Standardized Complication Rate risk adjustment model17.
The model utilized by the eCQM development team considers the number of procedures, sex, race, area-level household income (using zip code information), BMI, smoking status, language, and comorbid conditions (Table 1). The team utilized a test-retest approach to test the reliability of the predicted/expected ratios at the clinician group level. Within each clinician group, we randomly selected 50% of the THA/TKA admissions for a test sample, which was used to create the model. We used the remaining random sample of 50% of THA/TKA admissions as the validation sample. We ranked the predicted/expected ratios in the test and validation samples and then estimated the Spearman rank correlation coefficient to correlate the ranking in the test and validation samples. Additionally, the C-Statistic/Area under ROC Curve and the Hosmer-Lemeshow Goodness of Fit test was performed to validate the adequacy of the model.

**Measure Scoring**

The risk adjusted bleeding rate is the ratio of the number of “predicted” events to the number of “expected” events for each clinician group, multiplied by the overall rates calculated in our measure. The measure estimates clinician group-level bleeding rates using hierarchical logistic regression models. This approach models the log-odds of a patient experiencing a bleed using the risk adjustment variables and clinician group-specific intercepts. At the clinician group level, it models the group-specific intercepts as arising from a normal distribution. In this model, the clinician group intercept represents the underlying risk of a bleed for procedures performed by said group, after accounting for the patient risk factors in the risk adjustment model. If there were no differences among clinician groups, then after adjusting for patient risk, the group level intercepts should be identical across all groups.

The risk adjusted VTE and Bleeding rates are derived from a hierarchical binomial logistic regression model, where, for each patient, the outcome is the sum of the VTE outcome (1=yes, 0=no) plus the bleed outcome (1=yes, 0=no); the sum equals 0 (no events), 1 (either VTE or bleed, but not both), or 2 (both VTE and bleed). From this hierarchical binomial logistic regression model, the risk adjusted VTE and Bleeding rates are calculated by taking the (predicted/expected ratios) * (overall sample rate) * 100. Risk-adjustment of the VTE data was not possible due to the low number of events within the total sample. However, by combining the number of VTE and major bleeding events for each clinician group a risk adjusted composite score can be calculated. In our testing, the composite score (combination of VTE and bleeding) for each clinician group is calculated by (predicted/expected ratios) x (overall score) x 100, where the overall score is equal to the (number of VTE and bleeding events) / (Denominator * 2). Clinician groups can be ranked based on these performance metrics by using the predicted/expected ratios or the risk-adjusted rates and scores.

**Results**

The total sample included 17,333 patients from Site 1 (2016-2019) and 11,885 patients from Site 2 (2017-2019). From the total sample, 74.5% of Site 1 patients (n=12,913) and 89.6% of Site 2 patients (n=10,646) met the inclusionary criteria and were included in analysis. The eCQM team evaluated the population of patients included in our test and validation samples and found there were no differences between clinician groups (p = 0.999) or between Sites (p = 0.938). Descriptive statistics of the sample population can be found in Table 1.

**Statistical Testing and Analysis:**

**Alpha Testing**

Overall, the eCQM reliably captured 98% of the data elements required for rate calculation and risk adjustment. Smoking status was the only data element that was captured less than 90% of the time. Refer to Table 2 for more detailed information regarding data element reliability. Validity testing within Site 1 indicated that the manual chart review and the eCQM had excellent agreement by the end of the measure development process. In the final round of testing, the eCQM and chart reviewers agreed on 96% of the cases randomly selected from Site 1 and 93% of cases randomly selected from Site 2. Results of the iterative chart review process can be seen in Table 3. Overall, the results of alpha testing indicated that this eCQM can be readily implemented into Epic, Cerner, and other EHR systems that adopt recommended terminology standards.

**Beta Testing**

Site 1 (n=12,914) had an unadjusted major bleeding rate of 2.90% with clinician group performance ranging between (2.54%– 4.76%) and a VTE rate of 0.55% (0.20%– 0.84%). Site 2 (n=10,643) had an unadjusted bleeding rate of 4.86% (2.17%– 39.66%) and a VTE rate of 0.21% (0.00%– 2.65%). The unadjusted data shown in Table 4 also indicates that there was substantial variation in unadjusted bleeding and VTE rates between different clinician groups regardless of site.

However, the measurement of interest for each clinician group was the ratio of the number of “predicted” to the number of “expected” events. Both the predicted and expected numerator events were adjusted for age, gender, type of surgery (THA/TKA), insurance, race, household income, English as primary language, smoking status, body mass index and comorbidities. Table 5 below shows the predicted/expected ratios and 95% confidence intervals for the 17 clinician groups (blinded). Only the Major Bleeding and Composite predicted/expected ratios are shown since the development team was unable to risk-adjust the VTE data due to the low number of events within the total sample. The calculated rates/scores for all 17 clinician groups are shown in Table 6. The overall adjusted bleeding rate was 3.39%/3.398% and ranged between 1.987% – 5.656% for the Test and Validation Samples. The overall VTE/Bleeding composite score was 1.892/1.923 and ranged between 1.148 – 3.184 for the Test and Validation Samples.

740
Overall, when evaluating the risk-adjustment model, our results demonstrate strong reliability across the test and validation samples. As noted in Tables 5 and 6, the test and validation samples give similar rankings of the 17 clinician groups with respect to the predicted/expected ratios with a Spearman rank Correlation of .900 and .946 for Bleeding and the Composite Score respectively.

For major bleeding alone we estimated the intraclass correlation (ICC) between clinician groups and the ICC value was .054 meaning there is some variability across clinician groups as noted by the predicted/expected ratios in Table 5. When taking the VTE component into account within the composite score the ICC value is .041, indicating some variability between clinician groups.

**Adequacy of Model**

The resulting C-statistics for the test and validation sample were the following for Major Bleeding and the Composite Score: 0.796/0.779 and 0.782/0.773. Additionally, Hosmer-Lemeshow tests were conducted on the test and validation samples (p-values test/validation: major bleeding model 0.978/0.214 and composite score model 0.345/0.607).

**Discussion:**

This study reports on the initial testing of an eCQM for VTE/major bleeding across clinical groups within two healthcare systems for people undergoing THA and/or TKA. With regards to the feasibility of implementing this eCQM, the research team found that the required data elements for rate calculation and risk adjustment were reliably captured across both sites and clinician groups, missing less than 2% for most data elements. Since the vast majority of data elements were captured, the eCQM team did not believe that the missing data would bias results. Performance wise, beta testing indicated an overall unadjusted bleeding rate of 3.8% and a VTE rate of 0.4%, which is in line with the rates that are currently in the literature, ranging from 0.2% to 6.8% and 0.2% to 3.7% respectively. Upon initial observation, relatively large variations in both major bleeding and VTE rates were noted between clinician groups. These differences may indicate that inconsistent approaches to periprocedural anticoagulant prescribing practices exist between different clinician groups and health systems. This is unsurprising as the guidelines outlined by the American Academy of Orthopaedic Surgeons and the American College of Chest Physicians indicate that while VTE prophylaxis is recommended, no specific recommended regimen nor pharmacological agent exists. Even though anticoagulant prescribing practices may vary, variability within the patient population of each clinician group may additionally be contributing to the differences observed between clinician groups. However, the risk-adjusted results, which accounts for differences in patient population, for both the major bleeding and component scores indicate that clinically significant variations in performance can be seen between the 17 clinician groups. Statistical testing evaluating the model itself was conducted utilizing C-statistics and Hosmer-Lemeshow tests. The results indicated that our predictive model showed good discrimination of who would experience a VTE and/or major bleeding event. Additionally, there were no statistically significant differences between the predicted and expected results for either the major bleeding or composite models.

Adjusted Bleeding Rate = (predicted/expected ratios) x (overall rate) where overall rate = 0.038
Composite Score = (predicted/expected ratios) x (overall rate) x 100 where overall rate = 0.021
To our knowledge, this is the first measure that evaluates both the bleeding and VTE rate following TJA. The development team believes that this eCQM could enable a better understanding of how a specific clinician group’s post-operative anticoagulation and bleeding outcomes compare with their peers. Tying in monetary incentives through the MIPS participation pathway of the Quality Payment Program (QPP), orthopedic clinician groups will be motivated to improve their practices, ultimately driving quality improvement within the specialty of orthopedic surgery. Importantly, as an eCQM, measure scores can be calculated at any time, giving clinicians the ability to evaluate their performance at regular intervals as opposed to claims-based measures that are only published every two years.

Several limitations were acknowledged during eCQM testing. One limitation is that this eCQM can only be used within integrated health care networks that utilize an enterprise EHR system. For example, if a patient receives care from multiple health sites with different or unconnected EHR systems, a patient’s medical records could be scattered across several independent databases. Similarly, another limitation is the lack of consistent policies surrounding EHR documentation. At the Cerner Test Site, we discovered that some data elements were documented consistently (mandated) while others were optional due differences in policy (smoking status). With our risk-adjustment modeling heavily relying on data element availability, the ability to risk-adjust within other healthcare systems depends on current and future policies enacted by healthcare systems. Throughout our testing process, the eCQM team discovered that documentation procedures vary widely even between clinician groups within the same site as each clinician group may have different thresholds/protocols for the documentation or treatment of certain events. Another limitation of the measure is that bleeding and VTE harm are weighted equally because the current version of the CMS Measure Authoring Tool (MAT) is unable to assign unequal weights. VTE events are much less common than major bleeding events, but they pose a significantly greater risk of serious harm/death to the patient. In the future, once enhancements are made to MAT, the BWH team will ideally use the Harm Weights established by the AHRQ PSI 90 composite measure where Perioperative Hemorrhage or Hematoma Rate is assigned a harm weight of 0.0570 and PSI 12 Perioperative Pulmonary Embolism or Deep Vein Thrombosis Rate is assigned a harm rate of 0.1557. This would result in a Harm Weight Ratio equivalent to 2.7 for VTE events, and would be the score given to patients who experience a VTE event compared to the score of 1 for a Major Bleeding event. Lastly, the eCQM has only been tested within clinician groups at two large academic healthcare care systems with two different EHR vendor systems. Testing at additional sites is needed to fully understand the feasibility and meaningfulness of this eCQM. However, we conclude that this appears to be a useful measure for these procedures especially as it includes the competing risks of clotting and bleeding.

The BWH eCQM team has submitted this measure to the 2021 CMS Measures under consideration (MUC) List and plans to obtain NQF endorsement to facilitate implementation into the CMS’ QPP. If implemented, this VTE and Major Bleeding eCQM will enhance the MIPS pathway by providing clinicians with a minimally burdensome method to monitor the impact of their anticoagulation practices while minimizing provider time spent collecting and submitting data to CMS.

Identifying Sleep-Related Factors Associated with Cognitive Function in a Hispanics/Latinos Cohort: A Dual Random Forest Approach

Abstract
Disordered sleep is associated with poor cognitive function and cognitive decline. However, little is known regarding the association of sleep-related factors with cognitive function in underrepresented cohorts such as the Hispanic/Latino population. Leveraging the National Sleep Research Resource, one of the most comprehensive collections of sleep studies, we identified a Hispanic/Latino cohort of 1,031 lower cognitive function cases and 2,062 normal controls. We developed a novel dual random forest (DRF) approach to discriminate cases against controls for estimating the potential impact of sleep-related variables related to the decline of cognitive function. Several important sleep-related factors were identified which may be associated with cognitive function in the Hispanics/Latinos cohort, such as heart rate, sleep duration, trouble falling asleep, and apnea/hypopnea index, which are consistent with existing research findings. Our DRF approach is effective in validating the association between disordered sleep and cognitive decline in this unique minority population.

1 Introduction
Sleep is a growing and under-appreciated determinant of health and well-being1–4. Disordered sleep-wake cycles and sleep duration (quantity), efficiency (quality), apnea, latency, and stages (rapid eye movement [REM] and non-rapid eye movement [NREM]) have been considered as important markers of sleep architecture associated with cardiovascular disease2,3,5,6, depression7,8, diabetes9,10, hypertension11, and lately, Alzheimer’s disease and related dementias (ADRD)12–14. Alzheimer’s disease (AD), a debilitating neurological condition that impairs memory, thought processes, and function, has become a public health crisis15. AD affects about 5.7 million Americans16,17 and one in ten people (10%) aged 65 and older. As AD occurs primarily among older adults, the number of individuals with ADRD is projected to double by 2050 due to the aging American population. The cost of AD to society is substantial as people with ADRD require significant expenditures for health care, intensive long-term services, and support. The total costs of health care for individuals with AD in 2017 is estimated at almost $260 billion18.

The Mini Mental State Examination (MMSE) is a gold-standard measurement in clinical and research settings for estimating global cognitive function status and screening for dementia19. It consists of 30-point questions assessing orientation, attention, memory, language, and visuospatial skills19, such as repeating lists of words, the time and place of the test, arithmetic, language use and comprehension, and basic motor skills20. The Six-Item Screener (SIS) is a simple test derived from the MMSE (consisting of 3-item recall and 3-item temporal orientation) for identifying subjects with cognitive impairment to meet the needs of being brief, sensitive, and easily remembered in time-limited situations such as the emergency department21,22 and primary care setting21.

A large number of prior studies has focused on the relationship between disordered sleep duration and poor cognitive function or cognitive decline using MMSE or similar measures4,13,24–30. For example, Terri et al. reported modest cross-sectional associations of wake after sleep onset and self-reported long sleep with cognition decline among the older community25,26. Alberto et al. indicated long sleep duration was associated with worse MMSE performance in an elderly community cohort from the Northern Manhattan Study27. Mari et al. reported that short-term memory appears to decline with disturbed sleep (day and overnight shifts)28. Obstructive sleep apnea (OSA) was found to be associated with a greater risk of mild cognitive impairment or dementia13,29,30.

In this paper, we leverage a Hispanics/Latinos cohort in the National Sleep Research Resource (NSRR) to investigate the potential sleep-related factors that can differentiate lower cognitive function (LCF) group from the normal control (NC) group according to the SIS, using a novel dual random forest (DRF) approach. The main contributions of this work are: (1) we presented a methodology that is the first time to derive discriminative sleep-related factors for
cognitive function and classify different levels of cognitive function in a Hispanics/Latinos cohort; (2) we leveraged a rich collection of de-identified clinical data from NSRR; and (3) we obtained representative sleep-related factors consistent with the results of existing studies, demonstrating the validity of our approach.

2 Background

2.1 National Sleep Research Resource (NSRR)

The NSRR (R24HL114473; 2013-19)\textsuperscript{31–33} offers free and open web access to large collections of de-identified, well-annotated national repository of sleep data, including polysomnograms (PSGs) which are linked to risk factor and outcome data for participants in major NIH observational studies and clinical trials. This national repository of sleep data, the first of its kind, is significant because neurophysiological data has not been previously made available at such a large and systematic scale. The NSRR provides opportunities for investigators to address critical questions about the impact of sleep disorders on important clinical outcomes, thereby enhancing clinical and translational work in human sleep medicine and physiology. NSRR further provides users with a suite of tools to facilitate data exploration and data visualization. Launched in 2014, more than 10 billion data files, totaling over 500 terabytes, were downloaded by 4,000 registered researchers around the world from the NSRR portal (sleepdata.org). Recently, NSRR has been designated one of the Open Domain-Specific Data Sharing Repositories by the Trans-NIH BioMedical Informatics Coordinating Committee.

2.2 The Hispanic Community Health Study / Study of Latinos (HCHS/SOL)

The Hispanic Community Health Study / Study of Latinos (HCHS/SOL)\textsuperscript{34}, one of the datasets integrated in the NSRR, is a multi-center epidemiological study of Hispanic/Latino populations consisting of more than 16,000 self-identified Hispanics/Latinos. The aims of HCHS/SOL are to identify the role of acculturation in the prevalence and development of specific diseases, and to identify risk factors playing a protective or harmful role in Hispanics/Latinos. HCHS/SOL was sponsored by the National Heart, Lung, and Blood Institute (NHLBI) and six other institutes, centers, and offices of the National Institutes of Health (NIH) contributed to the first phase of the project as well.

3 Methods

We develop a computational framework to investigate sleep-related factors that could be discriminative regarding cognitive function (as shown in Figure 1). This framework consists of five steps: (1) extracting variables from dataset and grouping subjects based on SIS, (2) identifying covariates using the first random forest model (as RF-A in Figure 1), (3) matching and selecting subjects using similarity score matching (SSM), (4) applying bivariate analysis on sleep-related clinical variables, and (5) discriminating LCF cases and NCs using the second random forest model (as RF-B in Figure 1). Steps 1-3 create a cohort that contains subjects from both the LCF and NC groups such that both groups have similar covariate distributions. Step 4 removes variables that are not statistically relevant to cognitive function and reduces data dimensionality. Step 5 generates the feature importance of selected candidates.

![Figure 1: The overall framework to investigate discriminative sleep-related factors associated with cognitive function.](image)

3.1 Data description

We leverage the HCHS/SOL dataset in NSRR, which contains large collections of de-identified clinical data elements from over 16,000 Hispanics/Latinos. We extract 230 clinical data elements/variables from 15 categories including social demographic (e.g., age, gender, and education status), blood pressure (e.g., overall ankle branchial index), dental (e.g., periodontitis severity), global physical activity (e.g., total physical activity per week), anthropometry
(e.g., body mass index and waist to hip ratio), laboratory measures (e.g., insulin fasting), quality of life (e.g., 10-Item state trait anxiety inventory), clinical characteristics (e.g., alcohol use), medications (e.g., highest reported frequency of sleeping medication usage), respiratory (e.g., bronchodilator responsive by 15% change), health survey (e.g., aggregate physical health score), medical history (e.g., stroke and diabetes), sleep monitoring (e.g., mean peripheral capillary oxygen saturation [SpO2] desaturation), sleep questionnaire (e.g., feel sleepy during the day), and sleep summary (e.g., average sleep duration and insomnia severity index). As in total, 8,216 subjects in the age group of 19 to 76 years are used in further covariate analysis and subject selection. The subjects are categorized into two groups, LCF and NC, based on SIS score, which are dichotomized to 4 or less, or above 4 based on previous studies of neurocognitive impairment\textsuperscript{35}.

3.2 Covariate analysis

To focus on the relationship between cognitive function and sleep-related factors, we need to reduce the confounding effects of other covariates that correlate with the incidence of LCF, such as demographic background and certain risk factors. We randomly select subjects from NC group with the same number of subjects in the LCF group, and apply the random forest model to the selected subjects using extracted clinical variables as features. We run this process 10 times and select the variables with high average feature importance (the higher the value, the more important the feature) as covariates. Also, we manually add confounders mentioned in the previous studies\textsuperscript{36} as covariates, such as hypertension, stroke, and body mass index (BMI).

3.3 Subject matching and selection

Among 8,216 subjects, we select NCs that match with LCF cases with a 2:1 ratio in terms of covariates to cognitive function. Inspired by the cohort matching method used in recent machine learning studies\textsuperscript{37}, we apply a similar idea to perform a logistic regression based SSM to reduce or eliminate selection bias in observational studies by balancing covariates between the case (i.e., LCF case) and control group (i.e., NC). Therefore, the analysis results of variables are independent of the outcome conditioned on the confounders\textsuperscript{38}. There are two steps in SSM to match NC to the LCF case. First, we obtain an estimation for the similarity scores using logistic regression. Then we match each LCF case to one or more NCs based on similarity scores using caliper matching, which finds the first 2 NCs that fall within a predefined distance threshold between similarity scores. The criterion for selecting the threshold is to make the covariate statistics of the case group and the control group as similar as possible. The threshold tuning is to ensure our threshold is small enough such that we can get close matches.

3.4 Bivariate analysis

Bivariate analysis is the simultaneous analysis of two variables\textsuperscript{39}. It studies the empirical relationship between two variables, such as whether there is an association and the strength of this association, or the differences and the significance of these differences between two variables\textsuperscript{39}. To remove variables that are not statistically relevant to cognitive function and to reduce data dimensionality, we perform bivariate analysis between each sleep-related variable and SIS score with selected subjects and generate the sleep factor candidates (with p-value < 0.1). Then we feed those candidates to the random forest model. For numerical variables in our bivariate analysis, we use Kendall rank correlation coefficient\textsuperscript{40}, which is a statistic used to measure the association between two measured quantities. For categorical variables, we perform Kruskal-Wallis H test\textsuperscript{41,42}, which is the one-way analysis of variance (ANOVA).

3.5 Random forest

Random forest (RF) is an ensemble learning method for classification or regression by constructing a group of decision trees. The overall output for a specific sample is obtained by weighted combination of the output generated from each decision tree in RF. The weight of each tree is adjusted according to misclassification and out-of-bag measures. There are four steps to build the random forest with the technique of bootstrap aggregating (bagging)\textsuperscript{43}, which is an ensemble method to reduce the variance without increasing the bias for decision tree algorithms (as shown in Figure 2). Given a training set, the first step is to generate several sub-training sets by selecting a random number of observations and features. Steps 2 and 3 are to build and train each decision tree with generated sub-training set and apply an out-of-bag error estimate, which obtains an unbiased estimate of the test set error internally and reduces the overfitting in a
random forest, and there is no need to use further cross-validation\textsuperscript{43}. These three steps are repeated multiple times to build several decision trees. In the last step, the output for unknown samples can be made by averaging the output from all the individual decision trees.

Compared to other traditional classifiers, such as K-nearest neighbor, support vector machine, artificial neural network, RF has the following four advantages. (1) Adaptability: RF estimates the importance of variables and provides a way for tuning with additional training data by assigning different weights for each decision tree; (2) Scalability: RF can handle thousands of input variables and work efficiently on large datasets; (3) Robustness: RF can balance error in datasets with unbalanced class population\textsuperscript{44}; (4) High interpretability: We could use the trained model to gain insight on our data via the learned relationship between feature and response variables (e.g., feature importance). Thus, RF is one of the most popular machine learning methods in feature selection and binary/multi-class classification problems.

4 Experiments and Results

4.1 Covariates and similarity score matching

We obtained top 15 variables (including 11 non-sleep-related and 4 sleep-related variables) and selected 7 covariates based on the feature importance (>0.3, as shown in the Table 1), which was generated by the first RF model with clinical data elements from 15 categories in the HCHS/SOL dataset. We also manually added 5 covariates, including hypertension, stroke, smoke status, alcohol status, and BMI, based on the findings of existing studies\textsuperscript{36}.

To create our training dataset for the RF model, we selected NCs from HCHS/SOL by using similarity score matching to reduce the effect and bias of covariates. After matching, we obtained 1,031 LCF cases and 2,062 NCs at a 1:2 ratio. The summary of the statistics on covariates before and after the matching is shown in Table 2.

4.2 Bivariate and random forest analysis

We performed bivariate analysis based on 124 sleep-related variables and obtained 47 candidates with p-value < 0.1 for further RF analysis. We measured the discrimination based on the accuracy and area under the receiver operating characteristic (ROC) curve (AUROC), two important evaluation metrics for checking a classification model’s performance\textsuperscript{45}, to classify LCF cases and NCs. Table 3 shows the performance with different settings of the number of trees in RF with the metric of Gini impurity. To compute the feature importance, we used the number of trees as 1,000 since it achieved the highest AUROC.

The feature importance of all 47 candidates are shown in Table 4. We also applied our analytical framework to the data source in terms of different genders. There were 542 LCF cases and matched 1,084 NCs for female-specific analysis. For males, we obtained 489 LFC cases and 978 NCs. Figure 3 shows the top 20 important sleep-related variables for females and males, respectively.

5 Discussion

5.1 The Hispanic/Latino population

With the increase of diverse populations in dementia research and clinical trials, the risk of leaving behind racial and ethnic minorities is heightened, and improving the understanding of ADRD among ethnic minorities is essential to facilitate diverse representation in prevention and treatment research. Hispanic/Latino covers more than 20 ethnic ancestries, with substantial diversity in ancestry, sociodemographic and cultural characteristics, immigration, and geographic distribution in the U.S.

Although Latinos have sociodemographic disadvantages (e.g., lagging behind Whites and African Americans on average in education), high rates of diabetes, and the lowest healthcare insurance coverage rates of any major ethnic/racial group in the U.S., the average life expectancy of Latinos is four years higher than that of Whites. With long life expectancy, high morbidity, low education, and limited healthcare access, the Hispanic/Latino population faces major risks for age-related disorders, specifically ADRD. In a recent study, Perales-Puchalt et al. reported that Latinos are at higher risk of mild cognitive impairment. Our results in Table 1 indicate that, in addition to well-known factors (e.g., age and education status), sleep-related factors may be associated with cognitive function. Thus, it is important and meaningful to understand whether and how different sleep-related factors may be associated with cognitive function in the Hispanic/Latino population.

5.2 Machine learning based approach

We developed a machine learning approach to find potential sleep-related factors for general cognitive function in a Hispanics/Latinos cohort. In our analytical framework, we used the first RF for covariate analysis and estimation of the importance of different variables. The covariates identified by RF, such as age, education status, yearly household income, gender, and anxiety inventory, were consistent with the confounders in the existing studies, which proved the validity of our method. As shown in Table 2, the SSM results demonstrated that the distributions of each selected covariate in LCF and NC group are similar; for example, before matching, the percentage of yearly household income with “$40,001 - $50,000” in NC group was twice as much as in LCF group (6.39% vs. 3.13%, respectively), and it was much more balanced after matching (2.76% vs. 3.59%). After matching, we used bivariate analysis to select the sleep-related variables, which were considered as candidates (with p-value < 0.1). It reduced the input data.
dimension (more than 50%) and the cost in computation time for learning decision trees in the second RF. As a result, RF performance was improved using selected candidates compared to using all sleep-related variables.

Parameter selection is an important problem in classification as changing parameters may significantly impact the performance of the classifier. We performed several experiments with different settings of the number of trees, and the performance only had slight changes, indicating that random forest is not sensitive to its parameters (i.e., high stability). At the end, we selected the number of trees (N=1,000) for further analysis.

To perform cross-model validation, we compared the importance ranking of sleep-related variables using different models, including six random forest models with the different number of trees and XGBoost\(^3\), which is another widely used machine learning algorithm to obtain feature importance after training. Table 5 shows the comparison results. The ranking of top 20 sleep-related variables in Table 4 obtained from the random forest with 1000 trees (RF-1000) was used as the benchmark for the comparison (see labels A-T in Table 5). As can be seen, although the rankings are slightly different, most of these variables (over 75%) are also in the top 20 with other RF models, indicating that the parameters do not have a significant effect on the results. For the XGBoost model, 60% of the top 20 sleep-related variables overlap with those obtained by the benchmark RF model.

### Table 5: Cross-model ranking comparison of the top 20 sleep-related factors.

| Model   | A     | B     | C     | D     | E     | F     | G     | H     | I     | J     | K     | L     | M     | N     | O     | P     | Q     | R     | S     | T     |

#### 5.3 Consistency with existing research findings

The results in Table 4 show that several variables play important roles in classifying LCF cases and NCs, which were also consistent with existing research findings, such as: (1) heart rate – heart rate variability was reported as a promising early biomarker of cognitive impairment in populations without dementia or stroke\(^4\), and cardiovascular risk is also a risk for cognitive function in middle-age among Hispanics/Latinos\(^5\); (2) sleep duration – the previous study with HCHS/SOL demonstrated that people with long sleep duration (> 9 hours per night) had a worse cognitive function, and people with intermediate sleep duration (6 to 8 hours per night) had the best cognitive function\(^6\); (3) trouble falling asleep – longer sleep-onset latency has been reported to affect global cognitive function through decreased slow-wave sleep and was associated with declines in verbal learning and memory in the previous study with HCHS/SOL\(^7\); and (4) apnea/hypopnea index – several existing research demonstrated that severe obstructive sleep apnea patients may have impaired cognitive function\(^8\), the treatment of sleep apnea syndrome slows cognitive decline\(^9\), and Ramos et al. reported that obstructive sleep apnea was associated with poor cognitive function in a cohort of Hispanic/Latino women in the U.S.\(^10\). The consistency with existing research findings in part validates the effectiveness of our DRF method. Also, our results were consistent across gender-specific analyses (female vs. male).

#### 5.4 Potential sleep-related factors

We categorized the 47 sleep-related variable candidates in to 7 categories: (1) \textit{SpO2 measures}, including “Baseline SpO2”, “Minimum SpO2”, “Mean SpO2”, “Standard Deviation SpO2”, and “Percent Time SpO2 < 95”; (2) \textit{Sleep durations}, including “Total Time in Bed (hours)”, “Average sleep duration (hours)”, and “Weekday sleep duration (hours)”; (3) \textit{Trouble to sleep}, including “Trouble falling asleep”, “Wake up several times at night”, “Wake up earlier than you plan”, “Take sleeping pills”, “Sleep difficulties make irritable (SLEA9)”, and “Trouble getting back to sleep”; (4) \textit{Feel sleepy}, including “Feel Sleepy during the Day”, “Typical night’s sleep in past 4 weeks”, “Doze Off Situations: Lying down to rest in afternoon”, “Doze Off Situations: Sitting and talking”, “Doze Off Situations: At the dinner table”, “Doze Off Situations: While driving”, and “Nap for 5 min or more during a usual week”; (5) \textit{Legs discomfort}, including “Sensation in legs discomfort”, “Need to relieve discomfort in legs”, “Discomfort in legs worse when at rest”, and “Discomfort in legs worse later in day or at night”; (6) \textit{Heart Rate}, including “Maximum Heart Rate” and “Standard Deviation Heart Rate”; and (7) \textit{Apnea/Hypopnea measures}, which includes the rest of variables, such as
We calculated and ranked the average feature importance for these 7 categories: Heart Rate (0.98), SpO2 measures (0.84), Sleep durations (0.76), Apnea/Hypopnea measures (0.70), Trouble to sleep (0.65), Feel sleepy (0.54), and Legs discomfort (0.34). The consistency with existing research findings indicate that our method can be used to explore additional potential sleep-related factors that may be associated with cognitive function. As shown in Table 4, sleep-related variables, such as “Mean SpO2” in SpO2 measures, “Wake up several times at night” and “Trouble getting back to sleep” in Trouble to sleep, and “Feel Sleepy during the Day” in Feel sleepy, may be associated with cognitive function for Hispanics/Latinos population.

5.5 General applicability

Although our DRF approach was developed to identify sleep-related factors for cognitive function, its framework (Figure 1) has been designed and implemented to be generally applicable for factor exploration of other diseases and cohorts. For a new disease/cohorts, the DRF approach can be readily used once the data is provided according to the needs of the disease/cohorts.

5.6 Limitations and future work

In this paper, we mainly focused on estimating the importance of various sleep-related variables for discriminating LCF cases and NCs. The relationship/association among these variables has not been studied. In future work, we plan to explore the correlations among these variables. In addition, finding a representative variable for each sleep characteristic instead of using multiple variables (such as “Mean SpO2”, “Minimum SpO2”, and “Standard Deviation SpO2”) is still a challenge and needs further investigation.

6 Conclusion

In this paper, we analyzed sleep-related factors to differentiate a lower cognitive function group from a normal control group in a Hispanics/Latinos cohort using a novel dual random forest approach. The random forest-based analysis enables the estimation of the importance of sleep-related variables for cognitive function. Our analysis obtained several specific sleep-related factors that may be associated with cognitive function in the Hispanics/Latinos cohort, such as heart rate, sleep duration, trouble falling asleep, and apnea/hypopnea index, which are consistent with existing research findings. Our dual random forest approach is effective in exploring the association between sleep-related factors and cognitive function.

Abstract

This study investigates a missing value imputation approach for longitudinal growth data in pediatric studies from multiple countries. We analyzed a combined cohort from five natural history studies of type 1 diabetes (T1D) in the US and EU with longitudinal growth measurements for 23,201 subjects. We developed a multiple imputation methodology using LMS parameters of CDC reference data. We measured imputation errors on both combined and individual cohorts using mean absolute percentage error (MAPE) and normalized root-mean-square error (NRMSE). Our results show low imputation errors using CDC reference. Overall height imputation errors were lower than for weight. The largest MAPE for weight and height among all age groups was 4.8% and 1.7%, respectively. When comparing performance between CDC reference and country-specific growth charts, we found no significant differences for height (CDC vs. German: p=0.993, CDC vs. Swedish: p=0.368) and for weight (CDC vs. Swedish: p=0.513) for all ages.

Introduction

The problem of missing data commonly exists in observational studies.1 We explored imputation methodology to address missing values in childhood growth data from prospective natural history studies of type 1 diabetes (T1D), including two in the US (DAISY2, DEW-IT3) and three in the EU (BABYDIAB4, DiPiS5, DIPP6). The primary aim of these studies was to study development of islet autoimmunity (IA) and progression to type 1 diabetes (T1D) in infants and young children with high genetic or familial risk. Study subjects were followed for development of IA for a period of up to 15 years or until diagnosis of T1D, whichever came first. Data collection efforts mainly focused on immunological (islet autoantibodies) and metabolic markers (blood glucose levels) that are implicated in development of T1D.

In a collaboration with JDRF and their academic partners, the type 1 data intelligence (T1DI) study group combined and harmonized data from these large observational studies into the T1DI cohort. The cohort has over 24,000 subjects and the study group is currently evaluating various outcomes of interest from this large dataset, including the potential effect of childhood growth on risk of IA and development of T1D. In practice, childhood growth is often assessed via measurement of height and weight at periodic intervals (e.g. 6m, 1y, 2y visit) during pediatric office visits. During study follow, a subject may not have growth assessment at every visit for blood sampling for autoantibody or blood glucose measurement. In order to test interesting hypotheses, such as the effect of childhood growth on IA development, we need to link available growth data from patient charts with research data measured at more frequent intervals (i.e. every 3 to 9 months in these studies). However, this linking, which may be fuzzy based on nearest age visit or similar methods) often creates holes (sparsity) in the longitudinal research data making them difficult or impossible to analyze unless meaningful imputations are performed for growth variables.

In the T1DI cohort, missing data exist in weight and height measurements of children participating in follow-up. For meaningful inclusion of these variables in association analyses or predictive models (such as for IA development and T1D onset), data need to be imputed to coincide with timing of research visits. Furthermore, on the
basis of the observed/imputed body weight and height, other growth measurements such as the Body Mass Index (BMI) or other derived features such as percentiles and velocities of weight, height, and BMI may be computed which can then be also included in downstream models. Of note imputation of growth data for the T1DI cohort is hindered by a lack of a common reference for childhood growth data. The T1DI cohort growth data are from disparate geographic areas with variable demographic compositions and applicable population growth references may vary. For example, in the US, CDC growth charts\textsuperscript{7} are used widely and are parameterized for childhood and adolescent growth from age 2 to 20 years in intervals of 6 months\textsuperscript{8}. In many EU countries, country-specific growth charts or references exist.\textsuperscript{9,10} However, these references are either not easily available or parameterized for similar use. Thus, in this study we hypothesized that the childhood growth in the T1DI cohort could be imputed using the CDC LMS parameters. We further hypothesized that using the CDC reference for imputation would produce overall low error rates. This approach could provide several other advantages in large international studies such as use of one common reference, model and fit. In this work we test our hypotheses using a novel multiple imputation (MI) methodology as described below.

Regardless of the reference data used, missing data should be handled and analyzed with caution depending on variable types and their mechanism of missingness. The missingness mechanism can be broadly classified into three types according to the characteristics with regards to randomness\textsuperscript{11}: missing not at random (MNAR), missing at random (MAR), and missing completely at random (MCAR). Significant interactions between observed variables are an indicator of MNAR data. In general, missing value imputation for MNAR is not recommended, and hence few algorithms exist for this type of data. In contrast, a wide variety of methods are available for handling missing values in MAR and MCAR types. In practice, selecting the most appropriate method depends on the problem to be addressed and the available data. Single imputation methods simply replace missing data points with a single fixed value (e.g., zero, the mean, median, or most frequent value) by assuming that the data are MCAR. These methods could reduce variability of data and generate biased estimates of error variances.\textsuperscript{12} Advanced methods such as model-based methods impute the missing values using a predictive distribution that models the underlying data missingness mechanism. The most commonly used model-based imputation methods include multiple imputation (MI), full information maximum likelihood (FIML) and maximum likelihood expectation-maximization (EM) imputation. In particular, MI assumes MAR and has been widely applied in analysis of clinical data.\textsuperscript{13} Some popular algorithms in this category include nonparametric missing value imputation using random forest\textsuperscript{14}, K-nearest neighbors (KNN), multiple imputation by chained equations (MICE)\textsuperscript{15}, and Amelia.\textsuperscript{16} More recently, more sophisticated models have been used for missing value imputation including multilayer perceptron, self-organizing maps as the predictive models. These have been applied to estimation of missing data for applications such as breast cancer diagnosis and cardiovascular data for clinical trials.\textsuperscript{17,18} In our study, we use a general MI method and apply it to missing values of growth data in pediatric studies.

**Methods**

To describe characteristics of data missingness, we calculated missing value ratio. CDC growth charts and LMS parameters as well as country-specific growth charts are used for missing value imputations. We describe these sources below followed by our particular implementation of the MI algorithm, which considers uncertainty of the missing data and combines multiple sets of plausible imputed values.

**Data Missingness:** Missingness for height and weight were separately assessed for each subject in every dataset. We define missing value ratio as the number of rows (visits) where measurement (for height or weight separately) was missing divided by the total number of rows for that subject in the longitudinal dataset. For example, if the missing value ratio of height is 0.1, then 10% of longitudinal measurements of height were missing for that subject.

**CDC Growth Charts and LMS Parameters:** In the United States, the CDC growth charts\textsuperscript{19} are widely used to monitor growth patterns of children and adolescents during clinical care. CDC charts describe values for height or weight at different percentiles by gender and age in months (from birth to 20-years in increment of 1 month). The smoothed percentile curves can be reproduced using LMS parameters, i.e. median (M), generalized coefficient of variation (S), and the power in the Box-Cox transformation (L). These parameters were calculated based on the Box-Cox transformations to normality. From these parameters, a measurement value can be calculated if the percentile is known, and vice versa. CDC growth charts span the age range of 0 – 36 months and 2 – 20 years. The LMS parameters, for 3rd, 5th, 10th, 25th, 50th, 75th, 90th, 95th, and 97th percentiles for weight, height and BMI are provided. For finer age intervals, interpolation could be used to obtain the LMS values. In this study, we use the
CDC reference to impute missing values in the body weight and height using the LMS parameters. We evaluate these values against the country-specific growth charts.

**Country-specific growth charts:** These were obtained from our collaborators for Swedish (DiPiS) and German (BABYDIAB) cohorts. There was no similar reference chart available for the Finnish cohort to our team. We used country-specific charts to impute missing values and compared these with CDC growth charts. The Swedish growth charts cover the age range of 0 – 2191 days (72 months) and 61-228 months. It provides the values of standard deviations (-5, -4, -3, -2, -1, 0, 1, 2, 3, 4, 5) for weight, height, and BMI. These growth charts were used for imputing missing values in DiPiS. Note that the LMS parameters are not provided in these charts. The German growth charts cover the age range of 0 – 216 months. They list the LMS parameters and the percentiles (3rd, 10th, 25th, 50th, 75th, 90th, and 97th) for weight and height. They also provide the LMS parameters and the percentiles (3rd, 10th, 50th, 90th, and 97th percentile) for BMI. These charts were used for imputing missing values in BABYDIAB.

Of note, CDC growth charts cover measurements for up to 20-years of age, the German growth charts up to 18 years, and the Swedish charts up to 19 years. Thus, to address measurements until age of 20, extrapolation was used for the latter two cohorts. In this study, we imputed the missing values in the body height and weight using CDC growth charts for all five (US and EU) data sets.

**Missing Value Imputation method:** We use the growth charts with LMS parameters for missing value imputations and in that respect, it is a model-based method. Additionally, we apply multiple imputations to derive the missing value, i.e. “multiply impute” missing data in a single cross-section from an available time series of data. The flow chart is illustrated in Figure 1. The work was implemented using R (v3.6.3). The inputs of this algorithm include sex and age of a subject; the outputs are the imputed values and the corresponding percentiles for height/weight. This missing value imputation procedure consists of the following steps: For a growth measure (height or weight),

- **Step I:** For an individual subject, locate the ages at which the measurement values were missing and find the sex. Then identify the most proximal previous and subsequent ages with observed values. For each of the ages with missing values, repeat the following steps II-IV:

  - **Step II:** For the previous age with known measurement value, use growth chart to compute the corresponding LMS values for that age through interpolation (if needed). Using the observed measurement and interpolated LMS values, compute its percentile (the percentile of the previous measurement) using the LMS formula. Do the same for the subsequent visit with a measured value to compute its percentile.

  - **Step III:** if both the previous and the subsequent percentiles are obtained, take the average of these two as the percentile for the age at which we want to impute the missing value; otherwise, just use the available percentile (either the previous percentile or subsequent percentile).

  - **Step IV:** for the age with a missing value, use the growth charts to obtain the LMS values through interpolation of the interval covering that age. Using the percentile value calculated in Step III and the interpolated LMS values to determine the imputed value, which is used to replace the missing measurement at that age.

---

**Figure 1. Flow chart for missing value imputation using the growth charts**
Note that in Step III, in case that only a single percentile is available, extrapolation is used to impute the missing values and could cause larger imputation errors since it assumes that the growth percentile remains unchanged regardless of the length of time interval.

Performance measures: To assess the validity of missing value imputation method and compare the performance of the missing value imputation using country specific growth charts, we calculated imputation errors as follows. First, we randomly selected 20% of observed measurements and then removed their values creating a knock-out dataset. We then applied the missing value imputation method to the knock-out dataset and imputed the “missing” values. Finally, the imputation errors were computed. The same procedure was implemented using CDC or country-specific references. We used the following metrics for the imputation errors—mean absolute percentage error (MAPE) and normalized root-mean-square error (NRMSE). MAPE is defined as

\[
MAPE = \frac{1}{n} \sum_{i=1}^{n} \left| \frac{y_{i}^{imp} - y_{i}^{act}}{y_{i}^{act}} \right|
\]

where \(y_{i}^{imp}\) and \(y_{i}^{act}\) are imputed and actual (observed) measurement values, respectively, for \(i = 1, 2, \ldots, n\) and \(n\) is the total number of imputed values. There is some variation in NRMSE definitions; however, the most common one we used in this study as follows,

\[
NRMSE = \frac{\frac{1}{n} \sum_{i=1}^{n} \left( y_{i}^{imp} - y_{i}^{act} \right)^{2}}{\frac{1}{n} \sum_{i=1}^{n} y_{i}^{act}}^{1/2}
\]

where the denominator is the average of actual measurements. From the above definitions, we can see that MAPE is more sensitive than NRMSE to the errors when the actual values are small, while NRMSE puts more weight on larger deviations than MAPE.

We calculated mean and standard deviation of MAPE or NRMSE values using 100 repetitions of knock-out and imputations and computed p-values for comparison with country specific references. All significance was tested at \(P < 0.05\) using the Student’s \(t\) test.

Results

In total there are 23,201 subjects for whom growth data were available (Table 1). Overall DIPP is the largest dataset with a frequent follow up compared to the overall T1DI cohort, and consequently had the smallest missing value ratios for both height and weight in our study. However, the two US datasets (DAISY and DEW-IT) had lower missing value ratios (for both height and weight) when compared to the other two EU sites (BABYDIAB and DiPiS). These differences are primarily due to differences in the individual study protocols and the frequency of follow up within them.

**Imputations in combined T1DI cohort:** Figure 2 illustrates the MAPE and NRMSE values for missing value imputations in weight and height for the combined dataset (from 5 data sources) using the CDC growth charts. The MAPE values are plotted by the age group (6 groups from birth to 20-years as covered by CDC) as labeled on the y-axis. For the 0-2 year age group, the largest MAPE value for weight is 4.8% and the largest error for height is 1.7%.
The NRMSE values of the imputation errors are illustrated in Figure 2(b). The largest value is 6.0% for weight in age group 18-20 years and 2.1% for height in 0-2 years. From Figure 2(a) and 2(b), we find that the imputation errors for height are overall smaller than those for weight (in terms of both MAPE and NRMSE). In addition, for the same growth measure (height or weight), the MAPE values are smaller than the NRMSE values because NRMSE puts more weight on larger absolute measurement errors.

Figure 2. Imputation errors in weight and height for TIDI cohort using CDC (a) MAPE; (b) NRMSE

Figure 3-1. Imputation errors in weight and height for DAISY using CDC (a) MAPE; (b) NRMSE

Figure 3-2. Imputation errors in weight and height for DEW-IT using CDC (a) MAPE; (b) NRMSE

Figure 3-3. Imputation errors in weight and height for DIPP (a) MAPE; (b) NRMSE
**Imputations in US datasets:**

The MAPE and NRMSE values for two US data sources (DAISY and DEW-IT) are shown in Figure 3-1 (a and b) and Figure 3-2 (a and b) respectively. The imputation was implemented using CDC as reference. For DAISY, the largest MAPE values of weight are 5.1% for 0-2 years and 1.9% for height in the same age range. The largest NRMSE values for the same age group are 6.5% for weight and 2.3% for height. When compared to DAISY, the DEW-IT dataset has larger imputation errors in both height and weight. In terms of MAPE, the largest errors are 6.8% in weight and 3.3% in height for 0-2 years. The largest NRMSE values are 10.2% in weight and 4.6% in height for 8-12 years.

**EU datasets and comparison to country-specific growth charts:**

As the Finnish growth charts were not available for comparison, only CDC charts were used for imputing missing values in DIPP. The imputation errors in DIPP for height and weight can be found in Figure 3-3 (a) MAPE and (b) NRMSE. The largest MAPE values for weight using CDC growth charts are 4.1%, and 1.9% for height. The largest NRMSE values are 5.0% and 1.9% for weight and height, respectively.

For the other 2 EU datasets, we compared performance of imputation method using country specific growth charts. For BABYDIAB, we compared imputation method using the CDC growth charts and the German growth charts. For simplicity, we only plotted the MAPE values here on Figure 4-1 (a - height and b - weight). Since the German charts cover age up to 18 years, only the results from birth to 18 years are shown here. The largest MAPE values for weight in BABYDIAB (Figure 4-1) using CDC and German growth charts are 6.8% and 6.7% respectively, and the largest MAPE for height are 2.4 % and 2.3%, respectively. The Student’s test results computed for all ages together show no significant difference in the MAPE values of height using CDC ($p =0.993$), but the mean MAPE for weight using CDC is greater than that using the German charts ($p < 0.001$). However, the difference between them was fractional (6.02% vs. 5.81%).

![Figure 4-1. MAPE of the imputed values in weight and height for BABYDIAB (a) height; (b) weight](image1)

![Figure 4-2 MAPE of the imputed values in weight and height for DiPiS (a) height; (b) weight](image2)

The MAPE results of DiPiS are shown in Figure 4-2 (a- height and b-weight) for which both CDC charts and Swedish charts were used. The age range of DiPiS is 0 – 12.99 years, therefore the largest age group is also 12-18 years. Due to the large missing value ratio, the largest MAPE values for weight in DiPiS using CDC and Swedish growth charts are 16.4% and 15.5% respectively, and the largest MAPE for height are 6.0 % and 5.4%, respectively.
The Student’s t test results computed for all ages together show that there is no significant difference in the MAPE values of height using CDC or Swedish growth charts ($p = 0.37$), and this is also true for weight as well ($p = 0.51$).

**Discussion**

In this study, we developed a missing value imputation method for data from multiple countries using CDC growth charts and a multiple imputation methodology. We assessed imputation performance using the large T1DI cohort and its constituent five real-world data sets. We also compared the CDC-imputed datasets to country-specific growth charts where available. From these experiments, we show that CDC reference may suffice to impute growth measurements in US and international (EU) pediatric studies. We further show that using this method, the imputation errors (as measured by MAPE and NMRSE) are within reasonable errors of margin (<10%) in the T1DI cohort. Furthermore, we found that the errors for imputed height are less than those for imputed weight across all datasets. This can be explained by the fact that height is much more tightly regulated by genes than weight which is strongly influenced by environment and eating behavior. Thus, height can be easily predicted on the basis of surrounding growth pattern, whereas weight can vary much over time.

There are a few country-specific findings. The imputation errors in BABYDIAB (Germany) and DAISY (U.S.) were much smaller than those in DIPIS (Sweden). These may be due to two reasons, overall low missing value ratio in the DAISY and BABYDIAB data sets and well calibrated CDC and German growth charts. However, there is no significant difference between the error results using the CDC reference vs. the country-specific charts. The imputation errors are higher in DiPIS perhaps because of larger missing value ratios compared to the other data sets (Table 1) so that the average of the previous and subsequent observed percentiles are not a good estimate for the percentile at the age with missing growth measures.

There are several advantages of our approach. First, one common CDC growth reference for imputation in all datasets may facilitate imputations where standards don’t exist or are unavailable, such as for the Finnish dataset. As the CDC reference comes from a large, diverse US sample population and has been studied extensively, it may also be the best guesstimate where growth patterns are unknown (or less studied) and almost certainly change by age groups (e.g. from early childhood to tween and adolescent age groups). Furthermore, using imputed growth measurements based on a reference model, one can derive many other features such as annual growth velocity and percentiles for downstream analyses. A second advantage is that the CDC reference covers a wide age range (0 to 20 years); therefore, one can use it to impute the missing values over the entire growth trajectory. This in comparison to a best fit approach offers significant advantages when rate of change (or slope) in longitudinal data are unknown and where a change detection by age is needed. In these latter scenarios multiple models may be needed to assess different segments. Third, our approach is also useful when the task at hand is to perform an association study (limiting data to a landmark age for prediction in future). In our use case of studying growth features and their potential contribution to development of islet autoimmunity, we found that imputations were reasonable. Finally, as the approach relies on the underlying model, our methods may be useful for other kinds of clinical data, for example for imputing missing blood pressure or glucose measurements.

As with all such studies, our approach also has some limitations. First, we base our results on data collected in the past (in many instances these studies started before 2000), i.e. before the CDC reference was widely available. However, this may have only made our results stronger in showing there is no significant difference between country-specific or CDC reference-based imputations over time. Second, it may not be the best approach to use when one needs to analyze outcomes based on observed growth to a time point (i.e. where we cannot avail ourselves of future information). In those situations, another model-based imputation method (e.g. using linear or polynomial multi-variable regression) may be a better fit. We believe the strength of our multiple imputation approach lies in where references such as the CDC are available for characterizing longitudinal pediatric growth trajectory. In addition, since the approach assumes MAR for the missing data, departures from this assumption should be assessed through sensitivity analyses.

**Conclusion**

Childhood growth variables measured during follow-up of children and adolescents up can be imputed using multiple imputation method and CDC reference parameters even when data represents geographically disparate US
and EU pediatric sites. Advantage of this approach include being able to derive many other features, such as annual growth velocity and growth percentiles; these features may be useful for downstream analyses.

Abstract
Overabundance of information within electronic health records (EHRs) has resulted in a need for automated systems to mitigate the cognitive burden on physicians utilizing today’s EHR systems. We present ProSPER, a Problem-oriented Summary of the Patient Electronic Record that displays a patient summary centered around an auto-generated problem list and disease-specific views for chronic conditions. ProSPER was developed using 1,500 longitudinal patient records from two large multi-specialty medical groups in the United States, and leverages multiple natural language processing (NLP) components targeting various fundamental (e.g. syntactic analysis), clinical (e.g. adverse drug event extraction) and summarizing (e.g. problem list generation) tasks. We report evaluation results for each component and discuss how specific components address existing physician challenges in reviewing EHR data. This work demonstrates the need to leverage holistic information in EHRs to build a comprehensive summarization application, and the potential for NLP-based applications to support physicians and improve clinical care.

Introduction
Electronic health records (EHRs) are one of the primary sources of clinician burnout. Many studies have analyzed physician time spent in EHRs with respect to various interactions such as chart review, documentation, orders, and inbox management, with several identifying time spent on reviewing information within the EHR, i.e. chart review, as a major component of physician interaction with the EHR. A descriptive study on ambulatory medical subspecialists and primary care physicians observed that chart review accounted for the highest proportion of active physician EHR time at 33%. Another study analyzed audit logs to measure time requirements for EHR use by ophthalmologists and concluded that most of the time spent in the EHR is on reviewing information.

Several factors contribute to the difficulty in reviewing information in EHRs. Traditionally, the patient medical record was mainly used to document a patient’s medical history and clinical care process to assist physicians in providing informed care. However, the transformation from paper-based to electronic patient records have expanded the scope of documentation to also serve a variety of non-clinical purposes, including administrative, legal, research, and education. This transformation has resulted in lengthy and complex documentation dominated by content not directly relevant to clinical care, such as text meant for billing purposes, quality improvement measures, avoiding malpractice, and documenting compliance. Further exacerbating this problem are issues of note bloat, where use of structured data imports, templates and copy-paste have introduced unnecessary, redundant or erroneous data into clinical notes, worsening the problem of information overload and physician stress. A human factors engineering perspective to the information chaos in primary care identified five information hazards: information overload, information underload, information scatter, information conflict, and erroneous information. These information hazards result in additional workload for physicians, such as spending extra effort to search through charts, asking more questions of the patient to clarify conflicting documentation, or re-working a diagnosis to investigate potentially erroneous information. Together these factors contribute to excess clinician workload and burnout, with adverse outcomes on clinician well-being, patient care, and the health care system.

Previous research has explored several automated summarization and enhanced visualization methods to enable physicians to efficiently navigate and discern complex data within EHRs. Summarization efforts include problem identification from a given set of clinical notes, extraction of clinical concepts or relations, and various ways to display such information along with other information in the EHR. Another research direction has focused on improved data visualization and interactive displays to facilitate more efficient and accurate information retrieval and an overall more user-friendly interaction with the EHR. Evaluation of such systems in real or simulated clinical settings have received positive feedback from physicians and resulted in improved physician performance. A common theme in many of these systems is the idea of a problem-oriented medical record (POMR), and the use
of timelines to gain a longitudinal history of the patient. We rely on these principles to build Problem-oriented Summary of the Patient Electronic Record (ProSPER), an application which extends the idea of a POMR by enhancing it with clinically meaningful insights extracted from unstructured clinical notes, such as adverse drug events (ADEs), and displaying them on a timeline with relevant structured elements of the EHR.

During the past several years, we have developed and validated the usability of several components that contribute to the creation of a comprehensive patient record summarization application. The purpose of this paper is to build on our previously published work and present ProSPER, an artificial intelligence-based system that extracts, analyzes, and summarizes patient clinical information from electronic health records, with the goal of reducing the cognitive burden on physicians due to information chaos within the EHR. We present the overall system architecture and pipeline, describe the underlying components needed to build such a system, and discuss how these components address information chaos within the EHR. ProSPER differs from previously published systems in that it presents (1) an auto-generated problem list, (2) disease-specific dashboards, (3) a stacked timeline view incorporating both structured data and insights extracted from unstructured data to allow reasoning across different data elements, and (4) a textual summary of each clinical encounter for a selected disease of interest.

Materials and Methods

Combining the well-established idea of a problem-oriented medical record with the different workflows using EHRs that rely on electronic dashboard summary screens as well as individual progress notes, we envision a workflow for reviewing patient information prior to a clinic visit as follows.

1. Patient overview: gain an overview of the patient, including the patient’s name, demographics, allergies, and a summary of the active problems, current medications, allergies, vital signs, and laboratory results.
2. Snapshot of a specific problem: focus on a specific disease by surfacing current medications and recent laboratory results and procedures relevant to the specified disease.
3. Longitudinal history of a specific problem: investigate a specific disease through a timeline view of relevant medications, laboratory results, procedures, past encounters and clinical events extracted from clinical notes.

Dataset

Effective natural language processing (NLP) techniques are essential to development of the proposed system. To achieve this, we used a set of 1,500 de-identified longitudinal patient records from two large ambulatory multi-specialty medical groups in the United States. Subsets of this corpus were manually annotated by medical students and practicing physicians to generate ground truth for development of smaller NLP components that are used in building the overall system. All annotations were doubly-annotated and adjudicated to ensure the quality and consistency of the ground truth. Details of the ground truth generation process for each task are provided below.

The dataset for problem list generation consists of 399 randomly selected patient records annotated by over 17 fourth year medical students. Annotators reviewed each patient record, created a problem list for a comprehensive health assessment, normalized identified problems to the clinical observations recordings and encoding (CORE) problem list subset of Systematized Nomenclature of Medicine-Clinical Terms (SNOMED CT) in a one-to-many mapping, and evaluated how closely the SNOMED CT concept represents the problem.

The dataset for relation detection consists of 24,537 unique problem-medicine pairs, 11,318 unique problem-procedure pairs, and 23,402 unique problem-laboratory test pairs created using structured data from 100 randomly selected patient records. Four fourth year medical students reviewed each pair of entities and indicated if a positive association was present, defined as medications that treat or prevent the problem or its symptoms, and laboratory tests or procedures that can be used to screen, prevent, evaluate, diagnose, or manage the problem.

The dataset for extractive summarization consists of 3,453 clinical notes over 762 patients with recent documentation of at least one of five common chronic diseases (hypertension, diabetes mellitus, hyperlipidemia, heart failure, chronic obstructive pulmonary disease) and authored by physicians or nurse practitioners. The corpus was annotated by 12 physicians with emphasis on only annotating the most important insights relevant to physicians’ decision-making.

The ground truth for medication insights, specifically ADE and medication change events, was annotated at the note-level. For ADEs, 602 notes were annotated with medications and their associated adverse events. For medication change events, 38,895 medication mentions were annotated to indicate (1) the presence of a medication change event and (2) the multi-dimensional context (action, temporality, certainty) for identified medication change events.
The dataset for evaluation of semantic find is derived from 10 randomly selected patient records. For each patient record, a physician generated a set of relevant search terms based on the patient’s last progress note and problem list. The final dataset consists of 169 search terms, covering a variety of semantic types (e.g., symptoms, drugs), single and multi-word concepts, different parts of speech, and commonly-accepted medical abbreviations.

**Pipeline and framework**

ProSPER was built using the open-source Apache Unstructured Information Management Architecture (UIMA) library, a software architecture that provides capabilities to construct pipelines consisting of a sequence of components or analysis engines (AE) that inspect the input data, perform analysis, and store resulting annotations. The system consists of several such components that work together to process an input EHR. These components write their output to a shared data structure called a common analysis structure (CAS). The system achieves high performance by using UIMA Asynchronous Scaleout, a set of capabilities supported for achieving scale-out and Distributed UIMA Cluster Computing, a cluster management system providing tooling, management, and scheduling facilities to automate the scale-out of UIMA applications. Figure 1 shows the high-level flow and underlying NLP components of ProSPER. ProSPER’s NLP components, all tailored towards EHR text, can be broadly divided into three levels, described below.

![Figure 1. A high-level architecture of ProSPER.](image-url)
Fundamental and clinical NLP components

Despite the success of current open-domain NLP systems for syntactic and semantic analysis, several studies\textsuperscript{34,35} have shown that substantial effort is needed to adopt existing systems to the clinical domain. Clinical notes are written under considerable time pressure, using a combination of ad-hoc formatting and liberal use of parenthetical expressions, jargon and acronyms to increase the information density\textsuperscript{35}. For example, sentence ends are frequently indicated by layout rather than punctuation, and white space is not always present to indicate token boundaries (eg, “50mg”). To handle such issues, two deep parsing components\textsuperscript{36} were used: a domain-adapted English Slot Grammar parser for core linguistic analyses (tokenization, segmentation, morpho-lexical analysis, syntactic analysis), and a predicate-argument structure (PAS) builder for simplification and abstraction of the ESG parse. These components incorporate domain-specific rules sensitive to low-level features such as punctuation, capitalization, text-wrap properties, and indentation of clinical documentation.

Rule-based, machine learning (ML)-based and lookup-based methods are three major approaches for extracting useful information from natural language texts. Many components in ProSPER use a combination of hand-crafted rules and ML-based methods for their operation. The rule engine in ProSPER uses a pattern language for describing rules on the output of PAS builder. Details about this rule engine are included in Boguraev et al.\textsuperscript{37} Two ML frameworks, feature-based learning and deep learning frameworks, were developed to support concept and sentence classification, sequence labeling, sequential sentence labeling, sentence pair scoring, and relation extraction. The feature-based learning framework provides implementations of traditional ML algorithms such as Support Vector Machines\textsuperscript{38}, Conditional Random Fields (CRF)\textsuperscript{39}, and domain-independent and dependent feature extractors. Similarly, the deep learning framework provides implementations of state-of-the-art deep learning architectures, such as Bidirectional Long Short-Term Memory – Conditional Random Fields\textsuperscript{40} and pre-trained transformer-based models\textsuperscript{41}. These frameworks were tailored to more effectively process clinical notes. They provide the ability to (1) easily integrate feature extractors or architectures, (2) leverage evidence from both structured and unstructured data simultaneously to develop consolidated models, and (3) streamline models or feed predictions from one or more auxiliary tasks to subsequent tasks. ProSPER uses UIMA’s ConceptMapper\textsuperscript{42}, a tool for lookup-based methods, to link text in input documents with entries in a dictionary such as the Unified Medical Language System (UMLS) semantic network\textsuperscript{35}.

Several NLP components that extract useful information from clinical narratives have been developed using these frameworks. Details of these components have been described in our previous studies\textsuperscript{40,42,44–50}. These include (1) fundamental NLP components such as named entity recognition (NER) and disambiguation (NED)\textsuperscript{42,48,49}, entity linking\textsuperscript{51}, relation extraction\textsuperscript{47,48,52} and abbreviation recognition and disambiguation\textsuperscript{49}, and (2) components specific to clinical documentation (i.e. clinical insight extraction components) such as note section segmentation and classification\textsuperscript{53}, clinical semantic textual similarity (STS)\textsuperscript{50}, and assertion classification\textsuperscript{54}.

Clinical insight extraction components can be broadly categorized into (1) concept classification, (2) sentence classification, (3) sequential sentence classification, (4) semantic textual similarity, and (5) relation extraction. Concept classification components, such as assertion classification and medication change extraction, provide one or more categorial labels on a concept based on the surrounding context. Assertion classification uses a deep learning-based model that assigns each disease mention in a note with one of the following labels: present, absent, possible, hypothetical, conditional, associated with someone else; medication change extraction leverages multiple ML models that assign each medication mention in a note with labels corresponding to several dimensions: action (start, stop, increase, decrease), temporality (past, present, future), and certainty (certain, hypothetical, conditional). Sentence classification components assign one or more labels to a sentence in a clinical note; examples include binary classification models such as plan\textsuperscript{55}, follow-up, and goal extraction. Sequential sentence labeling components assign a label to each sentence in a given sequence, which are useful in capturing the inherent dependencies of sentences within a clinical note to assign the correct label for each sentence. For example, the note section classification model identifies the layout of a note with respect to its semantics by assigning one of a set of pre-defined section labels to each sentence (e.g. Review of Systems, Physical Exam). Clinical STS employs a combination of multi-task learning\textsuperscript{56} and fine-tuned pre-trained language models\textsuperscript{57,58} to compute the semantic equivalence between a pair of text snippets. Relation extraction components extracts entities from clinical notes and identifies relations between them. An example is ADE extraction which uses a joint deep learning model that extracts medications and related ADEs simultaneously.

Summarization components

Summarization components are high-level analytics built on top of the fundamental NLP and clinical insight extraction components. These include problem list generation, relation detection, disease-specific extractive summarization, consolidated medication timeline, and semantic find.
Evaluation of NLP components can be classified into intrinsic and extrinsic methods\(^6\). Intrinsic methods evaluate the functionality of a component against a predetermined gold standard, whereas extrinsic methods focus on the component’s contribution to the overall objective of an application and often requires a human-in-the-loop. As highlighted in by Pivovarov et al.\(^{13}\), extrinsic evaluation of NLP systems in a clinical setting is a challenging task due to reasons including (1) vendor EHR systems often do not support interaction with outside applications, and (2) hospitals often request evidence supporting the usefulness of an informatics system before investing resources for implementation. As a result of these constraints, here we report an evaluation of our system based on intrinsic methods, with an extrinsic evaluation of the overall application planned for the future.

As is common in information retrieval, recall (R), precision (P), and F\(_1\) score was used to evaluate our components. Recall, also known as sensitivity, is the number of true positives found given the total number of ground truth annotations. Precision, also known as positive predictive value, is the number of true positives given the total number of system predictions. F\(_1\) score provides a balanced measure of recall and precision. Specificity, also known as true negative rate, is not useful for our tasks as the number of true negatives are significantly higher than that of true positives, thereby yielding a less meaningful accuracy distinction.

**Problem list generation:** To extract an open-ended list of the patient’s active problems from the entire patient record, problem list generation was framed as a multi-label classification and ranking task. The model was based on an alternating decision tree, which used outputs from many upstream analytics (described above) as features, including but not limited to UMLS concepts identified by the NER/NED components and mapped to the CORE problem list subset of SNOMED CT, their assertions and distribution over the longitudinal record, and the degrees of alignment in temporal space between the identified candidate problems and their related medications, laboratory tests, and procedures. This method produced a human interpretable model, which is a desirable property in the clinical domain. To the best of our knowledge, this was the first successful open-ended problem list generation system\(^{15,44,45}\).

**Relation detection:** An ensemble approach with two supervised ML models was used to associate problems with related medications, laboratory tests, and procedures\(^9\). One method used features extracted from distributional semantics and UMLs; the second used features mined from historical, actual patient data. The results of relation detection were used both internally as features to support other components, and as a user interface functionality to sort structured data tables and highlight relevant data elements for a selected problem in the problem list.

**Disease-specific extractive summary:** Extractive summarization was modeled as a sequential sentence labeling problem, where each sentence in a given note is classified as being relevant (or not) to the management of the specified disease of interest. Outputs from upstream components, such as plan extraction and note section segmentation and classification, were leveraged in a linear-chain CRF model to automatically generate disease-specific summaries from clinical notes. As a post-processing step, boilerplate statements, which are often either not patient-specific or meant for purposes other than clinical care, are downweighted based on frequency analysis on all notes in our corpus. Next, deduplication of semantically equivalent sentences enabling the generation of more salient summaries was achieved by leveraging clinical STS. Details of the extraction summarization system was published in Liang et al.\(^{31}\).

**Consolidated medication timeline:** Data from structured medication orders, medications extracted from clinical notes and their related insights were aggregated to build a comprehensive medication timeline. In building this timeline, there were two key challenges: (1) some medications are only documented in unstructured data\(^5\) and (2) daily dosage, although present in many medication visualization designs\(^21,22\), is generally not available as a discrete field and requires understanding free text medication instructions (i.e. Sig). To address this gap, our system leveraged NER and NED components to identify medications and their attributes in clinical notes and Sigs, then normalized these attributes to calculate daily dosage\(^6\). To further enhance the timeline, outputs from clinical insight components (e.g. ADE and medication change extraction) were displayed as popovers on the timeline for the relevant medication.

**Semantic find:** Semantic find is an NLP-based search that leverages UMLS and distributional semantics to perform different kinds of search, such as conceptual search, which leverages UMLS to match clinically equivalent concepts (e.g. lisinopril/Zestril) and ISA relations to match more specific (e.g. cancer/sarcoma) or more general (e.g. gi bleed/hemorrhage) variations of the search term, and associative search, which uses Latent Semantic Analysis\(^51\) to measure the probability of an association between the search term and target term, and returns concepts with a score above 0.5 (e.g. asthma/wheezing). Details for semantic find are available in Prager et al.\(^32\).

**Evaluation metrics**

ProSPER application

ProSPER consists of (1) a problem-oriented patient summary centered around an auto-generated problem list, and (2) disease-specific views for several chronic conditions. The problem-oriented patient summary allows users to gain a quick overview of the patient, while the disease-specific views allow a deeper dive into a specific problem of interest.

The problem-oriented patient summary presents (1) an auto-generated problem list, (2) aggregated clinical data by type, (3) relations between problems and other data aggregates, and (4) a semantic search over the entire EHR. Figure 2 shows the user interface which presents several panels, one for each data type. When a problem is selected, related medications, laboratory results, and procedures are highlighted and brought to the top for easier review.

Figure 2. Problem-oriented patient summary with diabetes mellitus selected.
The disease-specific view allows further investigation of a problem by presenting all information relevant to the disease of interest on one screen. In this view, encounters in which the specified disease was discussed are displayed on a timeline, and an extractive summary of each of these encounters is produced containing only the most important information relevant for managing the specified disease. Relevant medications, test results and their trends are also displayed in timeline form, allowing users to identify potentially informative encounters, and also infer relationships between various elements of the patient record (e.g. medication prescribed after an increase in a particular laboratory result). Figure 3 shows the disease-specific view for diabetes mellitus in a patient.

Figure 3. Disease-specific view for diabetes mellitus.

Disease-specific extractive summaries for each encounter are displayed by hovering over icons in the encounter timeline, with the summary of the most recent encounter in the right panel for easy viewing. Orange indicators on the medication timeline represent medication insights extracted from clinical notes and are displayed as popovers. Semantic find can be launched using the search box on the top right if the user needs additional information.

Discussion

Challenges in developing an NLP-based application for use in a real-world clinical setting

There is a significant gap between what low-level NLP components can do as compared to the mental work physicians perform during chart review. Previous studies on applying NLP in the clinical domain either focused on advancing the state-of-the-art on a single task or using existing NLP toolkits with more emphasis placed on data visualization. This paper tries to bridge the gap between what low-level NLP components can provide versus what physicians want, by leveraging ML and NLP in all aspects of a chart review scenario.

Several components within our system have been previously published to advance the state-of-the-art on publicly available datasets. However, for many components there are no publicly available datasets, necessitating use of in-house datasets and ground truth. An additional challenge is the need for both structured and unstructured data in creating ground truth for many high-level tasks such as summarization.

Although NLP applications have reported good accuracy, studies have shown that these applications still have low adoption rates in clinical practice, largely due to uncertainty about minimal performance requirements rather than performance-related issues. The interpretation of a specific component’s accuracy in terms of the overall usefulness of a system as measured by an extrinsic evaluation still warrants more research attention.

How does ProSPER address physician challenges in reviewing EHRs?

To understand how ProSPER can support physicians in their review of EHR data, we discuss how specific components within the system address the five information hazards identified by Beasley et al.: information overload, information underload, information scatter, information conflict, and erroneous information. Information overload occurs when

769
there is too much data for the user to review, organize, synthesize, and act on. One way ProSPER mitigates this problem is by disease-specific extractive summarization, which leverages components such as note section classification and clinical STS to remove uninformative or redundant text\textsuperscript{24,64}, to produce a succinct summary of a clinical note. Information underload describes the lack of necessary information, such as missing information due to incomplete patient records, or information that is so difficult to find and for all intents and purposes, “missing”. ProSPER targets information underload in several ways, including semantic find, which searches the entire EHR based on a user-provided query, and ADE extraction, which surfaces rare yet important clinical events that have great impact on patient safety. Information scatter describes the problem of having information located in multiple places, thereby requiring additional effort to reconcile this information. The idea of a problem list was conceptualized as a way to address this issue by capturing all of the patient’s important health problems in one centralized location, but in practice it is rarely well-maintained rendering it mostly unusable\textsuperscript{65}. ProSPER supports problem list reconciliation through its problem list generation component, which has been validated by physicians in a small pilot study\textsuperscript{66}. The last two information hazards, information conflict and erroneous information, can be discussed together as conflicts within EHR documentation can be partially attributed to erroneous information. In providing a consolidated medication timeline containing information from both structured and unstructured sources, ProSPER allows users to more easily identify and resolve discrepancies in medication data between structured and unstructured data.

**Limitations and future work**

We acknowledge several limitations to this work. First, the results presented in this paper are based on an intrinsic evaluation of the NLP components using precision, recall, and F\textsubscript{1} score to compare against ground truth created by physicians or medical students. However, these metrics do not fully capture the nuances of what should or should not be included in a problem-oriented patient summary. For instance, a single missed ADE by the system may not have a significant impact when measured using the proposed quantitative metrics, but it may be critically important to patient management and should never be missed. Second, these results are specific to the datasets, which contain only EHRs from two healthcare organizations. Ground truth generation and evaluation on a more diverse dataset is needed to better understand the effectiveness of these approaches. Third, while some of the components were previously evaluated and published using publicly available datasets, others were developed using proprietary datasets not available to the research community. In addition to continuing to adapt and innovate novel methodologies to improve individual NLP components, which in-turn can benefit the overall application, we plan to take the following steps to address the limitations above:

1. Use extrinsic measures to capture the usefulness of ProSPER for practicing physicians at the point-of-care.
2. Create ground truth annotations on publicly available datasets such as MIMIC-III\textsuperscript{66} and organize challenges to invite community-driven efforts.

**Conclusion**

We present ProSPER, a novel problem-oriented summary of the patient record that leverages 3 levels of NLP informatics, including performing well-studied fundamental NLP tasks such as NER, extracting clinically meaningful events from clinical notes such as ADE, generating an active problem list from the heterogeneous, longitudinal patient record, and creating disease-specific extractive summaries from clinical notes. Components underlying ProSPER target specific information hazards within the EHR that lead to excess physician workload and mental exhaustion. Our work demonstrates the need to leverage holistic information in EHRs to build a comprehensive summarization application, and the potential for NLP-based applications to support physician and improve overall clinical care.

Extraction of Active Medications and Adherence Using Natural Language Processing for Glaucoma Patients

Abstract

Accuracy of medication data in electronic health records (EHRs) is crucial for patient care and research, but many studies have shown that medication lists frequently contain errors. In contrast, physicians often pay more attention to the clinical notes and record medication information in them. The medication information in notes may be used for medication reconciliation to improve the medication lists' accuracy. However, accurately extracting patient's current medications from free-text narratives is challenging. In this study, we first explored the discrepancies between medication documentation in medication lists and progress notes for glaucoma patients by manually reviewing patients' charts. Next, we developed and validated a named entity recognition model to identify current medication and adherence from progress notes. Lastly, a prototype tool for medication reconciliation using the developed model was demonstrated. In the future, the model has the potential to be incorporated into the EHR system to help with real-time medication reconciliation.

Introduction

The rapid adoption of electronic health records (EHRs) has generated large-scale clinical data that has been re-used for many purposes, including patient phenotyping, pharmacovigilance, comparative effectiveness research, clinical decision support, and quality improvement and research. Although secondary use of EHR shows many benefits such as improved healthcare quality, reduced healthcare costs, and effective clinical research, there are many challenges that still need to be addressed. One of the biggest challenges is the accuracy and completeness of EHR data, specifically medication information.

The accuracy of medication data is crucial for patient safety, quality of care, and clinical research. Inaccurate or incomplete medication records can lead to polypharmacy, adverse medication interactions, and decreased data reliability in research. The medication list is a structured record of a patient's medication data which is populated automatically by electronically prescribed medications or manually through medication reconciliation. However, the EHR system may not always capture medication data correctly or prevent errors in the medication list. Previous studies have shown that medication lists frequently contain errors, including duplicated documentation of medications, outdated discontinued prescriptions in the medication list, and missing medications prescribed elsewhere. In addition, prior studies show that physicians direct very little attention to EHR medication lists, and instead spend most time reviewing the impression and plan section. It seems reasonable to expect that medications recorded in narrative notes are more reliable and can be helpful with medication reconciliation. Medication reconciliation is a process to create and maintain patients' most current and accurate list of medications.

However, manual reviewing progress notes for medication data extraction in EHR is time-consuming and labor-intensive. Natural language processing (NLP) is a promising strategy for capturing medication information from the free-text progress note. With advancements in machine learning and the large text corpora available in EHR, NLP has been successfully used to process free-text EHR data, for deep contextualized word representations, information extraction, and semantic analysis. Named entity recognition (NER) is a sub-task of information extraction, which seeks to identify words or phrases into pre-defined categories with specific labels. Over the past years, the NER technique has been applied to extract medication information, such as drug names, frequency, dosage, adverse drug events, adherence, etc., from free-text documents. For example, a conditional random field (CRF) model was used to develop a NER model to detect medication attributes and adverse drug events. Also, bidirectional long short-term memory (LSTM) model was used for named entity recognizing for medication information. More recently, pre-trained deep learning models were widely used for biomedical information extraction. However, to our knowledge, there has not been a well-developed NLP tool to identify a list of current medications for a specific disease such as glaucoma and help with medication reconciliation.
The purpose of this study is to develop a NER model for extracting patients’ current ophthalmologic medication and adherence from free-text notes for glaucoma patients. Glaucoma is characterized by progressive degeneration of the optic nerve and irreversible visual field loss, and it is the leading cause of irreversible blindness worldwide.\textsuperscript{33} The majority of glaucoma patients are treated using medical therapy, and the accuracy of medication documentation is crucial in glaucoma management.\textsuperscript{34} However, the accuracy of glaucoma medication documentation is unclear. In addition, glaucoma patients’ medication non-adherence rate has been reported to vary from 24% to 59%.\textsuperscript{35, 36} Therefore, a reliable method to assess glaucoma patients’ current ophthalmologic medication and adherence is needed.\textsuperscript{37} Finally, the reliability of medication data is important for glaucoma research, such as prediction models for disease progression. In this study, we first manually reviewed patient charts for discrepancies in medication documentation between medication lists and progress notes. Next, we trained and tested a NER model for extracting current medication from progress notes and evaluated its accuracy. Finally, we demonstrated an approach for medication reconciliation using the NER model on small sample progress notes.

Methods

This study was approved by the Institutional Review Board at Oregon Health and Science University (OHSU). OHSU is a large academic medical center in Portland, Oregon. This study was conducted at Casey Eye Institute, OHSU’s ophthalmology department serving all major ophthalmology subspecialties. The department performs over 130,000 outpatient examinations annually and is a major referral center in the Pacific Northwest and nationally. In 2006, OHSU implemented an institution-wide EHR (EpicCare; Epic Systems, Verona, WI) to handle all ambulatory practice management, clinical documentation, order entry, medication prescribing, and billing.

The study contains three phases (1) Explore medication discrepancies between the medication list and the progress note for glaucoma by manually reviewing charts; (2) Develop a NER model to extract patients’ current ophthalmologic medication and medication adherence from progress notes for glaucoma patients and (3) Apply the NER model to perform medication reconciliation.

Progress notes and medication list data from EHR were extracted for 150 randomly selected Casey Eye Institute patients with encounter ICD10 diagnosis codes related to glaucoma from January 23, 2019, to September 28, 2020. The patient’s most recent office visit notes were manually reviewed by three independent reviewers. The medications recorded in the narrative notes were abstracted and compared to the EHR medication list at the time of visit. All ophthalmologic medications and over-the-counter (OTC) medications (e.g., artificial tears) were collected. All medications listed in the notes but not on the medication list or vice versa were labeled. Cross-validation among the three reviewers was conducted by using a subset of 20 encounter notes (96.4% agreement).

2. NER Model for Extracting All Ophthalmic Medications

We sampled a dataset with 507 progress notes from office visits at the Casey Eye Institute from January 01, 2019, to December 31, 2019, with encounter ICD10 codes associated with glaucoma. The dataset was constructed by random stratified sampling from all ophthalmology visits according to the department and primary provider name. The documents were manually annotated for nine categories: Drug Name, Route, Frequency, Dosage, Strength, Duration, Adverse Drug Event (ADE), Adherence, and Current Medication Use. All medication names, including generic names, brand names, and abbreviations, were sourced from publicly available online resources and glaucoma specialists. An open-source tool (Doccano; Open source: Doccano; 2018) was used to annotate the documents.\textsuperscript{38} Due to the limited number of ADE entities, we discarded this category and kept the other eight entities. Figure 1 displays an example of the annotation. The annotated dataset was randomly split into 75% for training and 25% for testing. A 10% randomly sampled subset of documents from the training data was used as a validation set for turning the hyperparameters. Table 1 presents the description of the datasets and annotation statistics.
Figure 1. Example of note annotation by an open-source tool. Medication drug name, strength, dosage, frequency, route, duration, current use, and adherence are identified.

We used named entity recognition, a sub-type information extraction technique, to extract medication information and adherence from clinical notes. The NER model was developed in Python 3.7.6 using the spaCy library. The spaCy library is a free open-source library for NLP. The architecture of spaCy’s NER model is based on convolutional neural networks which uses a word embedding strategy using sub-word features and "Bloom" embeddings. In this study, the training task contains 200 epochs with experiments with multiple hyperparameter settings. Different learning rates (initial at 1e−2, 1e−3, 2e−3, 1e−4, 2e−4) were tested and adjusted by two optimizers: Adaptive Moment Estimation (Adam) and stochastic gradient descent. We use a decaying dropout rate (0.5 - 0.35; 1e−3) to avoid overfitting. Also, we experimented with different batch compounding sizes and regularization schemes to optimize the model. The results of the NER model’s extraction for the test set were determined by comparing the manually annotated and the NER model’s extracted entities. The model performance was evaluated by using F1 score, precision, recall, and the micro-averaged score, which aggregates the contributions of all categories to calculate the average metrics.

Table 1. Distribution of annotated entities and number of progress notes in training and testing datasets.

3. Medication Reconciliation Using NER Model for Current Medications

Finally, we developed a prototype medication reconciliation tool using the optimized NER model. For this purpose, we are focusing only on medications the patient is currently using as documented in progress notes. Figure 2 demonstrates an example of medication reconciliation using our prototype tool. First, our NER model extracted the patient’s medications and "Drug Use" label from the 150 sample progress notes which were manually reviewed in phase 1. The “Drug Use” label identified which medications that the patient was currently taking. Next, the current medications were standardized based on RxNorm Ingredient (IN). Finally, the standardized medications were compared to the manually identified medications from phase 1. Both ophthalmologic medications and over-the-counter (OTC) medications (e.g., artificial tears) were included. All medications listed in the notes but not on the medication list or vice versa were flagged.

![Figure 2](image_url)

**Figure 2.** Example of medication reconciliation using the developed NER model

**Results**

The randomly sampled 150 patients’ notes and medication lists contained a total of 450 medications, including glaucoma eye drops, mydriasis eye drops, antimicrobials, corticosteroids, and OTC medications. Prescription medications were most common \((n = 355; 79\%)\), followed by OTC medications \((n = 95; 22\%)\). Around 57% of patients had at least one medication mismatch for all categories in their records. However, only 36% of patients had at least one medication mismatch for prescription medications \((n = 298)\). Nearly 66% of medications could be reconciled between the progress notes and medication list. Around 34% \((n = 152)\) of medications are mismatched for various reasons, including medications prescribed by clinicians from different institutions, medications with duplicated prescriptions, medications that were prescribed and entered in the medication list but not recorded in the progress note, and old medications that were not discontinued in the medication list. Figure 4 displays the distribution of medication mismatches among the two categories in the EHR by location. The most frequent mismatch was found with prescription medications \((55\%)\) followed by the OTC medications \((45\%)\). The OTC medications were more commonly recorded in the progress notes but not entered into the medication list. In contrast, mismatched prescription medication more often appeared in the medication list but not in the progress notes.
Figure 3. Medication documentation mismatches were stratified based on the number of mismatches that occurred per patient for prescription (blue), OTC (green), and all medications (yellow).

Figure 4. Summary of medication mismatches across 150 patients.
2. NER Model for Extracting Current Ophthalmic Medication
The custom NER model was trained with 381 progress note documents that were manually annotated with eight named entities and then tested on 126 progress notes. Table 2 presents the overall micro-averaged and per-entity performance for the optimal NER model on test data (126 progress notes). The overall performance of the NER model across all categories was F1 score = 0.955, Precision = 0.951, and Recall = 0.957. Higher performance was observed on medication-related entities: Drug, Name, Route, Frequency, Dosage, and Strength, compared to patient’s behavior-related entities: Adherence and Current Medication Use. An error analysis was performed for false negative and positive on Drug Name, Adherence, and Current Medication Use to recognize the source of error predictions. Several causes of errors were identified, such as different wordings for medication adherence, mislabeled current medication use and drug name due to similar sentence structure, eye exams or warm compress mislabeled as drug name, and misclassification when entity information was contained in a short sentence. (Table 3).

3. Medication Reconciliation Using the NER Model

The prototype medication reconciliation tool identified 408 current medications from the 150 progress notes that were manually reviewed in phase 1. After standardizing the medications to RxNorm, 14 medications were removed for a final list of 394 medications. Among the 394 medications, there were 379 medications matched with the manually abstracted current medications. The prototype tool achieved a good performance of F1 score = 0.969, Precision = 0.959, and Recall = 0.979.

Discussion

In this study, we explored medication discrepancies in the EHR data and evaluated the performance of a custom NER model's applicability to extract current medication for glaucoma patients. We also used the developed NER model in a proof-of-concept application to perform medication reconciliation in a subset of our patients. The key findings from our study were (1) Medication discrepancies in patient charts were found to be present in a large proportion of office visits; (2) The custom NER model can accurately extract current medication and adherence for glaucoma patients; (3) The NER model can be used to reconcile the medication documentation.

The first key finding is that medication discrepancies were found to be present in a large proportion of office visits. Our study shows that approximately twenty percent of medications prescribed to glaucoma patients had at least one discrepancy between the medication list and the progress note. Overall, more than one-third of patients in this study had at least one medication mismatch between both data sources. These inconsistencies in the EHR medication records may increase the risk of medication errors and affect the reliability of research that relies on this data. These findings are similar to other studies, including a study for microbial keratitis demonstrating 76.9% of medication agreement between progress notes and medication lists and another study for inflammatory bowel disease reporting 78.6% of medications agreement between clinical narrative and medication list. The findings from these studies indicate that the accuracy of the medication list is a common problem. An accurate tool for medication reconciliation of medication lists and further qualitative studies to understand the causes of medication data discrepancies is needed.

The second key finding is that our NER model can accurately identify current medication and adherence from progress notes from outpatient glaucoma visits. In our study, the model reached a micro-averaged F1 score of 0.955 across all categories. The NER model was developed to recognize eight categories from free-text progress notes, including drug names (including generic, brand, and abbreviation names), the route of administration, prescription frequency, the dosage of the drugs, drug strength, duration, medication adherence, and current medication use. The NER model could accurately identify medication-related entities (except duration) but showed lower performance on patient behavior-related entities, such as adherence and current medication use. The difference could be ascribed to the limited number of training cases and the higher variety of wordings. As shown in Table 1, there are only 35 annotated duration entities and 132 annotated adherence entities in the training data. In addition, the words and phrases to indicate adherence and current medication use are various, and some of these phrases are located in different sentences than the medications. Nevertheless, the most common error of drug name identification is mislabeling other terms such as “warm compress” or “OTC readers” as a drug name due to similar sentence structure. For example, “warm compress left eye PRN” or “Vision has been good. Just using OTC readers.” In these cases, these mislabeled drugs will easily be filtered out of the results in practice during the conversion to RxNorm names.

Finally, our NER model can be used to reconcile medication documentation. As shown in the phase one study, we can manually abstract the medication records from their progress notes to compare with their medication list. Similarly, the NER model was able to recognize common medications as well as identify text related to current medication use. This is the first study, to our knowledge, to develop NLP models to recognize current medication use from free-text progress notes. With the ability to identify the current medication use, we are able to capture the whole picture of current medications for the target patients and reconcile it with their medication list. As previously mentioned, the medication reconciliation between progress notes and medication lists was only reported from 76.9% to 79.6% for three different diseases, including microbial keratitis, inflammatory bowel disease, and glaucoma. And more than one-third of patients had at least one discrepancy for ophthalmic prescription medications. In our study, the NLP tool can correctly identify current medications for glaucoma patients on 150 sample progress notes (F1 score = 0.969). Figure 2 displays an example of medication reconciliation using the NLP tool. In this prototype tool, we focused on reconciling the drug names since physicians did not always record the other attributes, such as route, frequency, and dosage along with the medications. In future work, we plan to extend this medication reconciliation method to use the
information from both narrative progress notes and medication lists to construct a current medication list for glaucoma patients.

Our study has limitations future work may address. First, some of the entities are naturally less frequently recorded in the progress notes that affect the performance of the NER model. For example, text related to drug duration appeared much less frequently than other entities, such as drug name, route, and frequency. Thus, it is challenging to train the model correctly recognize these entities. A similar finding was reported in another study.31 Second, the model was trained on a set of notes for glaucoma patients from a single institution; it is unclear if the model can be generalizable to other subspecialties within ophthalmology or other healthcare systems. Finally, the application of the custom NER model for medication reconciliation is a proof of concept. We conducted the test of medication reconciliation using the NER model on a limited number of samples. Our intention is to extend and replicate these study methods to different specialties and institutions to increase the generalizability of our model. In the future, the custom model could be incorporated into the EHR system to help with medication reconciliation.

**Conclusion**

Discrepancies in medication documented in the medication and in progress notes were observed in more than one-third of encounters for glaucoma patients. Inaccurate medication lists in the EHR may affect the reliability of the research or clinical decision support using this data. Since physicians often record current medication information in the progress notes this data could be used for medication reconciliation. In this study, we developed an NLP model to accurately identify current medication information from free-text EHR data that can be applied to perform automated medication reconciliation; the performance of the model is similar to the best performing published NLP models for medication extraction studies.25-31,46 This has implications in improving the data quality and usefulness for medication data in both research and clinical care.

Abstract

Inaccurate body weight measures can cause critical safety events in clinical settings as well as hindering utilization of clinical data for retrospective research. This study focused on developing a machine learning-based automated weight abnormality detector (AWAD) to analyze growth dynamics in pediatric weight charts and detect abnormal weight values. In two reference-standard based evaluation of real-world clinical data, the machine learning models showed good capacity for detecting weight abnormalities and they significantly outperformed the methods proposed in literature (p-value<0.05). A deep learning model with bi-directional long short-term memory networks achieved the best predictive performance, with AUCs ≥0.989 across the two datasets. The positive predictive value and sensitivity achieved by the system suggested more than 98% screening effort reduction potential in weight abnormality detection. Consequently, we hypothesize that the AWAD, when fully deployed, holds great potential to facilitate clinical research and healthcare delivery that rely on accurate and reliable weight measures.

Introduction

Body weight, as an important parameter in pediatrics, is widely utilized to track growth and development of children and to calculate drug doses in clinical settings1–4. It is also an important variable for secondary data analysis in clinical research such as computerized phenotyping5. In current practice, body weight is usually measured and entered into the electronic health records (EHRs) by clinical staff manually, and can be recorded incorrectly in various ways, including improper operation of weight scale, typing errors, conversion errors (e.g., weight scale in pounds, and documentation in kilograms), and weight estimations instead of actual measurements4. Inaccurate body weight data have a high risk of causing patient harm; literature studies have reported that 18-22% of medication errors are resulted from “improper dose/quantity” in pediatrics, which is significantly higher than that in adult settings2,3. The erroneous data also hinder the full utilization of EHRs for research purpose due to error propagation in downstream analysis.

Manual chart review is currently standard practice in correcting weight abnormalities, which is labor-intensive and impractical to perform in busy clinical settings. In particular, capturing weight abnormalities with high accuracy can be difficult, especially for neonates, and growing children who have acute or chronic medical conditions. There is a critical need to develop an accurate and cost-effective approach for detecting abnormalities from pediatric weight charts to prevent weight-based dosing/medication errors. The approach can also be applied to cleaning abnormal weight values from EHRs to provide high-quality data for subsequent research.

By using recent informatics technologies, several approaches have been proposed to identify abnormal weights from patient charts4. One established method is developed by the Centers for Disease Control and Prevention (CDC), which standardizes weight points with z-score normalization and identifies outliers based on their standard deviations from the mean7. Another computerized approach is proposed by Children’s Hospital of Philadelphia, which compares standard deviation of a weight point against a weighted moving average in the chart to identify abnormal values8. In our earlier study, we also develop a regression approach to model weight trend in a chart and determine if a weight point is an outlier9. However, all the methods are rule-based, where empirical thresholds are developed based on subjects’ age and gender to identify abnormal values. Even though they are easy to implement, the approaches have low detection capacity, particularly for complex weight charts.

Machine learning is a field of artificial intelligence that utilizes computerized algorithms to learn the relation between, and make prediction on, sets of data. The technologies have been widely used on a variety of clinical decision support tasks, including patient clinical status detection, workflow optimization, and computerized phenotype discovery10-12. More recently deep learning, a branch of machine learning focusing on developing neural network-based algorithms, has gained increasing popularity in clinical informatics and has been applied to analyze sequence data such as clinical narratives13-15. Nevertheless, no studies have used machine learning for analyzing patient weight charts.
Our research is specifically directed at developing an accurate and scalable informatics-based solution, an automated weight abnormality detector (AWAD), to identify errors in pediatric weight charts. In our earlier studies, we developed a visual annotation tool to enable large-scale annotation of weight abnormalities. To take the next step, this study focused on developing an automated approach to analyze patient charts and identify abnormal weight values. We hypothesized that with using state-of-the-art machine learning and deep learning technologies, the AWAD could detect weight abnormalities for individual charts with high sensitivity and specificity. The study is the first, known to us, to investigate detection of weight abnormalities in a large-scale via machine learning technologies.

**Materials and methods**

Figure 1 diagrams the overall processes of the study. We first collected and selected weight charts from the institutional EHRs (process 1 in Figure 1). Annotation was then performed to identify abnormal weight values for individual charts (process 2). Features were extracted from each weight chart to capture weight characteristics and growth dynamics (process 3), which were then fed into machine learning- and deep learning-based algorithms to detect abnormal weight values (process 4). Finally, a separate annotated weight set was applied to assess the generalizability of the developed algorithms (process 5).

**Data collection and weight chart selection**

A total of 4.3 million weight points was collected from the EHRs for all 347,056 patients visiting Cincinnati Children’s Hospital Medical Center (CCHMC) between 2010 and 2018. Use of the de-identified dataset was approved by the University of Cincinnati Intititional Review Board (study ID: 2017-2075). Following our earlier study, we excluded three types of weight points from analysis: 1) weight points documented in the first 24 months (1,137,410 points from 31,876 patients) because newborns could have more complex weight changing patterns, 2) weight points recorded after 240 months (17,211 points from 7,932 patients), and 3) all weight points from patients with less than four weight measures (213,388 points from 87,013 patients) to ensure sufficient information in each weight chart. After data exclusion, a secondary polynomial regression model was built to identify charts with potentially abnormal weight values based on five parameters including 1) maximum absolute residuals, 2) median absolute residuals, 3) root mean square errors, 4) maximum ratio of absolute residuals to fitted values, and 5) mean ratio of absolute residuals to fitted values. The regression model identified 107,336 candidate charts with at least one weight point outside its 99% confidence intervals. A set of 15,000 charts (denoted by MAIN dataset) were randomly sampled from the 107,336 dataset for weight abnormality annotation.

**Weight abnormality annotation**

We recruited domain experts with appropriate medical training and knowledge to review the selected weight charts and identify abnormal weight values. The annotation guideline suggested 1) weight points should be evaluated retrospectively based on all available points in a chart, and 2) weight points should be labeled as abnormal based on their clinical importance and risk for leading to patient harm. By using the guideline and a visual annotation tool developed in-house, the 15,000 weight charts were annotated by 18 domain experts to create a reference-standard set of weight abnormalities. During annotation, each expert was assigned to a random sample of 2,500 patient charts such that each chart was reviewed by three annotators. An example chart with annotation is presented in Figure 2. All weight points were considered normal and defaulted to blue. Abnormal points with high clinical importance were labeled as red, while potentially abnormal values requiring second opinions were labeled as orange.

A scoring approach was applied to summarize the annotations, with red scoring two, orange one and blue zero. A weight point was considered abnormal if sum of scores from the three annotators were greater than two (i.e., at least one red and one orange decisions or three orange decisions). Weight points scoring two were further reconciled by
our clinical champion (Dr. Spooner) to determine their abnormality. Adjacent data points with identical age and weight values were reviewed manually to avoid diluting the effects of predictors by contradictory outcome labels. The inter-rater agreement (IRA) was calculated using Fleiss’ Kappa.

**Figure 2.** An example chart with weight abnormality annotation. The weight characteristics presented in the box were available to annotators during annotation. Color codes: 1) blue represents normal weight entries, 2) red represents abnormal weight points with high clinical importance, and 3) orange represents potentially abnormal points requiring second opinions.

**Weight feature extraction**

For each weight point, nine variables were generated to capture weight characteristics and growth dynamics: 1) subject weight in kilograms, 2) subject age in years, 3) subject sex, 4) the Box-Cox transformation, median and generalized coefficient of variation- (LMS-) based z-score according to subject sex and age, 5) modified LMS-based z-score using the weight-for-age data from a reference population provided by CDC to identify extreme weight values, 6) percentage of the population that was below a weight value (denoted by percentiles), 7) absolute age difference from the immediate previous weight point, 8) absolute weight difference from the immediate previous weight point, and 9) absolute z-score difference from the immediate previous weight point. The numerical variables were standardized with z-score normalization. The categorical variable (i.e., sex) was binarized with a dummy variable to avoid linear dependencies. After feature extraction each weight point was represented by a nine-dimensional numerical vector.

**Traditional machine learning classifiers**

We model detection of weight abnormalities as a binary-class classification and implemented five machine learning classifiers including LR with L1 and L2 normalization, support vector machines with linear (SVM-L), polynomial (SVM-P) and radial basis function (SVM-R) kernels, decision trees (DTs), random forests (RFs), and one-layer artificial neural networks (aNNs).

**Deep learning models**

Differed from traditional classifiers that make predictions on individual examples, the long short-term memory (LSTM) network is capable of propagating information in a data sequence to improve prediction capacity. Literature studies have shown the effectiveness of LSTM-based models in processing sequence data such as free-text narratives and time-series signals. To achieve the best detection capacity, we also developed a LSTM-based model to capture growth trends and identify weight abnormalities. Weight feature sequence of each chart was used as model input. Zero padding was implemented to ensure that all charts had the same length of weight records. The padding values would be identified by the masking technique and ignored during model training and evaluation. A bi-directional LSTM (Bi-LSTM) was developed to aggregated information from a weight chart forwards and backwards to detect weight abnormalities. To simulate a prospective setting where future weights are not available, we also developed a one-direction LSTM model in the study. Appropriate variants such as LSTM with conditional random field models were explored but were excluded from further analysis due to lack of performance improvement.
Baseline approaches
The machine learning and deep learning models were compared with three baselines proposed in the literature. The first method was developed by CDC (denoted by CDC), which computed the modified weight-for-age z-scores based on a weight chart and considered weight points outside the range of [-5,8] normal. The second method was a computerized approach developed by Children’s Hospital of Philadelphia (denoted by CHOP). The method compared standard deviations of weight points against a weighted moving average in the chart to identify abnormal points that had significant deviation between recorded and expected values. We re-coded the algorithm based on the supplement code from the publication. Two error types identified by the CHOP method including 'duplicate' measurements on the same day and 'carried forward' weights within 90 days of prior measurement, were allowed and considered ‘normal’ in our study. The third method was a regression approach developed in our earlier study (denoted by REG), which modeled weight trend based on age, sex, previous weight values, and time from previous weight points to determine if a weight point was an outlier. It is worth noting that the CDC method identified weight abnormality based on the current weight point and its immediate previous one, while the CHOP and REG methods used all weight points in a chart.

Experimental setup
A stratified random sampling was performed based on individual subjects to split the MAIN dataset into two parts, 70% for training and 30% for evaluation. Ten-fold cross-validation was utilized to train the machine learning and deep learning models, where grid search parameterization was applied to optimize hyper-parameters including 1) cost parameters for L1- and L2-normalized LR, SVM-L, SVM-P and SVM-R (screened from 1e-6 to 1e6); 2) minimum number of observations in a node (3, 5, 10, and 20) and complexity parameters (screened from 1e-6 to 1e3, 0.3, 0.5 and 0.8) for DT; 3) number of trees (screened from 2^6 to 2^11) and minimum number of observations in a node (3, 5, 10, 15, 25, 40 and 50) for RFs; 4) optimal degree for SVM-P (2 and 3); 5) parameter γ for SVM-R (screened from 2^{-8} to 2^{-2}); 6) number of neurons (10, 15 and 20) and activation functions (rectified linear units [ReLU] and hyperbolic tangent [tanh]) for aNNs; 7) number of neurons (screened at 50 increments from 50 to 200) for LSTM and Bi-LSTM, and 8) learning rates for aNN, LSTM, and Bi-LSTM (screened from 1e-4 to 1e-2, 2e-4 and 5e-4). Stratified down-sampling was integrated into cross-validation to improve class imbalance. The machine learning and deep learning classifiers were implemented with R or Python.

Generalizability validation
To evaluate system generalizability, a separate set of 223,725 weight points were extracted for 7,190 patients in the CCHMC Discover Together Biobank. The data were collected as part of a larger study of the Electronic Medical Records and Genomics network. The dataset was processed using the same procedure as described above. Twenty percent of the charts were randomly selected and annotated by two study team members (Lei Liu and Dr. Ni) specialized in clinical informatics (denoted by the eMERGE dataset). The best-performing model as identified in our earlier experiments was trained on the full MAIN dataset and validated on the annotated eMERGE data. The results were compared with those generated from the baseline methods for model comparison.

Evaluation measures
We adopted the area under the ROC curve (AUC) as the primary measure and reported positive predictive value (PPV), sensitivity (SEN), negative predictive value (NPV), specificity (SPEC) when SEN reached 90% (a level required for production). To identify its limitations, we also performed an error analysis for the best-performing model on the MAIN test set, where patient charts with false positive or false negative predictions were visualized and inspected manually to identify potential causes of system errors.

Results
Descriptive statistics of the datasets
The summary of the annotation outcomes on the MAIN dataset (15,000 patient charts with 260,912 weight points) is presented in Table 1. We received a total of 775,670 annotation records. One hundred and forty-six records from 142 patient charts (0.95%; categories 3-4 in Table 1) contained display error and incomplete annotation and were excluded from analysis. The IRA between experts and the scoring-based outcome was substantial (Fleiss’ Kappa = 0.644, p-value <0.05). During data quality inspection we further excluded 14 charts (0.09%) due to clear abnormal weight values (i.e., LMS-based z-score ≥100), resulting in a set of 257,989 weight points from 14,844 patient charts. The abnormality rate of the dataset was 0.60% (1,549 abnormal weight values in 1,412 patient charts). After stratified sampling the training set contained 181,008 weight points from 10,391 charts, and the test set had 76,981 weight points from 4,453 charts. No missing values were presented in the training or test set. In the eMERGE dataset 215,736 weight points from 6,049 patients met inclusion criteria. We randomly selected 20% of the charts for annotation, resulting in a validation set of 44,747 weight points (1,209 charts) with an abnormality rate of 0.61%.

Predictive performance on the MAIN dataset

Figure 3 summarizes the performance of different machine learning models and baselines, where the detailed results are presented in Table 2. All machine learning and deep learning models achieved significantly better AUCs over the baseline approaches (p-value <0.05). Among the machine learning models, Bi-LSTM achieved the best performance, with an AUC of 0.996/0.989 on the training/test data. It also achieved the best PPV and SPEC when SEN was adjusted to ≥90%. The improvements of Bi-LSTM over the other models were statistically significant at 0.05 level. RF achieved the second-best performance, followed by aNN, SVM-R, and LSTM.

Predictive performance on the eMERGE dataset
To assess its generalizability, the Bi-LSTM model optimized on the full MAIN dataset was compared with the baseline approaches on the eMERGE dataset (Table 3). We presented results with three probability thresholds: 1) the natural threshold (0.5), 2) the threshold when Bi-LSTM reached 90% SEN on the MAIN dataset (0.026), and 3) the threshold when Bi-LSTM reached 90% SEN on the eMERGE dataset (0.0014). Again, Bi-LSTM achieved significantly better performance than the baselines (p-value <0.05). Its AUC (0.989) was close to that achieved on the MAIN dataset (0.996/0.989 on training/testing). When using the probability threshold estimated by the MAIN dataset, the model had a SEN of 63.60% and a PPV of 68.65%. To yield a SEN of 90% on the eMERGE dataset, the system required a substantially lower threshold.

Error analysis
By adjusting SEN to 90.11%, the optimized Bi-LSTM model achieved a PPV of 35.91% on the MAIN test set, resulting in 764 false positive (in 617 charts) and 47 false negative predictions (in 44 charts). We performed an error analysis on these patient charts to identify potential causes of error. Table 4 summarizes the error categories and the example charts are visualized in Figure 4.

Discussion
In this study we developed an AWAD to analyze patient weight charts and detect abnormal values from a pediatric population and setting. Compared with the error detection methods proposed in literature, the machine learning-based approaches demonstrated significantly better detection capacity (Table 2). The finding illustrates the advantage of machine learning technologies over knowledge-driven rules by learning latent patterns from the data. In particular, the deep learning-based Bi-LSTM achieved excellent performance and its improvements over the other classifiers were statistically significant (p-value <0.05). The PPV (35.91%) and SEN (90.11%) achieved by Bi-LSTM on the test set suggested that when using AWAD, a researcher could capture over 90% of abnormal weight values by reviewing only 1.56% of the data. Nevertheless, the one direction LSTM did not show improved performance over traditional classifiers such as RF, aNN and SVM-R, suggesting that the advantage gained by bi-LSTM was the aggregated information from future weight points. The similar performance of Bi-LSTM on the eMERGE dataset confirmed its improvements over the literature methods and validated its generalizability (Table 3). The results also suggested that different probability thresholds would be needed to balance sensitivity and specificity on different datasets.

The developed algorithms and findings could have potential for a significant impact on both research and clinical care. For instance, the Bi-LSTM approach can be used to facilitate data cleaning and improve data quality for secondary analysis (e.g., EHR-based phenotyping as conducted by the eMERGE network). Its PPV and SEN (35.91%/90.11%) suggest potential for more than 98% screening effort reduction in weight abnormality detection. In practice, the abnormality predictions could be enumerated with an empirical probability threshold to balance sensitivity and specificity. On the other hand, the developed system can be implemented in prospective settings to improve healthcare delivery. For example, weight-based medication orders are created based on the most recent weight point in EHRs. By predicting and visualizing abnormality predictions on a weight chart, additional review and timely correction could be made to mitigate effects of entry errors on patient safety. Even though Bi-LSTM is not directly applicable due to unavailability of future weight information, the high performance achieved by the second-best RF (0.961/0.961 AUCs on the MAIN training/test sets) still assures the effectiveness of our application.

Error analysis, limitations and future work
The error analysis on the Bi-LSTM uncovered several areas of improvement. Over 25% of false positives (category 1 in Table 4a) were due to weight fluctuation in measurements within a very short time period (48 hours). Similarly, a large portion of errors (category 4) were caused by different tolerance to change between the annotations and model predictions when weight values were small, particularly at younger ages. We hypothesized that the annotators could have different tolerance of weight variation in a short time period and on low-weight points such that the model captured a “compromised” tolerance that optimized the predictive performance. This issue could potentially be addressed when we perform the study in prospective settings, where the weight abnormalities collected are true weight errors. In addition, the model often labeled large weight changes as abnormal (category 2), which however, could be weight gain or weight loss caused by factors such as health conditions, medication effects, and changes in living environment. Enriching the feature set with more comprehensive patient information (e.g., medical history, medication use) may contribute to better performance, and should be explored in future studies. Finally, 23% of errors (category 3) were due to lack of information because the weight point was the first or last one in a chart. The finding revealed a major limitation of data-driven technologies and incorporating knowledge-based rules might help mitigate this issue. For false negatives, approximately 50% of errors (category 1 in Table 4b) were caused by a pattern when there was a large weight change between two adjacent measures with a long time interval. The errors might be caused by insufficient documentation between ages and will be further investigated in the future. The other causes (categories 2-4) were similar to those from false positives. Few errors were caused by successive abnormal weight points (category 5), which could potentially be addressed by data post-processing (e.g., if an abnormal point is detected, any adjacent points with close weight and age are classified as abnormal).

While this study makes an important contribution to advancing methods for weight abnormality detection, there are limitations to be considered. First, the analysis excluded weight measures before age two that could have more complex weight changing patterns. Additional development and evaluation are therefore required for this age group. Likewise, the system performance is based on data from a single pediatric institution. Built upon the work, a web-service-based AWAD has been developed to analyze weight charts, identify abnormal weight values, and visualize weight trends and errors. Once the web-service-based AWAD has been deployed, we anticipate assessing its generalizability with more diverse patient populations and institutions. It is worth noting that machine learning techniques support retraining the model when new data become available. As such, if generalizability is not satisfactory, appropriate active learning approaches could be implemented to re-tune the system automatically as new data become available7. Finally, this study was restricted to retrospective data. Once reliability and generalizability are established, the AWAD
can be transferred to a production environment to adequately assess its usability and utility with prospective data in future studies.

Conclusions
By utilizing machine learning technologies, we developed an automated approach, AWAD, to analyze pediatric weight charts and identify abnormal weight values. In two reference-standard based evaluation of real-world clinical data, the machine learning models showed good capacity for detecting weight abnormalities and they significantly outperformed the methods proposed in literature. The best-performing model (Bi-LSTM) achieved AUCs ≥0.989 across the two datasets, with good PPVs when sensitivities were adjusted to ≥90%. Given its high performance in this stage of development, we hypothesize that the AWAD, when fully deployed, holds great potential to facilitate clinical research and healthcare delivery that rely on accurate and reliable weight measures.

Acknowledgements
We thank Mr. Milan Parikh at University of Cincinnati for his effort on reviewing and documenting the scripts of the baseline approaches. We also thank the eMERGE network for providing the weight dataset. Particular thanks go to PJ Van Camp who developed the visual annotation tool and managed the annotation process.

Abstract

Numerous studies have shown that a person’s health status is closely related to their socioeconomic status. It is evident that incorporating socioeconomic data associated with a patient’s geographic area of residence into clinical datasets will promote medical research. However, most socioeconomic variables are unique in combination and are affiliated with small geographical regions (e.g., census tracts) that are often associated with less than 20,000 people. Thus, sharing such tract-level data can violate the Safe Harbor implementation of de-identification under the Health Insurance Portability and Accountability Act of 1996 (HIPAA). In this paper, we introduce a constraint-based k-means clustering approach to generate census tract-level socioeconomic data that is de-identification compliant. Our experimental analysis with data from the American Community Survey illustrates that the approach generates a protected dataset with high similarity to the unaltered values, and achieves a substantially better data utility than the HIPAA Safe Harbor recommendation of 3-digit ZIP code.

Introduction

Numerous studies have shown that a person’s health status is associated with their socioeconomic status (SES)1,4. For instance, in some populations, people with higher education attainment, larger income, and more prestigious occupations enjoy better health and longer lives5. By contrast, a lower level of socioeconomic status is associated with an increased risk of chronic disorders, such as cardiovascular disease6,8 and mortality9. It is evident that incorporating a patient’s SES information into clinical records, and research datasets, will promote more meaningful, as well as potentially actionable, medical investigations10.

However, in many situations, a patient’s SES information is not readily available11. In lieu of this information, it is possible to estimate a person’s SES level based on the neighborhood in which they live. Notably, the SES for a small geographic area, in the form of a U.S. Census tract, can be derived from the 5-year estimates of the American Community Survey (ACS)12 - information that is publicly available online. For the purposes of our analysis, we prioritized the set of census derived variables from Brokamp et al.13. An example is shown in Table 1. The socioeconomic factors in the dataset include: 1) assisted income, 2) high school education level, 3) median household income, 4) lacking health insurance level, 5) poverty level, 6) vacant housing rate, and 7) a deprivation index, which is a single value assigned to the census tract that provides a numerical summarization of the area’s overall deprivation. The deprivation index ranges from 0 to 1, with a higher value indicating a larger level of SES hardship. It was created based on a principal component analysis (PCA)14 on the six aforementioned socioeconomic factors in the ACS dataset. Throughout this paper, we refer to the six ACS factors and the deprivation index as census tract socioeconomic factors.

It is often the case that electronic health records (EHRs), and affiliated information, are utilized in a de-identified manner, as defined by the Health Insurance Portability and Accountability Act of 1996 (HIPAA). While census tract socioeconomic factors have been relied upon to estimate a patient’s SES in various research studies, such information has not been commonly integrated into de-identified records. One of the primary reasons for such a lack of SES information is that EHR data is often de-identified using the Safe Harbor implementation of the HIPAA de-identification standard. Under Safe Harbor, no geographic information granular than the initial three digits of the ZIP code (or a comparable indicator of geography) may be disclosed if it contains less than 20,000 people15. Census tracts tend to be geographic regions with relatively small populations. Specifically, the population covered by a census tract ranges from 20 to 65,000 people, with an average of 4,000 people. This is problematic because SES data elements are often unique to census tracts. For example, in 2017, only one census tract in the country has a median income of

---

1 Available for download from https://www.census.gov/data/developers/data-sets/acs-5year.html
entities be used to satisfy the Privacy Rule’s determination method requires that every census tract group covers at least 20,000 inhabitants. We achieved this by first clustering all the tracts into small groups, then iteratively merging groups that fail to satisfy the privacy requirements to their most similar group until all groups meet the requirements. We assessed the utility of the de-identified data with five years of ACS socioeconomic datasets. The result suggests that our approach achieves a substantially better data utility than HIPAA Safe Harbor recommended 3-digit ZIP code grouping. We also found that k-means model generates data with the highest overall utility, based on six socioeconomic factors and the composite deprivation index.

Table 1. Examples of six socioeconomic factors derived from the ACS dataset and the deprivation index. The Census Tract FIPS code is an 11-digit number that uniquely identifies each census tract in the United States. Rows 1 and 4 show two census tracts and their population, original SES values before de-identification. Rows 2 and 5 show the de-identification result of the two census tracts based on 3-digit ZIP code grouping. Rows 3 and 6 are the corresponding de-identification result based on our constraint-based clustering (CBC) approach.

Related Work

**HIPAA Safe Harbor**

The U.S. Congress enacted HIPAA to standardize the sharing of health insurance claims, as well as provide common protections for sensitive patient health information from being disclosed without a patient’s consent or acknowledgment. Several years later, the U.S. Department of Health and Human Services (HHS) issued the HIPAA Privacy Rule to further elaborate on privacy requirements. At the same time, HHS created the notion of a de-identified dataset, which corresponds to data that is no longer protected by the regulation, as it does not directly, and is unlikely to indirectly, uniquely identify the corresponding patient. The regulation indicates that two alternative methods can be used to satisfy the Privacy Rule’s de-identification standard: Expert Determination and Safe Harbor. Covered entities (and their business associates) must ensure data is compliant with one of the methods. The Expert Determination method requires that an expert use generally accepted statistical and/or scientific methods to confirm
that the chance a record could be re-identified is very small. Statistical perturbation methods, such as differential privacy\textsuperscript{18}, may provide support to de-identify aggregated geographic data for biomedical research.

By contrast, Safe Harbor provides a more straightforward approach to de-identification. Specifically, it enumerates 18 types of identifiers that must be removed before covered entities (or their business associates) can claim the data is compliant with de-identification. As noted, geographic location is one such type of information. Specifically, all geographic subdivisions smaller than a state must be removed, except for the initial three digits of the ZIP code if combining all ZIP codes with the same three initial digits contains more than 20,000 people. Thus, to devise a method that is compliant with Safe Harbor, it is necessary to ensure that each de-identified record covers multiple census tracts such that the combining census tracts contain more than 20,000 people.

\textit{K-anonymity}

K-anonymity is a privacy protection model designed to ensure data is non-unique\textsuperscript{16}. Specifically, a dataset is \textit{k}-anonymous if each record is indistinguishable from at least \textit{k}-1 other records in the same dataset. One the most popular approaches to achieve \textit{k}-anonymity is through generalization and suppression of data. Generalization replaces a data attribute's actual value with a more general value (or a range of values). Often this is accomplished via the assistance of value generalization hierarchy. Using the ZIP code as an example, it can be seen that 37203 and 37206 can be generalized to 3720\textsuperscript{6}. By contrast, suppression removes an entire attribute (or an outlying record) from the dataset. Achieving \textit{k}-anonymization is known to be an NP-hard problem\textsuperscript{13}, but there are several effective approximation algorithms that have been developed\textsuperscript{19-20}. As we show below, with some modification, these algorithms can be adapted to solve our problem.

\textit{Constraint-based Clustering}

Constraint-based clustering aims to find a clustering for data while satisfying a set of constraints. However, methods developed to date\textsuperscript{21,22} focus on constraints for specific data instances. For instance, a method might include certain \textit{must-link} constraints or \textit{cannot-link} constraints between data points. In our problem, there are no pre-defined constraints for the data points. Rather, the privacy constraints correspond to the clusters themselves.

Generally, the constraint-based optimization task can be modeled as an Integer Linear Programming (ILP)\textsuperscript{3} problem, where the privacy requirements can be addressed as constraints and the goal is to minimize the intra-cluster distance. Unfortunately, our problem is known to be NP-complete and, given the large search space (more than 70,000 census tracts by more than 10,000 clusters), such a program cannot find an optimal solution in a realistic amount of time.

\textbf{Materials and Methods}

In this study, we utilize the 2017 census tract-level deprivation index dataset\textsuperscript{4}. From the ACS data, we also generate four years of census tract-level deprivation index datasets from 2012 to 2015, according to Brokamp et al.\textsuperscript{2}. These four datasets have the same structure as the 2017 dataset. Due to a documentation problem, we did not generate a census tract-level deprivation index dataset for the 2016 ACS data. The 2017 dataset contains 72,943 census tracts, listed by their federal information processing standards (FIPS) ID and corresponding deprivation index, along with six ACS features used to derive the deprivation index. The population of each census tract can be acquired from the U.S. Census Bureau website\textsuperscript{5}. We represent the dataset with six ACS features as a matrix \textit{X}, where \textit{X\textsubscript{i}} represents row \textit{i}, a census tract record, \textit{X\textsubscript{j}} represents the \textit{j}th column, an ACS feature. The deprivation index is denoted by \textit{y}, where \textit{y\textsubscript{i}} represents the deprivation value of census tract \textit{t\textsubscript{i}}. We represent the population of tract \textit{t\textsubscript{i}} as \textit{pop\textsubscript{i}}.

In this section, we first introduce the de-identification pipeline and several clustering methods considered in this investigation. Next, we present the evaluation criteria to select the best clustering methods. As we indicated earlier, the unique linkage between a census tract ID and the values of socioeconomic factors for a census tract may induce the disclosure of a person’s geolocation. We mitigate this risk by changing the mapping between census tract and socioeconomic factor values from \textit{a one-to-one} mapping to \textit{a many-to-one} mapping. This is accomplished by grouping census tracts into clusters based on their similarities and replacing them with their mean socioeconomic factor values for census tracts associated with each cluster. This ensures that, one socioeconomic factor value is guaranteed to

\footnotesize
\begin{itemize}
\end{itemize}

795
correspond to multiple census tracts and, thus, encompasses all of the population in the tracts. To comply with the HIPAA Safe Harbor requirements, each cluster must satisfy the following privacy requirements:

1. Each cluster must contain at least two census tracts. \((\text{MinTract} > 2)\)
2. Each cluster must cover at least 20,000 individuals. \((\text{MinPop} > 20,000)\)

The de-identification pipeline is depicted in Figure 1. Given the dataset with six ACS features, we apply a clustering method. We considered several clustering methods to determine which would be most appropriate for the task at hand. Specifically, we investigated hierarchical models in the form of Agglomerative Clustering\(^2\) and divisive \(k\)-means\(^3\), a density based clustering model DBSCAN\(^4\), the classic \(k\)-means model\(^5\), and a Gaussian Mixture Model\(^6\), which is in effect a generalized \(k\)-means model. Some of these models require certain parameters to be defined by the user, such as the number of clusters in \(k\)-means. To determine an appropriate value for such a setting, we experimentally analyzed a range of values.

We also recognized that certain socioeconomic studies prioritize deprivation over all of the ACS features. As such, we also considered a greedy clustering methodology, that is based solely on the deprivation index (neglecting the six ACS features).

Given that the clustered candidate datasets are not guaranteed to satisfy the privacy requirements, when necessary, we apply a post-processing step to process such clusters to satisfy the \(\text{MinTract}\) and \(\text{MinPop}\) conditions. After completion of this post-processing step, we calculate the new deprivation index, which corresponds to the first principle component of the clustered dataset. We select the best clustering in the evaluation step and output the de-identified census tract-level socioeconomic dataset.

In the following subsections, we will introduce the selected clustering methods, the post-processing algorithm, the evaluation criteria, and a verification experiment with different years of the ACS data.

![Figure 1.](image)

**Figure 1.** The de-identification pipeline for census tract-level socioeconomic dataset.

**Clustering Models**

**Greedy Algorithm**

This clustering approach is based purely on the deprivation index and neglects the ACS features. It initially sorts the deprivation value in ascending order and then groups adjacent tracts into the current cluster (from top to bottom). Once the current cluster has a sufficient number of census tracts to satisfy the privacy requirements (i.e., \(\text{MinTract} > 2\) and \(\text{MinPop} > 20,000\)), this cluster is considered complete. The algorithm then generates a new cluster. This process iterates until all census tracts are clustered. The new deprivation index \(\bar{y}\) and the new ACS features \(\bar{X}\) are then the mean of the corresponding values \(y\) and \(X\) in the cluster. Since the clusters generated by the Greedy algorithm already satisfy the privacy requirements, this algorithm does not require any post-processing.

Unlike the Greedy algorithm, the following approaches focus on \(X\) as the dataset to be clustered.

**Hierarchical (Agglomerative) Clustering**

This algorithm begins with each record \(X_i\) as a singleton cluster. Next, the algorithm iteratively merges the two most similar clusters until there is only one cluster (i.e., the entire dataset) left. The similarity is measured as the sum of squared distances of all census tracts of pairs of clusters. After clustering, the algorithm walks down the generated hierarchical tree from top to bottom to find all the relevant clusters. Specifically, a node is a cluster of interest if, and only if, 1) the node satisfies the two privacy requirements and 2) at least one of its child nodes fails to satisfy the requirements. Note that this approach does not require any post-processing. The new census tract record \(\bar{X}_i\) is the mean of census tracts in one cluster and the new deprivation index \(\bar{y}\) is computed based on \(\bar{X}\).
**Divisive k-means**

This is a top-down hierarchical clustering approach. We initiate the method by assigning all census tracts to a single cluster. We then iteratively select the divideable cluster with the most population from the pool and split it into two new clusters using 2-means. The algorithm stops when there are no clusters can be split.

**K-means**

In this approach, we use the classic k-means to cluster the dataset into k clusters. k-means aims to make the intra-cluster points as similar as possible through an Expectation-Maximization (EM) process. In the E-step, the algorithm assigns points to their nearest cluster, according to the Euclidean distance from the point to the cluster centroid. In the M-step, the algorithm updates the centroids of each cluster. This process iterates until the system is stable (or until a maximum number of iterations is reached). To maximize the similarity between the clustering and the original data, the size of each cluster should be as small as possible, which implies that the choice of k should be relatively large. In our experiments, we vary k from 14,000 to 70,000, with a step size of 4,000. It is possible that some clusters generated by k-means fail to meet the privacy requirements, such that we perform post-processing after clustering.

**DBSCAN**

This is a density-based clustering model that assumes that a cluster should be determined by the density of data distribution. DBSCAN measures the density and extends a cluster based on reachability. It uses neighborhood parameters r (radius of a neighborhood) and MinPts (minimum points within a distance of r) to describe the reachability. Based on the data, we plot the k-distance graph, and set MinPts to 3 and r to 0.5. DBSCAN returns a clustering with noise (data points do not belong to any clusters). To ensure the clustering result meets the requirements, we treat each noise point as a new cluster and perform post-processing accordingly.

**Gaussian Mixture Model**

This is a probabilistic model that assumes data points are generated and sampled from a mixture of k Gaussians with unknown parameters (means and covariance of Gaussians). The cluster of each data point is determined by the posterior probability of mixture components given the point. GMM can be solved by an iterative EM algorithm. The E-step calculates the posterior probability of the data points (i.e., census tracts) belonging to a cluster based on the parameters of the latest iteration. In the M-step, the algorithm updates parameters using maximum likelihood estimation given current clustering. In our experimental analysis, we vary the number of components (k) from 4,000 to 8,000.

**Post-Processing**

To post-process a clustering, we iteratively modify the clusters that fail the privacy requirements until no such clusters are left. In each iteration, the algorithm selects the cluster with the smallest population and reassigns the corresponding census tracts to their nearest cluster, according to the Euclidean distance between tracts and cluster centroids. The algorithm then updates all of the clusters' centroids. This process iterates until no clusters require post-processing.

**Evaluation Criteria**

Finally, we select the model that is most similar to the original dataset. We use KL-divergence to measure the similarity between the de-identified dataset and the original data. KL-divergence is an information-theoretic approach that measures the statistical distance between two distributions. Specifically, given two probability distribution P and Q on the same probability space, X, where P is the true (i.e., observed) distribution and Q is the approximated (i.e., modeled) distribution, the KL-divergence from Q to P, $D_{KL}(P||Q)$, is defined as the following equation:

$$D_{KL}(P||Q) = \sum_{x \in X} P(x) \log \left( \frac{Q(x)}{P(x)} \right)$$

The divergence score is non-negative, and a score of 0 indicates the two distributions are identical, where a higher divergence score suggests a larger divergence from Q to P. It should be recognized that, unlike Jenson Shannon (JS) divergence, the KL-divergence is an asymmetric distance measure, such that $D_{KL}(P||Q) \neq D_{KL}(Q||P)$. The intuition is that when the true probability $p$ for an event $x$ is large, but the approximated probability $q$ is small, there is a larger divergence. By contrast, when the approximated probability $q$ is large but the true probability $p$ is small, the divergence is not as large as the previous case.
We adopt KL-divergence instead of other symmetric measures because it is a natural fit for our problem. The original dataset is the true distribution of the data, and the de-identified protected datasets can be treated as the approximated distributions. We are only concerned about the projection from the original into the protected space, instead of the inversion. Thus, we compute the KL-divergence for all features and compare the models in two scores: the KL-divergence of the deprivation index and the sum of the KL-divergence of all features. These two scores represent two different usage scenarios. That is, when a researcher is more interested in using only one feature to capture the entirety of community deprivation level, then the deprivation index divergence score should drive which clustering to select. And, when a researcher is concerned about the overall data utility, then overall KL-divergence should serve the selection criterion.

**Experimental design**

We apply our de-identification pipeline on the 2017 census tract-level deprivation index dataset and select the clustering model that yields the protected clustering with the lowest KL-divergence. Given that this process is based on one year’s data only and that this selection may suffer from certain bias, we assess the generalizability of our model selection. To do so, we run the same experiment on four additional census tract-level datasets, one from each of the years between 2012 and 2015.

**Results**

Figure 2 presents the KL-divergence scores of the protected datasets generated by the six clustering models. The y-axis represents the overall KL-divergence score of seven socioeconomic factors and the x-axis is the divergence score of the deprivation index. The lowest KL-divergence achieved by the Greedy algorithm (for the deprivation index) was only 0.018, but the overall divergence is substantially higher than the other models (4141.05). The k-means model achieved the smallest overall KL-divergence (388.96) and the second smallest KL-divergence for the deprivation index (7.92). We do not show the DBSCAN model in this figure because the divergence score is too high (overall 13136, deprivation index 1667). This method was discarded from further consideration given its obvious inferiority to the other clustering methods.

![Figure 2](image.png)

**Figure 2.** The KL-divergence of the protected datasets generated by the various clustering models. The y-axis represents the sum divergence score of seven socioeconomic features, whereas the x-axis is the KL-divergence score of the deprivation index. The six clustering models are: Greedy, hierarchical clustering (Agg), divisive k-means (DivKM), k-means, Gaussian mixture model (GMM), and 3-digit ZIP code (ZIP3). The results for DBSCAN model not shown as it is substantially higher in divergence than the other methods.

In addition, for comparison purposes, based on HIPAA Safe Harbor recommendation, we grouped the census tracts according to their 3-digit ZIP code, which we refer to as the ZIP3 de-identified dataset. It is evident that except for
DBSCAN, the ZIP3 model exhibits the highest overall divergence score (1414.27) and the highest deprivation index divergence score (414.11).

**Figure 3.** The change in the KL-divergence as a function of the initial $k$ in the $k$-means clustering process. The orange line corresponds to the sum of KL-divergence of the seven socioeconomic features. The purple line corresponds to the KL-divergence of the deprivation index.
Figure 4. The overall KL-divergence of the protected datasets generated by four clustering methods for the socioeconomic dataset associated with each of the years between 2012 and 2015. The four clustering models depicted correspond to hierarchical clustering (Agg), divisive $k$-means (DivKM), $k$-means, and the Gaussian mixture model (GMM).

Given the strong performance of the $k$-means clustering, we performed an in-depth analysis of this method. The $k$-means model in Figure 2 was initialized with 70,000 clusters. After post-processing, the model yields 10,429 clusters, with a median cluster size (the number of census tracts in one cluster) of 7. The change in the KL-divergence as a function of the initial $k$ is shown in Figure 3. It can be seen that the overall KL-divergence (shown in orange) drops quickly from an initial $k$ of 14,000 to 50,000. After this point, the change in the overall KL-divergence is relatively stable, but KL-divergence is minimized at a $k$ of 70,000, with a score of 390.72. The deprivation index line (shown in purple) shows similar behavior; however, the lowest deprivation divergence happens at a $k$ of 58,000, with a deprivation index divergence score of 7.81.

To assess the robustness of the clustering with the 2017 data, we compare the clustering models on the ACS datasets from each of the four years from 2012 through 2015. Figure 4 shows the overall KL-divergence for the projected datasets generated by the four clustering models in four years of data. It can be seen that the $k$-means model consistently achieves the smallest overall KL-divergence in all four years, followed by the hierarchical clustering, Gaussian Mixture Model, and the Divisive $k$-means.

Figure 5 shows the KL-divergence for the deprivation index for 2012 through 2015. In this situation, the Greedy algorithm achieves the lowest deprivation index KL-divergence (below 0.3) every year. The KL-divergence for the $k$-means model is around 8, while the other models all have scores greater than 10. Save for the Greedy algorithm, it can be seen that the $k$-means method generates the protected dataset with the lowest overall KL-divergence and the lowest deprivation index KL-divergence.

Discussion and Conclusions

This work introduced a pipeline to generate a geography-influenced socioeconomic data that maximizes its utility while remaining compliant with the de-identification requirements of the HIPAA Safe Harbor implementation standard. The pipeline consists of three parts: 1) clustering, 2) post-processing, and 3) evaluation. The pipeline can
automatically generate the protected dataset from a set of clustering models given predefined privacy requirements. We assessed the utility of the de-identification process with five years of ACS socioeconomic datasets. The result suggests that a $k$-means model generates data with the highest overall utility and the second-highest utility for the deprivation index. Notably, the de-identified dataset generated by the $k$-means model is substantially more similar to the original data than that achieved by grouping by the 3-digit ZIP code as suggested by the HIPAA Safe Harbor policy. We further showed that a simple greedy algorithm, which clusters data based on only the deprivation index, leads to the best utility for the deprivation index, but at a significant cost to the utility of other socioeconomic features.

For $k$-means clustering, when selecting a value of $k$, it is evident that larger values do not necessarily lead to better overall utility. Our empirical results illustrated that this was true both for the overall KL-divergence (for all socioeconomic features), as well as when the focus is on a single value (for the deprivation index). This suggests that one needs to consider a wide range of values when selecting the initial number of clusters $k$.

Finally, there are certain limitations to this work, which we believe serve as opportunities for future research. First, while KL-divergence is an information theoretic measure of the similarity of probability distributions, the values associated with census tract-level socioeconomic factors are not probability distributions. Second, though we evaluate data utility with a divergence score, this only illustrates similarity of the distribution of the data and does not indicate how the data changes influence any associations that may be inherent in the data.

Abstract

Documentation burden continues to be a critical issue in the adoption of comprehensive electronic health record systems. This case study demonstrates how the i-PARIHS framework can be applied to support the implementation of interventions in reducing documentation and EHR-related burden in a mental health context. As part of pre-adoption implementation activities for Speech Recognition Technology (SRT), a cross-sectional survey was conducted with physicians, residents, and fellows at an academic mental health hospital to explore their perceptions on SRT. Open-ended responses and follow-up interviews explored challenges and concerns on using SRT in practice. Through an analysis using the i-PARIHS framework, key considerations were mapped across the four components of the framework. This study demonstrates the value of applying well-established implementation frameworks, such as the i-PARIHS framework, in mitigating challenges related to documentation burden. Future studies should explore how implementation frameworks can be systematically embedded in addressing EHR-related burden.

Introduction

As electronic health record (EHR) systems with advanced features continue to be adopted worldwide1, unintended consequences related to documentation burden and potentially clinician burnout are increasingly reported2-4. Studies examining clinician burnout have suggested that physicians spend approximately double the time on documentation when compared to time dedicated to direct patient care5. These challenges are not unique to a profession or clinical domain, and are said to jeopardize patient care and safety6. Recently, the National Academies of Sciences, Engineering, and Medicine3 have recognized this challenge in their latest report on clinician burnout and healthcare professional well-being. Thus, there is a need to address these challenges in a timely manner.

As part of our organization’s Physician Engagement Strategy, we conducted a baseline survey with physicians to examine their level of satisfaction and EHR-related burnout7. Of the 208 respondents, about one in four physicians reported experiencing burnout related to use of the EHR7. Given that documentation burden is a well-established factor of burnout8, we decided to implement speech recognition technology (SRT) to mitigate documentation burden and clinician burnout7. SRT allows clinicians to directly dictate into the EHR system and is expected to enhance quality of care through reduced turnaround time and more accurate reports9-11. While the use of SRT mostly originated in radiology, it is increasingly adopted across primary care and internal medicine disciplines12. With the narrative documentation style in psychiatry, we hypothesize that SRT will reduce documentation time and increase efficiency with using the EHR. However, there remains a gap in evidence and guidance on the implementation of SRT in mental health settings. Our organization has previously rolled out a local, outdated version of SRT to a small group of physicians, however, it was not optimized and had low adoption levels over time13,14. Therefore, it was an organizational priority to explore a more robust implementation approach for the upcoming site-wide implementation of the improved SRT. The improved SRT solution is a cloud-based solution that promises improved accuracy of the dictations as well as the use of a mobile app solution to dictate into the SRT.

The i-PARIHS Framework

Implementation science frameworks outline important considerations required for successful implementation of innovations15. While many theories, frameworks, and models have populated this space over time, these tools have not been fully utilized to guide the implementation of health IT and address the contemporary issues in health care16,17. To our knowledge, there have not been studies that have explored the role of implementation science frameworks for planning, developing, implementing, and evaluating interventions that aim to address EHR-related burden in the
mental health setting. Hence, there is an opportunity to leverage this source of knowledge to address issues related to documentation burden.

The integrated Promoting Action on Research Implementation in Health Services (i-PARIHS) framework aims to guide usage of evidence in implementing healthcare technologies. Building on the original PARIHS framework, this revised iteration focuses on achieving the project’s implementation goals through interactions that occur across the technology, environment, and the end-users. In particular, the framework outlines four essential components (facilitation, innovation, recipients, context) required for successful implementation (Table 1). The i-PARIHS framework has been used to support implementations of digital health technologies across primary care, acute care, and behavioural health.

Objectives

In this case study, we applied the i-PARIHS framework to identify key considerations that are associated with implementing SRT in reducing documentation burden in mental health settings. In particular, we explore the following research question: What are the challenges and concerns that hinder the adoption of SRT as they pertain to each of the components of the i-PARIHS framework? While these insights were used to inform our implementation plan, we also aim to demonstrate the value of implementation frameworks in navigating complex issues such as documentation burden and identify any barriers in applying implementation frameworks, models and theories to these issues in a meaningful manner.

Methods

In order to apply the constructs of the i-PARIHS framework to identify key considerations for implementing SRT in mental health settings, a cross-sectional study design was used to gain insights into the needs, experiences, and perceptions towards SRT.

Settings and Participants

The study was conducted at a large academic and teaching mental health hospital located in Toronto, Ontario with a comprehensive EHR system. The hospital has obtained the highest level of adoption (Stage 7) on the HIMSS Electronic Medical Record Adoption Model (EMRAM). Prior to the roll-out of the improved version of SRT, some physicians had access to an earlier version of the SRT. Physicians without access to SRT either typed directly into the EHR system or used a back-end transcription service.

Physicians, residents, and clinical fellows were eligible to participate in this project if they held a full-time or part-time role at the organization as of January 2020 and completed documentation in the EHR system. Physicians who held a casual status were considered to not have sufficient experience with the EHR and were not eligible to participate in this study.

Data Collection

An online REDCap survey was developed using questions from existing literature, the SRT vendor, and our previous work to explore the innovation construct of the i-PARIHS. Participants were asked to indicate their previous experience with SRT at the organization and perceptions towards SRT on a 5-point Likert scale (Table 4). To build on the survey findings and explore the other constructs of the i-PARIHS and its relevant content (e.g., functionality, usability of the innovation), participants had the opportunity to provide additional thoughts, challenges, and concerns through open-ended responses and/or a follow-up interview. The survey was initially sent out in March 2020. Due to the COVID-19 pandemic, there was an organizational pause on all projects shortly after the first round of invitations. Data collection for the survey resumed in May 2020 and was completed in June 2020.
Follow-up interviews were conducted virtually by a member of the project team between April 2020 and September 2020 using a qualitative descriptive approach. The semi-structured interview guide (Table 2) queried their experience, perceptions, and concerns with using SRT. Like previous studies of this nature, interviews were not audio-recorded but notes were taken down by the interviewer. Participants of the follow-up interview were entered into a draw for three gift cards worth $25 CAD.

</tr>
<tr>
<td>7. If you were to switch to [SRT name], how can we better support you?</td>
</tr>
</tbody>
</table>

Data Analysis

The i-PARIHS framework guided our data analysis. Descriptive statistics (e.g., means, standard deviation) were used to characterize the sample and perceptions towards SRT. Differences in ratings amongst physicians with/without previous experience with SRT were determined using Kruskal-Wallis tests in SPSS Version 25. Deductive thematic analysis was conducted in NVivo 12 using the four constructs of the i-PARIHS framework where a single researcher coded the data. Investigator triangulation (including feedback from on-site experience) was used to enhance the trustworthiness of the qualitative findings. Since the survey was anonymous, there was no direct comparison between interview participants and their survey responses.

Ethical Considerations

Ethical approval was obtained through the quality improvement project review board at the Centre for Addiction and Mental Health. Numerous measures were taken to ensure the privacy and confidentiality of participants in this project. The survey responses were collected in an anonymous manner and the voluntary nature of participating in this project was reiterated in the email invitation. All survey and interview data is stored on the organizational secure server. Moreover, for the interviews, only data deemed relevant to the use and implementation of the SRT was coded and included in the data analysis. The interview data was also de-identified prior to the analysis.

Results

Seventy-eight individuals responded to the survey and 16 individuals completed the follow-up interview (Table 3). While respondents came from various clinical divisions, many respondents were staff physicians with outpatient duties. Less than half the respondents (n = 28) reported having previous experience with SRT. Findings from each i-PARIHS construct are discussed below.

</tbody>
</table>

The open-ended responses and follow-up interviews (Table 5) provided further insight into the perceptions observed in the survey. Many physicians without SRT experience frequently based their perceptions on testimonials voiced by other physicians. For example, in speaking about the accuracy of the dictations, a physician without experience (Quote 1A) was skeptical about the tool as they saw lukewarm success in their colleagues with using SRT. On the other hand, physicians with prior experience (Quote 1B) often cited their negative experience with previous versions of SRT, which generated reluctance towards using SRT. Thus, previous experience and testimonials from other physicians largely dictated their knowledge of SRT.

Some physicians also echoed specific challenges related to the features and functionalities of the SRT technology itself. One physician (Quote 2A) highlighted issues around the SRT recognizing homonyms and the added effort that is required to correct the mistakes. Alongside other issues such as dictating specific terminologies and formats (e.g., dates) (Quote 2B), these inconsistencies may lead to an unclear and poorly presented note for other clinicians.
Facilitation

In terms of facilitation, many respondents indicated that their lack of knowledge on the features of the SRT and how it should be used greatly hindered their decision to adopt SRT. For example, a physician (Quote 3A) suggested that addressing reluctance to change requires providing a tailored overview of the features of SRT, ideally in relation to how it may be used in practice. This may be accomplished through peer education where experienced users (e.g., super-users) of the system demonstrate how SRT can be used to perform and support the daily tasks of physicians (Quote 3B). As a result, ensuring physicians are aware of the features and value-add of adopting the SRT for their practice is critical to securing buy-in.

In terms of training and education, there were concerns around its content and delivery. Physicians had different preferred learning styles and constraints (e.g., time). For example, while some physicians preferred more independent and hands-off approaches for learning SRT (Quote 4A), others wanted more individualized training and support with mastering the skills of SRT (Quote 4B). There was also interest in a hybrid ‘curriculum’ approach that begins with self-learning of the basic features followed by training of more advanced features of the tool (Quote 4C). Several physicians (e.g., Quote 4D) also reiterated the value of ongoing technical and training support post-implementation. In summary, careful and continuous engagement with physicians is essential for obtaining the necessary buy-in for adoption and providing the required skills to use the solution.

Recipient

For the recipient construct, there was discussion on whether SRT is conducive to current practice workflows. Some physicians complete their documentation concurrently with the patient present and the additional layer of SRT can hinder the current workflow, and as one physician mentioned, may make the interaction uncomfortable for the patient (Quote 5A). Several additional considerations for implementing its usage with the organization’s EHR system were observed. For example, one physician highlighted how the setup of emergency department (ED) workflows at the organization would not be conducive to the use of SRT. In particular, the ED multidisciplinary assessment, which contains multiple tabs and many fields on each page, would hinder the use of SRT with more ‘clicks’ (Quote 6A). Other physicians also mentioned how SRT would conflict with their current habits and practices such as ‘copy-and-paste’ practices for documentation (Quote 6B). Thus, the individual practices, habits, and workflows of physicians and the environment can be a critical consideration in integrating SRT into practice.

Context

In terms of context, there was a focus on organizational factors and the setup of the environment. For example, many physicians complete their documentation at various locations, including at home, and some physicians question the equipment and setup needed to use SRT at each location (Quote 7A). Physicians also indicated that some of the current spaces are not set up for dictation of clinical notes. For example, from a privacy and confidentiality perspective, a physician (Quote 7B) highlighted the lack of quiet spaces to complete their documentation in between patients. This challenge was more prominent in certain environments, such as the emergency department.

Table 5. Sample quotes identified for each construct of the i-PARIHS framework  

<table>

| Innovation         | Understanding of SRT is based on experience and testimonials | Quote 1A: “see my colleagues constantly editing the note manually when they dictate using [SRT name]” (Survey Respondent 69)  
Quote 1B: “Speech recognition software DOES NOT RECOGNIZE MY VOICE ever (including statements such as ’Hello, my name is...’), even with [SRT name].”  
(Survey Respondent 9) |
|                    | Specific challenges and concerns around the SRT | Quote 2A: “Certain words, homonyms (phrases that sound the same), the context of [SRT name] struggles to differentiate between the words. Constantly misidentify would have to put down mic, use mouse, edit the word, and back and forth. Not the same as human context in understanding.” (Interview Participant 4) |
| Facilitation                  | Understanding the features and value of SRT | **Quote 2B:** “... some challenge is retraining with your voice, issues, some glitches with current one, date format, patient names, numerics and abbreviations, becomes a pain and leave, reread the dictation and there’s some silliness.” (Interview Participant 11) |
|                             |                                              | **Quote 3A:** “Change is always difficult, used to doing workflow one way, so there would be some kind of learning curve in trying to incorporate. Find it hard to say without knowing how it functions, lots of hesitancy with not knowing what [SRT name] is.” (Interview Participant 12) |
|                             |                                              | **Quote 3B:** “It would be great if we can get a physician who is proficient with using [SRT name] to demonstrate the benefits and usage of [SRT name]. Some are concerned with [the] learning curve so it can be hard to sell. However, if we can see first-hand how it is used, that would be great.” (Interview Participant 6) |
| Education and Training      | Training requirements for adopting SRT      | **Quote 4A:** “Personally, I would like videos that they can go through at their own speed. Follow up with someone if there is troubles (helpline)” (Interview Participant 13) |
|                             |                                               | **Quote 4B:** “Make it really easy to switch, good to have tutorials and not just have online teaching, can sit down and work with someone on it [the training] either 1 on 1 or [in] small groups” (Interview Participant 12) |
|                             |                                               | **Quote 4C:** “The level of familiarity varies quite a bit with using technology and [SRT name]. It would be great to have self-learning because it is quite intuitive... Follow up then with advanced features.” (Interview Participant 6) |
|                             |                                               | **Quote 4D:** “I think I had someone spend 15-20 minutes with me when I first got it and when you know someone you can call asking for help and that was super helpful. Clear instructions on who to call and need to know exactly who to call.” (Interview Participant 16) |
| Recipient                   | Impact on physician’s workflow for delivering care | **Quote 5A:** “documenting in a room, kind of awkward while in room with patient, [it] would be weird” (Interview Participant 4) |
| Impact on physician’s       | Impact on physician’s workflow for documenting in the EHR | **Quote 6A:** “[SRT name] [is] not good for multidisciplinary assessment [with] so many tabs. It causes disruptions and lots of time to click than just dictation” (Interview Participant 6) |
|                             |                                               | **Quote 6B:** “For purpose of documentation, need to copy and paste a lot, a lot of this information has already been made available so copy and pasting is a lot faster and easier” (Interview Participant 2) |
| Context                     | Setup of required resources for SRT          | **Quote 7A:** “Communicating with IT around installing on different computers, microphone issues, shared offices, etc. I was unable to coordinate fixing the technical issues” (Survey Respondent 23) |
|                             |                                               | **Quote 7B:** “… if I have to dictate, then I would probably go see all my patients, [take] notes and then dictate at end of day. If on the run, [in a] nursing station with 5-6 team members, I probably wouldn’t document there” (Interview Participant 2) |

**Discussion**

As organizations explore ways to support the efficient and effective use of the EHR system, SRT continues to be an attractive option for many organizations. However, the lackluster adoption of an earlier version of SRT at our organization suggests the need for a thorough consideration of factors relevant for implementing SRT in practice. Implementation frameworks can offer great value in supporting the evidence-based and systematic implementation of innovation, yet their use has not been fully realized. In this study, we demonstrate the value of applying an implementation framework (i-PARIHS) in addressing the current challenges of documentation burden (Table 6).
Table 6. Summary of findings for each construct of the i-PARIHS framework 18.

Previous studies on using SRT have identified a catalogue of factors related to the adoption of SRT 12. However, these studies do not provide insight on the dynamic interactions that are likely required for successful implementation 30. The analysis of the collected data using the i-PARIHS framework 18 provides a unique perspective on understanding the relationships and issues related to the implementation of SRT. For example, in examining the facilitation and innovation constructs, there was a clear need for expectation-setting as part of communication 9, 30. While many of the respondents showed neutral perceptions towards its utility in reducing documentation time and ease of use, they remained interested in using SRT for documentation. Mastering SRT is associated with a steep learning curve, 30 however novel end-users may not be aware of this. This may lead to unrealistic expectations and early disengagement with SRT. Thus, there is a need to ensure that those in leadership positions have the appropriate knowledge and skills to manage expectations effectively 31.

Moreover, through the probing and questions of the interviews, the application of the framework highlighted the importance of implementing processes (facilitation aspects) that consider the challenges observed in the recipient, innovation, and context concepts. For example, in mental health, the suboptimal accuracy of dictating non-medical terminology (e.g., patient names) may translate to additional revisions or confusing documentation that can hinder patient safety 32. As a result, as part of the implementation process, providing adequate training on methods for correcting mistakes using SRT is instrumental to the ongoing improvement of the tool. 30 In addition, from a contextual perspective, the increased use of shared space can jeopardize the privacy of patients. Considering how SRT and similar technologies 33 can be used while maintaining patient privacy and confidentiality is needed 34. Lastly, from the perspective of physicians (the recipient), there are increasing concerns around how care can be delivered through and with digital technologies 35. As voiced by a few physicians, the use of SRT during the patient encounter can generate additional layers of complexities that hinder the therapeutic relationship with the patient 36. As such, identifying ways to maintain delivery of care while using SRT is needed to maximize its utility and value.

Implications for health care organizations

This study provides an example of how implementation frameworks can be applied in addressing EHR-related burden and clinician burnout and suggest that these frameworks can be valuable in implementation success. Healthcare leaders and administrators may consider leveraging a framework in guiding the implementation and evaluation of their own health informatics projects 17. While we selected the i-PARIHS 18 framework for this project, many other implementation frameworks could be used and the suitability of each alternative should be considered based on the objective and role of the project.

These findings also have implications for healthcare organizations interested in implementing SRT into their organization. From this study, it is evident that there are distinct nuances in psychiatry and mental health settings.
that may present a challenge for adopting SRT. For example, the use of unstructured, narrative documentation may necessitate robust training with the SRT to ensure that both medical and non-medical terminology are dictated correctly. Moreover, given the heightened privacy considerations around mental health issues, private offices or spaces to complete their documentation are needed.

Based on the findings from the application of the i-PARIHS framework, several recommendations are identified for implementing SRT in mental health settings. Foremost, given the additional training associated with accurate dictations by the SRT, there is a need to clearly communicate features and expectations associated with the ‘learning curve’ of adopting SRT. In particular, demonstrating how advanced features such as custom dictionaries and autotext can help address issues related to inaccuracies would be useful. This may be captured as part of a comprehensive training curriculum that includes both basic and advanced features of the solution. Dedicated workflows for optimizing the accuracy of dictations (e.g., the addition of commonly used non-medical terminology in the custom dictionary) may also be useful for supporting the ongoing optimization of SRT. Finally, identifying the workspace and workflow requirements to support the use of SRT is needed. This may include ensuring appropriate equipment and private spaces to complete documentation and implementing convenient locations to complete documentation throughout clinical settings.

Implications for Research

This study outlines opportunities for future research on the use of implementation frameworks for addressing EHR-related burden. With the numerous frameworks that are available, it may be useful to develop guidance on the selection and implementation of implementation frameworks on similar projects. As part of this work, building up a greater evidence base on the role of these frameworks for addressing unintended consequences arising from health IT use (e.g., administrative burden) is warranted.

In terms of the use of SRT in mental health settings, this study provides a baseline description of the perceptions and challenges towards adopting SRT for clinical documentation. Future studies may choose to explore how different implementation and optimization techniques can enhance the level of satisfaction and perceptions towards SRT for clinical documentation. The challenges identified from this study also provides the basis for building appropriate interventions to enhance implementation success. The impact of these interventions may then be evaluated using adoption metrics, EHR log data, and survey questions.

Limitations

Several limitations should be kept in mind when considering the results of this study. This study is only limited to the perceptions of physicians, residents, and clinical fellows from a single site. As the organization has already implemented the use of a comprehensive EHR system for many years, it is unclear if these perceptions are similar to those in organizations at a different stage of EHR adoption. More research is also needed to understand whether these perceptions can be translated to nurses and professional practice staff. Methodologically, this study was conducted using a cross-sectional design, and analysis was limited to a single implementation framework. The anonymous nature of the survey also prevented the ability to correlate the interview responses to the Likert scale and open-ended responses of the survey. In addition, the application of the implementation framework was only done as part of the analysis and not during the development and collection of the study. This may have hindered the value the i-PARIHS framework provided in addressing this issue. Lastly, the study was conducted when the COVID-19 pandemic was announced. Given the circumstances of the situation, we had a lower than expected response rate (~12% for staff physicians). With a smaller sample size, it is likely that there may be more participation from those with inherently greater interest for SRT (volunteer bias). Moreover, as the pandemic has led to dramatic shifts in the delivery of care, it has forced the uptake of various digital health tools including virtual care. It is unclear if the perceptions from this study have evolved since the rapid adoption of technologies during the pandemic.

Future Directions

As SRT continues to be an area of interest in addressing documentation burden, this study provides a foundation for further research on the use of SRT for clinical documentation in mental health settings. Foremost, it would be useful to explore the value of other implementation frameworks (e.g., RE-AIM) in supporting the mitigation of EHR-related burden. These frameworks may be considered in the implementation of other interventions for documentation burden such as EHR optimization sprints. In terms of implementing SRT in mental health settings,
there is a need to explore appropriate interventions to address the challenges observed in this case study. Building a strong body of evidence on SRT implementation in mental health settings can inform guidance on maximizing the value of these tools in reducing clinician documentation burden. Lastly, it may be useful to consider further sub-group analyses to characterize populations (e.g., demographics) that may be more/less reluctant to adopt SRT. Identifying these insights with a larger sample size for mental health as well as for other specialties (e.g., radiology) may be helpful for developing targeted and more effective interventions.

Conclusions

Through the application of the i-PARIHS framework on the implementation of SRT, this study demonstrates the value of applying well-established implementation frameworks in the implementation of digital health tools. Future implementations should consider the use of implementation frameworks to ensure success in using digital health to address challenging issues such as documentation burden and clinician burnout. In addition, several key considerations for implementing SRT in mental health settings were identified. Careful consideration of these challenges using robust education, support, and communication interventions are likely needed for project success.

Funding Sources

There were no formal sources of funding for this work, but in-kind contributions were provided by the Centre for Addiction and Mental Health.

Acknowledgements

The authors would like to thank all the physicians who kindly took the time to participate in this project. We would also like to acknowledge co-op students Dennis Hang, Hazel Walker, Kerry-Ann Smith and Surya Pandiaraju for their support with the initial stages of the project.

Abstract

Heart failure (HF) is a major cause of mortality. Accurately monitoring HF progress and adjusting therapies are critical for improving patient outcomes. An experienced cardiologist can make accurate HF stage diagnoses based on combination of symptoms, signs, and lab results from the electronic health records (EHR) of a patient, without directly measuring heart function. We examined whether machine learning models, more specifically the XGBoost model, can accurately predict patient stage based on EHR, and we further applied the SHapley Additive exPlanations (SHAP) framework to identify informative features and their interpretations. Our results indicate that based on structured data from EHR, our models could predict patients’ ejection fraction (EF) scores with moderate accuracy. SHAP analyses identified informative features and revealed potential clinical subtypes of HF. Our findings provide insights on how to design computing systems to accurately monitor disease progression of HF patients through continuously mining patients’ EHR data.

Introduction

Heart failure, also commonly referred to as congestive cardiac failure, is a clinical syndrome when the heart is unable to pump sufficiently to maintain blood flow to meet the body’s needs. According to CDC, HF is one of the most prevalent diseases and with highest mortality rate within the US, with the estimating that 6.2 million adults are affected. When a patient has a clinical encounter, their signs, symptoms, labs and other data is input into the EHR and the treatment plan is tailored to their specific physiologic condition. Thus, accurately monitoring disease states and adjusting the regimen in a timely manner can prevent or slow heart failure progression. The availability of an incoming stream of patient data including (but not limited to) weight and blood pressure readings, symptom monitoring and medication tracking has significantly lowered the mortality rates of heart failure patients, readmission rates, medical expenses, and improved patient satisfaction. Accurately monitoring disease progression and timely adjusting regimen to prevent or slow progression would improve HF patients’ life expectancy and quality. With prevalent availability of EHR, continuously mining of the EHR by computational agents to accurately detect and report disease progression will likely become a component of long term care of HF patients. In this study, we investigated the feasibility of using computational agents to assess disease stage and characteristic clinical features that provide information about disease and progression.

An objective measurement of heart function is the EF of left ventricle of heart. Broadly classified, there are 2 types of heart failure: heart failure with reduced ejection fraction (HFrEF) and heart failure with preserved ejection fraction (HFpEF). The difference lies in whether the systolic or diastolic capabilities of the left ventricle is affected, which is primarily measured by the left ventricle ejection fraction (LVEF or EF) score. The relation between EF score and HF is shown in Table 1. According to 2016 European Society of Cardiology (ESC) Clinical Practice Guideline, an EF score less than 40% typically suggests HFrEF, while an EF score greater than 50% is often a sign of HFpEF. As a distinct quantitative measure of heart failure stage, therefore, compared to other symptoms of heart failure, EF score is an effective

Table 1: Relation between EF score and HF

¹This work is completed during Dr. Chen’s visit at the University Pittsburgh
variable to use when applying machine learning methods to predict a patient’s heart failure status. Currently, EF score is measured using an echocardiogram during inpatient/outpatient visits, but the frequency of echocardiogram can be few and far between in comparison to recordings of other clinical data. Furthermore, encounters of a HF patient with a health system are multi-faceted and occur in multiple settings, e.g., outpatient visits, nurse call, pharmacy visits, etc. All these encounters are usually recorded in the EHR of a comprehensive health system like the University of Pittsburgh Medical Center (UPMC). Therefore, EHR is an ideal resource for exploring indicators for diagnoses and outcomes, and we hypothesize that the continuous mining of EHR to detect disease progress would be of high clinical value in future.

Machine learning models have been increasingly applied to explore medical scenarios related to heart failure. In general, interpretable models are preferred over “black box” models in clinical settings. Among modern machine learning models, tree-based models, e.g., the XGBoost, is often favored in clinical settings, because they are easy to interpret, capable of handling missing values, and solve overfitting and underfitting problems effectively with the help of regularization methods. However, most earlier studies concentrate on model performance or feature importance, paying little attention to fully understanding and explaining the predictions with interpretable methods. That is, a human user not only is interested to know what features are informative with respect to a prediction task, but also would like to know how to interpret an observed value of a feature with respect to the prediction task. To this end, machine learning methods have been developed to identify informative features and their interpretations in a model-agnostic fashion. For example, a model-agnostic interpretation method, such as SHAP, can take a dataset and different prediction models as inputs, apply the models to the data, and subsequently discover the characteristics of data features in each prediction model (thus model-agnostic) different prediction models.

In this paper, we investigated the utility of XGBoost model in predicting heart failure stages, which is represented by EF scores based on structured EHR data. We evaluated informative features and investigated their interpretability and characteristics using the SHAP framework. Finally, based on the characteristics of features and their values, we applied unsupervised cluster learning to discover subtypes (subpopulations) among HF patients. To our best knowledge, few studies attempt to address the same questions as reported here, and we anticipate that our approach lays a foundation for future development of computational agents capable of monitoring HF patient disease progress by continuously mining the EHR data of health systems.

Materials and Methods

Data Collection and Preprocessing

All the EHR data were obtained from UPMC from 2014 to 2019 and contained clinical conditions of the patients who have been diagnosed with HF before, identified using ICD9/ICD10 codes (I428.* and I50.* respectively) which indicate heart failure. The original dataset consisted of 9 different CSV files that were extracted from the UPMC EHR system, including demographics (DEMO*), vitals (VL_*), labs (LB_*), medical dispenses (MD_*), medical fills (MF_*), medical orders (MO_*), order results (OR_*), problem lists (PL_*), and diagnoses (DL_*). Each patient had a unique ID, and each file was a collection of data from over 2,000,000 encounters from 60,835 unique patients. In order to build a profile for each patient, we cleaned the raw CSV files based on rules, extracted each patient’s record from the CSV files and finally aggregated the information. The workflow is illustrated in Figure 1:

The rules for data processing were:

1) For medical fills, medical orders, medical dispenses, problem lists and diagnoses, only keep the drug and disease names that appear over 10,000 times (10,000/2000,000 = 0.5%) in the dataset as valid features.

2) For numerical features like age, BMI, and blood pressure, in order to exclude outliers as much as possible, normalize the values and only keep the ones between 1% and 99% percentile, and values outside this range are then set to the value of 1 percentile (MIN) or 99 percentile (MAX).

3) The medical fills, medical orders, and medical dispenses are mixture of the National Drug Code (NDC) and the Anatomical Therapeutic Chemical (ATC) code. The problem lists and diagnoses are mixture of the ICD-9

---

[ii] Data acquired through the Health Record Research Request (R3) of University of Pittsburgh under the IRB# PRO18080460
and ICD-10 code. For the sake of consistency, all drugs NDC codes are mapped to ATC codes, and all ICD-9 codes are mapped to ICD-10 codes with the help of Apache Lucene.

After data cleaning, 1894 features from the 9 categories were retained and the values were stored tables. Details are available in Feature Table.

Figure 1: Data clean & aggregate workflow

The EF scores were directly obtained from patients’ echocardiogram reports. We extract the rest of structure EHR data of a patient within 45 days of EF measure, and we processed the EHR to derive a feature vector matching an EF measurement. Since each patient can have multiple EF measurement across time, and a patients disease may progress through such time, we treat EF measurements and match features from a patient that were separated by more than 180 days as ”independent” cases. Finally, we obtained 130,727 cases. We then split the dataset: 70% for training, 20% for validation and 10% for testing.

XGBoost Model for Regression

We applied XGBoost for our prediction task. XGBoost is an optimized distributed gradient boosting library and has been successfully applied in medical studies. Boosting algorithms is to combine weak classifiers together to form a powerful one. XGBoost is a boosting tree model that combines many CART regression tree models.

The regression tree model attempts to predict the original EF score with structured tabular EHR data. We tuned several hyperparameters with the evaluation of 5-folder cross validation for the XGBoost model before reaching the final model. The parameters are tuned with the sklearn.model_selection.GridSearchCV package, with coordinate descent as the strategy. The final tuned parameters are listed in Table 2:

SHAP for Model-Agnostic Interpretation

SHAP stands for SHapley Additive exPlanations. It is a game theoretic approach to explain the output of a machine learning model. It connects optimal credit allocation with local explanations using the classic Shapley value from game theory and their related extensions. SHAP assigns a unique SHAP value to each feature in a sample for an EF prediction. The SHAP value represents the deviation from the average predicted value for each case prediction brought by each feature. For our work, we applied the SHAP model to firstly generate SHAP values for all our test dataset cases, and then illustrated the SHAP summary plot and SHAP scatter plot using a publicly available SHAP API for a global understanding of our dataset.

T-SNE clustering with SHAP values

T-SNE (t-distributed Stochastic Neighbor Embedding) is a visualization machine learning algorithm based on stochastic neighbor embedding. In particular, it models each high-dimensional object with a 2D or 3D point, with similar
cases placed as nearby points in t-SNE space.

For our work, after assigning a SHAP value for each feature of a subject, we represented a sample using a feature vector of SHAP values and clustered data points accordingly. We examined whether this approach could reveal different subtypes of HF patients by inspecting the clusters in comparison to clustering samples in original feature space. We applied t-SNE algorithm to map the 1894 features in 2D to visualize the clustering results.

Model implementing details

The experiments were conducted on an on-prem server of 72 of CPU(Intel(R) Xeon(R) Gold 6140 CPU @ 2.30GHz). The operating system was Ubuntu 18.04.4 LTS. All the codes for the task were written in Python 3.6.

The XGBoost model was implemented with xgboost 1.1.1 and scikit-learn 0.23; the SHAP interpretation was implemented with shap; t-SNE algorithm was implemented with scikit-learn.manifold.TSNE, where the perplexity was set to 100.

Results

Predicting performance of XGBoost model

The performance for XGBoost regression is $RMSE = 12.6303 \pm 0.00201$ (95% CI) with 100 random attempts on validation dataset. We evaluated the correlation between the predicted EF and real EF scores (Figure 2A), of which $R^2 = 0.264$, with a $p < 10^{-32}$. Figure 2B, shows the first tree (the most prominent out of 100 trees), which illustrates what features are utilized by the tree and how it splits samples to make final predictions. For example, the first feature for split is the DEMO_GENDER, which indicates that gender is a very important feature for predicting EF among HF patients. Note that our model only used structured data from the EHR to predict a numeric score with moderate accuracy. Besides, The predictions clearly follows correct trends.

Interpretation with XGBoost and SHAP

The XGBoost model and SHAP evaluate features from different perspectives. The XGBoost uses the coverage to reflect the importance of a feature, which denotes the percentage cases in which a feature is utilized during the decision pathway in making the final prediction. On the other hand, SHAP analysis assigns a SHAP value for a feature in each case (i.e., case-specific), which reflects the impact on the feature (measured as deviation from the mean predicted value) when different combinations of features (including or excluding the feature of interest) are used to predict the target value of a case. The important features provided by two methods are shown in Figure 3, where Figure 3A is the feature importance generated with XGBoost with coverage $\geq 0.01$, and Figure 3B is the top 20 most important features according to the SHAP analysis.

Interpretation of SHAP scores is as follows. For the SHAP value plot, each row presents the distribution of SHAP values assigned to a feature across all cases. The $x$-axis denotes the SHAP value, and the unit reflects how much the presence/absence of a feature with a particular value in a case will lead to deviation of predicted EF score (the unit is %) from the mean of prediction values using all possible combinations of feature sets from the case. The pseudo-color of a data point indicates the value of the feature of interest in a case. The further a point deviates from the mean of

---

https://github.com/Frank-LSY/XGB-SHAP-EHR-EF
predictions (which is 0), the more impact the features have on the prediction in the case. Therefore, a positive SHAP value that is on the right side of the mean on the x-axis, indicates the feature with the value in a case leads to a target value above the average predicted value, and below the average value on the left side. For example, for VL_BMI, the patient’s SHAP value is positive when the BMI is higher, and negative when the BMI is lower (except for extreme cases). That is, in the SHAP interpretation for our prediction model, heart failure patients tend to have EF scores higher than average if the BMI value is high and vice versa.

As shown in Figure 3C, the two methods identified a common set of informative features as well as some disjoint features, but the overall ranking of the features is similar. Firstly, the most important features that have highest coverage for XGBoost feature importance and highest SHAP value impact is DEMO_GENDER. If we dive deeper, like what is shown in Figure 4, we can see that female patients tend to have about a 5% higher EF score compared to male patients (female is represented as 0 and male as 1). Additionally, both XGBoost and SHAP interpretations treat DI255 (Ischemic Cardiomyopathy), DI428 (other Cardiomyopathies) and DI429 (Cardiomyopathy, unspecified) as critical diagnoses; MD_C03CA (Sulfonamides, plain) as critical medical dispenses, OR_MITRAL_REGURGITATION (Mitral valve regurgitation) as critical order results, if presented. According to Figure 3B, BP_SYSTOLIC (systolic blood pressure) and BP_DIASTOLIC (diastolic blood pressure) all have relatively high SHAP values, but their contributions to the prediction are quite the opposite. As shown in Figure 5, the model tend to assign higher EF score value predictions if patients have higher systolic blood pressures, while assign lower EF score value predictions if patients have higher diastolic blood pressures.

Sample clustering analysis with t-SNE and SHAP value

SHAP analysis provides a new perspective for inspecting data points: it shows the case-specific impact of each feature of a data point. This provides us with an opportunity to inspect whether different cases share a common pattern (joint...
distribution) of SHAP scores that characterize a subset of cases, which would provide a new perspective to identify patients that may share a common underlying disease mechanism. We applied the t-SNE algorithm to visualize the distribution of samples in the original feature space as well as in SHAP score space. For the former, each case was represented in the original feature space, and for the latter, each case’s SHAP values were used as input features, and t-SNE projected the data points from both representation into a 2D space.

Figure 6: Clustering HF patients in different feature spaces

Figure 6 shows the general clustering result with original feature values and SHAP values of all features respectively. The color represents EF score for each case. Compared with Figure 6A, which is the clustering of samples based on original feature values, clustering based on SHAP values (Figure 6B) makes the data points with similar EF values closer on the plot. More specifically, patients with high EFs (HFpEF) appear to be evenly distributed among the patients with reduced EFs (HFrEF) in the t-SNE results based on the original features, whereas HFpEF patients tend to be more clustered together when SHAP feature values were used as inputs. Furthermore, the HFpEF patients form sub-clusters in the SHAP-derived t-SNE space, which indicates that there are distinct combinations of SHAP values (thereby clinical features) that were detectable by the t-SNE algorithm. In summary, representing data points in the SHAP space revealed characteristics of samples that were not detectable in the original data space. We then set out to investigate which features contributed to the sub-clusters in the SHAP-derived t-SNE analysis. For the 10 graphs in this section in Figure 7, we plotted each data point in the same position as they were in Figure 6B, and we used pseudo-color to illustrate the original values of different features in each sub-plot.

When inspecting the combination of features of different sub-clusters, it is interesting to note that gender appears to a major factor that leads to the division of two large sub-populations (Figure 7A). This finding agrees with the finding from XGBoost analysis as mentioned previously: gender is the most important feature to be considered when the XGBoost model trying to predict the EF score. The separation of patients according gender indicates that patients with different genders tend to have distinct combinations of characteristics of other features, which suggests there is a major difference in disease mechanisms of HF patients of different genders.

It can also be seen that mitral regurgitation is present in many patients except few smaller clusters. The presence of mitral regurgitation is usually associated with dilated left ventricles, which is frequently associated with reduced EF (HFrEF). For the rest of sub-clusters, each plot has at least one unique feature that clearly assumes a value different from that of the majority of the patients, reflecting the importance of such a feature in differentiate sub-populations of HF patients. It also provides a more in-depth understanding of the particular patterns of feature combinations and how they may reveal distinct disease mechanisms underlying these subgroups.
In this study, we showed that the XGBoost regression model could be trained to predict EF score (an objective measurement of heart function) with fair performance, only based on structured EHR data. Furthermore, we showed that SHAP analysis revealed information and patterns that could not be easily acquired through analyzing the original features identified by XGBoost. The results are encouraging in that they demonstrated the feasibility of monitoring HF patient disease stage, thereby progression of the disease, of HF patients through mining the EHR data. We anticipate that with more training cases and more information from detailed clinical notes that provide the information of symptoms and signs of HF patients, the accuracy of the predictive model can be further improved and eventually make such a system clinically applicable. Given the dominant impact of HF on human mortality, a small improvement in monitoring patient disease progression can be translated into a significant improvement in overall patient outcomes.

Some of our findings are confirmed by previous studies, which indicate the validity of our approach in discovering patterns and important features. For example, the 5% difference in EF values between men and women was reported in several publications. According to Chung et al. who reviewed 1435 women and 1183 men cMRI, and concluded whether there is heart failure or not, females have a median EF score of 75% and males have a median of 70%, $p < 0.001$. This is consistent with the 5% gender difference in our XGBoost predicted results. Moreover, earlier studies also reported that in patients with heart failure of different genders, females are more likely to be diagnosed with HFpEF, whereas males are more likely to be diagnosed with HFrEF. Some other recent findings also demonstrate that there are significant differences in the incidence, prevalence, disease course and pathophysiology of heart failure between biological males and females. Females tend to survive longer after a heart failure diagnosis and more often have diastolic dysfunction, while males have a overall higher incidence of heart failure. Additionally, the macro and microvascular pathology underlying the etiology of the heart failure has been proven to vary between males and females as well.

Our study also highlighted trends that have not yet been confirmed in previous publications: the relation between blood pressure and EF score. According to Katsuya et al., among patients with acute heart failure syndromes (AHFS), it has been reported that those with a reduced left ventricular ejection fraction (LVEF) tend to be hypotensive or normotensive, whereas those with a preserved LVEF tend to be hypertensive. Their study which evaluated 4831 patients led to the conclusion that patients with an admission SBP $< 120$ mmHg were more likely to have a reduced LVEF than a preserved LVEF. In contrast, patients with an admission SBP $\geq 120$ mmHg were equally likely to have a preserved or reduced LVEF, indicating that there was no relation between a higher admission SBP and the LVEF. However, we did not find references that suggest the changes in systolic and diastolic blood pressure would have opposite effects on EF score. Such a combination of characteristics in these features are apparent in our analyses. The discovery of such combination patterns, thereby sub-populations of patients, not only prompts further investigation.

---

**Discussion**

**Findings**

In this study, we showed that the XGBoost regression model could be trained to predict EF score (an objective measurement of heart function) with fair performance, only based on structured EHR data. Furthermore, we showed that SHAP analysis revealed information and patterns that could not be easily acquired through analyzing the original features identified by XGBoost. The results are encouraging in that they demonstrated the feasibility of monitoring HF patient disease stage, thereby progression of the disease, of HF patients through mining the EHR data. We anticipate that with more training cases and more information from detailed clinical notes that provide the information of symptoms and signs of HF patients, the accuracy of the predictive model can be further improved and eventually make such a system clinically applicable. Given the dominant impact of HF on human mortality, a small improvement in monitoring patient disease progression can be translated into a significant improvement in overall patient outcomes.

Some of our findings are confirmed by previous studies, which indicate the validity of our approach in discovering patterns and important features. For example, the 5% difference in EF values between men and women was reported in several publications. According to Chung et al. who reviewed 1435 women and 1183 men cMRI, and concluded whether there is heart failure or not, females have a median EF score of 75% and males have a median of 70%, $p < 0.001$. This is consistent with the 5% gender difference in our XGBoost predicted results. Moreover, earlier studies also reported that in patients with heart failure of different genders, females are more likely to be diagnosed with HFpEF, whereas males are more likely to be diagnosed with HFrEF. Some other recent findings also demonstrate that there are significant differences in the incidence, prevalence, disease course and pathophysiology of heart failure between biological males and females. Females tend to survive longer after a heart failure diagnosis and more often have diastolic dysfunction, while males have a overall higher incidence of heart failure. Additionally, the macro and microvascular pathology underlying the etiology of the heart failure has been proven to vary between males and females as well.

Our study also highlighted trends that have not yet been confirmed in previous publications: the relation between blood pressure and EF score. According to Katsuya et al., among patients with acute heart failure syndromes (AHFS), it has been reported that those with a reduced left ventricular ejection fraction (LVEF) tend to be hypotensive or normotensive, whereas those with a preserved LVEF tend to be hypertensive. Their study which evaluated 4831 patients led to the conclusion that patients with an admission SBP $< 120$ mmHg were more likely to have a reduced LVEF than a preserved LVEF. In contrast, patients with an admission SBP $\geq 120$ mmHg were equally likely to have a preserved or reduced LVEF, indicating that there was no relation between a higher admission SBP and the LVEF. However, we did not find references that suggest the changes in systolic and diastolic blood pressure would have opposite effects on EF score. Such a combination of characteristics in these features are apparent in our analyses. The discovery of such combination patterns, thereby sub-populations of patients, not only prompts further investigation.
of potentially distinct underlying disease mechanisms but also suggests that tailored prediction/monitoring models should be developed for different sub-populations (a mixture of expert models), to enhance their performance.

**Limitations**

This is an early attempt at using ML models to detect the stage of HF in patients. Currently, the model only utilizes the structured data from the EHR, missing a significant amount of information from clinical notes. Besides, the features we selected according to our feature engineering approach are not necessarily matching exactly with heart failure. This is why our XGBoost regression model only achieves fair performance. One future direction should be extracting an informative representation of symptoms and signs associated with HF to enhance the accuracy of the predictions. Another limitation is that the current model does not attempt to model the temporal trajectory of heart function, which is important for targeting earlier interventions in order to improve clinical outcomes. This will be addressed in future studies.

**Conclusion**

With the XGBoost model, SHAP interpretation and unsupervised clustering visualization, we can 1) predicted EF score from tabular EHR data with decent performance; 2) generated interpretations for both the XGBoost model and dataset; and 3) classified the subgroups of HF. The generated interpretations are consistent with HF diagnosis guidelines and human intuition. This article provides a basic understanding of certain variable associations with heart failure. The model demonstrated the variables such as gender, blood pressure, age, pulse, BMI, some diagnoses (miscellaneous cardiomyopathies), and medications (sulfonamides, alpha and beta blocking agents) all have an impact on heart failure stage. To a large extent, this indicates that the future use of machine learning models to construct clinical decision aids related to heart failure is justifiable and feasible.

Identifying ARDS using the Hierarchical Attention Network with Sentence Objectives Framework

Kevin Lybarger, PhD, Linzee Mabrey, MD, Matthew Thau, MD, Pavan K. Bhatraju, MD, MSc, Mark Wurfel, MD, PhD, Meliha Yetisgen, PhD
University of Washington, Seattle, WA, USA

Abstract

Acute respiratory distress syndrome (ARDS) is a life-threatening condition that is often undiagnosed or diagnosed late. ARDS is especially prominent in those infected with COVID-19. We explore the automatic identification of ARDS indicators and confounding factors in free-text chest radiograph reports. We present a new annotated corpus of chest radiograph reports and introduce the Hierarchical Attention Network with Sentence Objectives (HANSO) text classification framework. HANSO utilizes fine-grained annotations to improve document classification performance. HANSO can extract ARDS-related information with high performance by leveraging relation annotations, even if the annotated spans are noisy. Using annotated chest radiograph images as a gold standard, HANSO identifies bilateral infiltrates, an indicator of ARDS, in chest radiograph reports with performance (0.87 F1) comparable to human annotations (0.84 F1). This algorithm could facilitate more efficient and expeditious identification of ARDS by clinicians and researchers and contribute to the development of new therapies to improve patient care.

Introduction

Coronavirus disease 2019 (COVID-19) is caused by infection with the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) and is associated with high mortality.\textsuperscript{1} A high-risk complication of COVID-19 infection is the development of the acute respiratory distress syndrome (ARDS), which is characterized by severe inflammatory lung injury. Other common hospital diagnoses, such as sepsis, pneumonia, and trauma, are also associated with the development of ARDS. Interventions to prevent injury from invasive mechanical ventilation and differences in clinical management have improved clinical outcomes in patients with ARDS;\textsuperscript{2–4} however, ARDS is commonly under recognized by clinicians. In an epidemiologic study involving 500 intensive care units across 50 countries, over 40% of all ARDS cases were not recognized by clinicians, and the diagnosis of over 30% of ARDS cases was delayed.\textsuperscript{5} In another study, investigators demonstrated that delays in initiating evidence-based treatments was associated with increased hospital mortality in patients with ARDS.\textsuperscript{6}

The identification of ARDS requires the assessment of lung injury patterns in chest imaging. A primary contributor to undiagnosed ARDS is the challenge of incorporating radiologist-derived chest imaging findings into diagnostic algorithms for ARDS. Per the “Berlin Definition,” ARDS diagnosis requires:\textsuperscript{7}

- \textit{timing}: condition occurs within one week of a known clinical insult or new/worsening respiratory symptoms
- \textit{chest imaging}: bilateral opacities that are not fully explained by effusions, lobar or lung collapse, nodules, or masses
- \textit{non-cardiogenic edema}: alveolar infiltrates are not fully explained by cardiac failure or hydrostatic edema
- \textit{oxygenation}: oxygenation measurements meet defined thresholds (mild, moderate, and severe)

The \textit{oxygenation} component requires decreased oxygenation and is generally documented in structured data in the electronic health record (EHR). The \textit{non-cardiogenic edema} component requires an absence of hydrostatic edema, and the associated risk factors may be captured in structured admit diagnosis codes or the clinical narrative. The \textit{timing} component requires a proximal risk factor for respiratory failure, for example the presence of COVID-19, and may be documented through lab results or diagnosis codes. The information needed to assess the \textit{chest imaging} requirements is typically represented in chest radiographs (x-rays) and computed tomography images, as well as the associated free-text reports describing radiologists’ findings and interpretation. Data-driven computer vision approaches for directly analyzing the chest radiographs images are still in development and are computationally expensive. This work explores the automatic identification of the \textit{chest imaging} requirements for ARDS in free-text chest radiograph reports.

Natural language processing (NLP) explores the analysis, interpretation, and transformation of language. Information extraction is a common NLP task that automatically extracts structured representations from unstructured text. We use
information extraction techniques to identify descriptions of opacities (increased radiodensity), classify the opacities as parenchymal (indicative of alveolar edema/infiltrates) or extraparenchymal (outside the lungs or not indicative of alveolar edema/infiltrates), resolve sidedness (unilateral or bilateral), capture size information (small, moderate, or large), and indicate negation (“not present”). We developed detailed annotation guidelines that include summary document-level annotations and detailed relation annotations that characterize opacities. Using this novel annotation scheme, we created a new annotated corpus of 420 chest radiograph reports, referred to as the Pulmonologist Annotated Corpus (PAC). This work presents the Hierarchical Attention Network with Sentence Objectives (HANSO) framework, which is an end-to-end neural model that utilizes both the document-level and relation annotations. We introduce an approach for leveraging entity and relation annotations with noisy spans to improve document classification performance within the HANSO framework. We compare the performance of HANSO against two gold standards: manually annotated chest radiograph reports and manually annotated chest radiograph images. HANSO achieves very high performance in identifying the presence of bilateral infiltrates, a key indicator of ARDS, relative to both the annotated reports (0.87 F1) and annotated images (0.87 F1). HANSO also identifies factors that are less consistent for ARDS, specifically extraparenchymal opacities, with high performance (0.80 F1).

Related Work

Many works explore NLP information extraction techniques with radiology reports. Within this body of radiology research, several works explore the identification of pulmonary conditions in chest radiograph reports. Most prior pulmonory information extraction work implements discrete document classification models where labels are assigned at the document-level, without utilizing word-level annotations or predictions. Bejan, et al. identify pneumonia in chest radiograph reports using Support Vector Machines (SVM) with word n-grams, medical concepts, and other features. Yetisgen, et al. automatically identify acute lung injury in chest radiograph reports using Maximum Entropy (MaxEnt) models that utilize word n-grams and assertion predictions (present vs. absent). Afshar et al. and Mayampurath et al. predict ARDS in chest radiograph reports using word n-grams and medical concept features using discrete modeling approaches, including decision trees, k-nearest neighbors, naive bayes, logistic regression, and SVM. Mayampurath et al. achieves the best performance in predicting ARDS using unigram term frequency–inverse document frequency (TF-IDF) features with SVM, which we implement here as a baseline.

Some recent NLP work with chest radiograph reports utilizes continuous, neural modeling approaches. Datta et al. annotate approximately 2,000 chest radiograph reports using a detailed relation-based annotation scheme that characterizes radiology phenomena across multiple dimensions. Datta implements neural entity and relation extraction models, including a baseline model consisting of stacked bidirectional long short-term memory (bi-LSTM) and conditional random field layers, as well as transformer-based approaches using BERT and XLNet. Apostolova et al. investigate ARDS using both clinical text and structured EHR data from the MIMIC-III database, exploring ARDS likelihood, mortality, and risk factors using learned vector patient representations. Apostolova’s patient vectors incorporate information from clinical notes, diagnosis codes, and other structured data using Convolutional Neural Networks and Gradient Boosting Machine.

This work is differentiated from prior ARDS-related information extraction work in multiple ways. This work presents a new detailed annotation scheme that identifies indicators and confounding factors for ARDS, including document-level summary labels and detailed relation annotations describing the support or evidence for the document-level labels. It introduces a new end-to-end, neural multitask model that predicts the document-level labels and utilizes the detailed relation annotations to augment learning. Additionally, this work presents an approach for leveraging noisy entity and relation annotations.

Methods

Data

This work utilized two existing clinical data sets from the University of Washington Harborview and Montlake campuses. The first data set, Data set A, includes 831 chest radiograph reports for 173 patients from February-September 2020. Data set A includes patients that were being evaluated under suspicion for COVID-19 and admitted to a medical or trauma intensive care unit (ICU). Inclusion criteria were: (1) ICU admission; (2) suspicion for COVID-19; (3) inva-
sive mechanical ventilation; (4) presence of at least one partial pressure of arterial blood oxygen-to-fraction of inspired oxygen ratio (PaO2/FI02) less than 300 mmHg. For Data set A, an expert chest radiologist annotated 154 radiograph images using the Berlin criteria to identify patients with diffuse bilateral pulmonary opacities. The second data set, Data set B, includes 1,279 radiograph reports for 788 patients from March-November, 2020. Data set B includes all patients hospitalized with COVID-19, resulting in a broader patient population than Data set A with varying degrees of severity of illness from COVID-19 infection.

Annotation Scheme: We developed a detailed annotation scheme that facilitates the identification of lung infiltrates and extraparenchymal opacities. Table 1 summarizes the annotated phenomena, and Figure 1 presents annotation examples from the BRAT annotation tool. Each report was annotated with two categories of labels: document labels and relational labels. The document labels summarize the annotators’ overall assessment of each chest radiograph report with two multiclass labels: infiltrates – consistent with ARDS and extraparenchymal – less consistent with ARDS. The document classes are: none – insufficient information for assessment or absence explicitly stated; present – condition present but sidedness unknown; unilateral – explicitly one lung; and bilateral – explicitly both lungs. The string, “⟨⟨ INFILTRATES ⟩⟩ ⟨⟨ EXTRAPARENCHYMAL ⟩⟩,” was appended to each report to facilitate the assignment of these document labels.

The relation annotations are evidence for the document labels and include annotated spans and links between spans. Although the annotated spans are not necessarily noun phrases, we refer to the spans as “entities” here. The entity types include region, side, size, and negation. The annotation of region, side, and size includes an identified span and the assignment of a subtype label that normalizes the span contents, mapping the phrase to a clinically significant label. For example, all region entities include a subtype label of parenchymal or extraparenchymal. The negation entity only includes an annotated span without a subtype label, although the type label conveys the span meaning (i.e. “absent”). The relation annotations indicate whether a side, size, or negation entity are an attribute of a region entity. All attribute (attr) relation annotations are unidirectional, where the first entity in all relations has type region).

The annotation scheme provides the information necessary to categorize each chest radiograph report with respect to the radiologic criteria for ARDS; namely the presence of bilateral opacities that are not fully explained by effusions, lobar or lung collapse, nodules, or masses. The presence of opacities was qualified as infiltrates (indicative of alveolar process) and/or extraparenchymal (indicative of effusions, collapse, nodules/masses, and atelectasis) with additional annotation of any report text documenting laterality and size. This approach mirrors the clinical heuristic used by ex-
expert radiologists and pulmonary/critical care clinicians when assessing the likelihood that a chest radiograph indicates the presence of ARDS. In our annotation scheme the document labels, infiltrates and extraparenchymal, are the best indicators of ARDS, and the relation annotations are included to support the document labels.

Annotation Scoring and Evaluation: The goal of this work is to extract salient information from chest radiograph reports and convert it to a structured representation that will complement other types of structured clinical data (e.g. PaO3/FiO2 ratio) to predict ARDS. The assessment of annotator agreement and extraction performance focuses on the information in the annotation schema that is most relevant to the large-scale, automated assessment of ARDS. For each entity, the subtype label captures the important span information, such that the associated text span is less informative.

Figure 2 presents the same sentence annotated by two annotators. Both annotators label a region entity with subtype parenchymal that is connected to a side entity with subtype unilateral. Although the annotators label different spans for the region entities (“midlung, basilar opacities” vs. “opacities”), both annotations identify unilateral parenchymal opacities (i.e. opacities in one lung). For the purposes of predicting ARDS, these annotations are equivalent, even though there are span differences. For entities with equivalent type and subtype labels, the spans are evaluated under two criteria: any overlap and partial match. Under the any overlap criterion, spans are considered equivalent if there is at least one overlapping token, and the performance is assessed based on span counts. For the region annotation in Figure 2, the entity spans “midlung, basilar opacities” and “opacities” overlap, so there is one matching span. Under the partial match criterion, spans are compared at the token level to allow partial matches, and performance is assessed based on the number of matching tokens. For the region annotation in Figure 2, the entity spans have one matching token (“opacities”) and three mismatched tokens (“midlung, basilar”). There is only one relation type (attribute or attr), and two relations are equivalent if the entities paired by the attribute relation are equivalent under the any overlap criterion. Performance is evaluated using precision (P), recall (R), and F1-score (F1).

Annotation Statistics: The Pulmonologist Annotated Corpus (PAC) includes 420 chest radiograph reports, 120 from Data set A and 300 from Data set B. PAC was annotated by two pulmonary and critical care fellows, whom each annotated half the corpus. PAC has an 80%/20% train/test split. Figure 3 presents the histogram of the PAC document labels. The indication or reason for a chest radiograph in this patient population is a respiratory complaint, so positive labels (label ∈ {present, unilateral, bilateral}) are frequent: 75% of reports have a positive infiltrates label, and 43% have a positive extraparenchymal label. The corpus includes an average of 3.0 region, 1.3 side, 0.8 negation, and 0.2 size entities and 2.7 relations per report.

Annotator Agreement: As part of the annotation guideline development and annotator training, we doubly annotated 20 reports, assessed inter-annotator agreement, updated the annotation guidelines, and provided additional annotator training. At the conclusion of the project, we doubly annotated 10 additional reports, to assess the agreement for the annotated corpus. The agreement for these 10 reports is presented in Table 2. The agreement for both document labels is high (0.90 F1). The entity agreement under the any overlap criteria is also high (0.85-0.96 F1). The entity agreement using the partial match criteria remains high for negation and side entities; however it is relatively low for region. These results suggest the annotators are generally labeling the same phenomenon; however, they differ in the selected spans, similar to the example in Figure 2. Relation agreement is very high for region-negation entity pairs.
and lower for region-side pairs (0.76 F1). While the region span annotations are noisy, the entity and relation annotations, still contain useful information for assessing ARDS.

Information Extraction

The likelihood of a patient satisfying the chest imaging requirements for the Berlin definition of ARDS can be estimated from the document labels, infiltrates and extraparenchymal. We introduce the Hierarchical Attention Network with Sentence Objectives (HANSO) framework in Figure 4, to predict these document labels and incorporate the relation annotation information. HANSO is a neural end-to-end, multi-task model that includes sentence encoding and document encoding layers. It builds on Yang’s hierarchical attention network (HAN). HAN aggregates word-level information to the sentence-level and then aggregates sentence-level information to the document-level. Sentences are encoded using a multi-layer network consisting of a recurrent neural network (RNN) and self-attention, and documents are encoded using separate RNN and self-attention layers operating on the encoded sentences. We build on HAN, incorporating sentence-level prediction tasks to augment the learning of the sentence representations. The sentence targets are derived from the relation annotations. The sentence and document encoding layers in Figure 4 are implemented for each of the document labels, infiltrates and extraparenchymal, with a shared input recurrent layer. HANSO omits the additional RNN included in the document encoding layer of HAN.

In our initial experimentation, we implemented a span-based relation extraction model for the entity and relation labels, similar to our previous work, and tried using the extracted relation information to improve the prediction of the document labels. However, the entity and relation extraction performance was insufficient to improve the prediction of the document labels, which are the most important labels in our annotation schema. Contributing factors to the low entity and relation extraction performance include the small data set size and the variability in the annotated spans, especially for region entities. The subtype labels in our annotation scheme (e.g. unilateral and bilateral for the side entities) normalize the span information, so the noisiness in the annotated spans does not negatively impact the informativeness of the annotations. However, this noise in the span annotation does negatively impact model learning and span prediction.

To utilize the detailed relation information, the relations are converted to a one-hot encoding for each sentence, capturing the salient relation and entity information without explicitly identifying entity spans. Figure 5 presents examples of this relations-to-sentence label mapping process. Relations consisting of region-side pairs are represented as the subtype label pairs: \{parenchymal-unilateral, parenchymal-bilateral, extraparenchymal-unilateral, extraparenchymal-bilateral\}. Relations consisting of region-negation pairs are represented as the region subtype label and negation type: \{parenchymal-negation, extraparenchymal-negation\}. While this approach does not explicitly capture span in-
formation, this sentence-level encoding of the relations creates a summary of the most important annotated phenomena within each sentence. The size entities are infrequent within the corpus and are omitted from experimentation.

Figure 5: Relation-to-sentence label mapping example

In the description of the HANSO framework below, the subscripts $i$, $j$, and $k$ indicate the $i^{th}$ BERT word piece position, $j^{th}$ sentence, and $k^{th}$ document. We only include the $i$, $j$, and $k$ subscripts below that are needed to resolve ambiguity.

Input encoding: Input documents are split into sentences and tokenized using spaCy. The default en_core_web_sm spaCy configuration is used, except that line breaks always indicate a sentence boundary. Sentences are mapped to contextualized word embeddings using Bio+Clinical BERT. The contextualized BERT word piece embeddings feed into a bi-LSTM without fine tuning BERT (no backpropagation to BERT). We tried several different architectures involving fine tuning BERT but these architectures did not out perform HANSO, which is likely due to the very small training set. The forward and backward states of the bi-LSTM are concatenated to form $h_i$ with size $1 \times l_h$, where $i$ is the word piece position.

Sentence encoding: Each sentence is represented as the attention-weighted sum of the word piece vectors. The bi-LSTM hidden state for each word piece is nonlinearly projected from size $l_h$ to $l_p$ as

$$u_i = \tanh(W_u h_i + b_u),$$

where $W_u$ is weight matrix and $b_u$ is a bias vector. Word-level attention weights, $\alpha_u$, are calculated using dot product attention as

$$\alpha_{u,i} = \frac{\exp(u_i^T z_u)}{\sum_i \exp(u_i^T z_u)},$$

where $u_i$ is the projected word piece input and $z_u$ is a learned vector of size $l_p$. The representation of sentence $j$ is calculated as

$$s_j = \sum_i \alpha_{u,i} h_i,$$

where $s_j$ has size $l_h$. A set of binary sentence-level prediction tasks, $R$, are incorporated based on the one-hot encoding of the relations described above. For each sentence-level task, $r \in R$, the sentence vector is nonlinearly projected from size $l_h$ to $l_p$ as

$$v_{r,j} = \tanh(W_v, s_j + b_{v,r}).$$

Label scores for task $r$ are calculated using a linear projection from size $l_p$ to 2 as

$$\psi_{r,j} = W_{\psi,r} v_{r,j} + b_{\psi,r},$$

where $\psi_{r,j}$ are the label scores for task $r$ and sentence $j$.

Document encoding: The same attention framework defined in Equations 1 and 2 is used to calculate the sentence-level attention weights, $\alpha_s$. Separate attention weights and bias vectors are learned for the sentence and document encoders. The sentence representation is nonlinearly projected from size $l_h$ to $l_p$ as

$$x_j = \tanh(W_x s_j + b_x).$$
Each document is represented as the attention weighted sum of the projected sentence vectors as
\[
d_k = \sum_j \alpha_{s,j} x_j,
\]
(7)
where \(\alpha_{s,j}\) is the attention weight for sentence \(j\) and \(d_k\) has size \(l_p\). The classes for the \textit{infiltrates} and \textit{extraparenchymal} labels are \{\textit{none, present, unilateral, bilateral}\}. Document label predictions are generated by linearly projecting the document vector from size \(l_p\) to \(l_d\) as
\[
\phi_k = W_d d_k + b_d
\]
(8)
where \(\phi_k\) are the label scores for document \(k\) and \(l_d\) is the document label set size.

Separate sentence and document encoders are implemented for the \textit{infiltrates} and \textit{extraparenchymal} document labels, utilizing a shared bi-LSTM input layer. For the prediction of the \textit{infiltrates} document label, the binary sentence prediction targets include: \textit{parenchymal-unilateral}, \textit{parenchymal-bilateral}, and \textit{parenchymal-negation}. For the prediction of the \textit{extraparenchymal} document label, the binary sentence prediction targets include: \textit{extraparenchymal-unilateral}, \textit{extraparenchymal-bilateral}, and \textit{extraparenchymal-negation}. To assess the contributions of the sentence-level objectives to document prediction performance, we implement HANSO without the sentence-level learning objective in Equation 5 ("HANSO lite") and the full HANSO model ("HANSO full").

**Baseline:** As a baseline for prediction performance, we implement a SVM model with unigram TF-IDF features, similar to Mayampurath et al.’s recent work predicting ARDS in chest radiograph reports.\(^\text{12}\)

**Experimental Setup:** Model hyperparameters are tuned through 3-fold cross validation on the PAC training set. The best performing models are applied to the withheld PAC test set. HANSO is implemented in PyTorch, and the SVM is implemented with scikit-learn.\(^\text{20,21}\) The HANSO configuration includes layer normalization at the bi-LSTM output and dropout (do) after the bi-LSTM and nonlinear projections in Equations 4 and 6. Additional hyperparameters include the number of epochs (ne), batch size (bs as document count), learning rate (0.002), maximum document length (35 sentences), maximum sentence length (30 tokens), hidden size (\(l_h = 100\)), and projection size (\(l_p = 100\)). The Adam optimizer is used, loss is summed across all targets, and the gradient norm is clipped (\(g_{\text{max}} = 1.0\)). For \textit{HANSO lite}, \(do = 0.1\), \(ne = 400\), and \(bs = 40\). For \textit{HANSO full}, \(do = 0.2\), \(ne = 150\), and \(bs = 10\). The SVM configuration includes the kernel ("rbf"), regularization (\(C = 10.0\)), and convergence tolerance (0.001).

**Results**

HANSO is trained on the PAC training partition and evaluated here using two approaches: \textit{text-versus-text} and \textit{text-versus-image}. In the \textit{text-versus-text} approach, the trained HANSO model is evaluated on the withheld PAC test set. The \textit{text-versus-text} approach is a typical NLP performance evaluation, where the model is trained and evaluated on annotated text. In the \textit{text-versus-image} approach, we apply HANSO to a set of chest radiograph reports for which the associated chest radiograph images are directly annotated by an expert radiologist. The \textit{text-versus-image} approach compares labels derived from text reports against gold standard image annotations.

**Text-versus-text**

In this subsection, we evaluate model performance on the withheld PAC test set. We present performance results for three models: SVM, \textit{HANSO lite}, and \textit{HANSO full}. To account for the variance associated with model random initialization, each model is trained on the training set 10 times and evaluated on the test set to generate a distribution of performance values. Table 3 presents the average performance across the 10 runs for the document labels, \textit{infiltrates} and \textit{extraparenchymal}. Performance is presented for each label and the micro average across labels ("micro"). \textit{HANSO full} achieves the best overall performance (F1 micro) for both \textit{infiltrates} and \textit{extraparenchymal} with significance (\(p < 0.05\)), demonstrating that the inclusion of the sentence objectives contributes to document prediction performance. \textit{HANSO full} achieves a statistically significant improvement in identifying \textit{bilateral infiltrates} relative to the SVM (\(p < 0.01\)), and the improvement of \textit{HANSO full} over \textit{HANSO lite} barely misses significance criteria (\(p = 0.07\)). Significance is assessed using a two-side t-test with unequal variance. The average performance across all sentence-level tasks in the \textit{HANSO full} runs is 0.83 F1. Considering the sentence-level tasks represent the summarization of the most salient relation information without including any span information, this performance is high.
Table 3: Document label prediction performance and gold standard label counts. † indicates the best performing model with significance ($p < 0.05$).

To assess the receiver operating characteristic (ROC) for HANSO’s ability to identify bilateral infiltrates, we train a separate HANSO model (HANSO full) with binary document targets ($0 = \text{not bilateral}$ and $1 = \text{bilateral}$), where the none, present, and unilateral labels are mapped to not bilateral. This binary variant achieves similar performance (0.88 F1) in identifying bilateral infiltrates as the multi-class models in Table 3. Figure 6 presents the ROC for bilateral infiltrates identification using the binary HANSO model. The ROC area under the curve (AUC) is 0.92. Optimizing the prediction threshold using Youden’s J statistic yields $J = 0.77$ at $FPR = 0.08$ and $TPR = 0.84$.

Text-versus-image

In this subsection, we compare the manual PAC annotations and automatically generated HANSO labels against annotated chest radiograph images. An expert radiologist annotated 154 chest radiograph images from Data set A with quadrant-level consolidation scores that can be mapped to the infiltrates labels none, unilateral, and bilateral, which we treat as the gold standard labels in this section. The annotated radiograph images correspond with 44 annotated reports in PAC (35 train and 9 test). The manual report labels are evaluated for the 44 reports in PAC that have a corresponding annotated images. The HANSO labels are evaluated for the 119 (154-35) annotated radiograph images not associated with reports in the PAC train set. Table 4 presents the performance of the manual and HANSO infiltrates labels. While the performance for none and unilateral is lower for both the manual and HANSO labels, the performance for bilateral is high for both the manual labels (0.84 F1) and HANSO labels (0.87 F1). ARDS diagnosis requires the presence of bilateral infiltrates, so the bilateral label performance is most important. HANSO achieves a sensitivity (recall) of 0.85 and specificity of 0.75 for bilateral in a one-versus-rest evaluation (bilateral vs. not bilateral). As the manual and HANSO performance is assessed using different samples, the significance of the performance differences cannot be assessed.
Conclusions

We introduce a new annotated corpus of chest radiograph reports, PAC, which includes document, entity, and relation annotations associated with ARDS. We also introduce the multi-task, end-to-end HANSO classification framework, which hierarchically encodes documents by encoding the word in sentences and the sentences in a document. Inter-annotator agreement for the PAC document labels is high (0.90 F1). The agreement for the entities indicates the annotators are generally identifying the same phenomenon in the chest radiograph reports (“any overlap” agreement 0.85-0.96 F1), although there is variability in the bounds of the annotated spans for the entities (“partial match” agreement 0.49-0.92 F1). The annotation scheme defines entities with type and subtype labels that normalize each span and capture the information most relevant to ARDS, so the variability in the bounds of the span annotations does not materially impact the clinical meaning of the annotations. However, this variability makes span extraction (entity recognition) challenging. To leverage the entity and relation annotations, we introduce an approach for mapping relations to a one-hot encoding of the entity pairs in each relation and use this one-hot encoding of the relations to create a set of sentence classification tasks. The one-hot encoding captures the most important annotated relation information, without requiring the prediction of entity spans. The primary objective of the HANSO framework is the prediction of the document labels associated with ARDS; however, HANSO includes a secondary objective associated with the prediction of the sentence-level one-hot encodings of the relations. The inclusion of the sentence-level objective increases performance, with significance, for the document labels; infiltrates increases from 0.71 to 0.79 F1, and extraparenchymal increases from 0.74 to 0.80 F1. The presence of bilateral infiltrates is predicted with very high performance (0.87 F1). HANSO predicts the one-hot encoded relations with high performance (0.83 F1), indicating the model is able to identify the key information from the fine grained annotations without explicit knowledge of span information. HANSO also outperforms a strong SVM baseline from recent ARDS information extraction work, with significance. We also assess the performance of manual (human) and automatic HANSO chest radiograph reports labels relative to annotated chest radiograph images. In the identification of bilateral infiltrates, HANSO achieves high performance against the annotated images (0.87 F1), which is comparable to the human performance (0.84 F1).

ARDS is a common complication of COVID-19 infection with high mortality; however, the identification of ARDS is often delayed or missed entirely. Delays in diagnosis lead to delays in evidence-based therapies that can improve clinical outcomes in COVID-associated ARDS. To our knowledge, this is the first study in COVID-19 that uses radiology reports to develop an automated NLP algorithm for identifying indicators of ARDS. The extracted ARDS indicators can be combined with additional clinical data to implement the real-time surveillance of ARDS in COVID-19 infected populations and ensure early implementation of evidence-based strategies for decreasing ARDS mortality. As next steps, we will complete an external validation of the data set and modeling framework to prepare for the deployment of an ARDS diagnostic tool. Specifically, the developed HANSO algorithm and trained model will be incorporated into a larger diagnostic tool that will be released and validated within the Electronic Medical Records and Genomics (eMERGE) Network to support pulmonary phenotyping efforts across different sites.

Toward Understanding Clinical Context of Medication Change Events in Clinical Narratives

Diwakar Mahajan\textsuperscript{1}, MS, Jennifer J. Liang\textsuperscript{1}, MD, Ching-Huei Tsou, PhD
IBM T.J. Watson Research Center, Yorktown Heights, NY

Abstract

Understanding medication events in clinical narratives is essential to achieving a complete picture of a patient’s medication history. While prior research has explored identification of medication changes in clinical notes, due to the longitudinal and narrative nature of clinical documentation, extraction of medication change alone without the necessary clinical context is insufficient for use in real-world applications, such as medication timeline generation and medication reconciliation. Here, we present a framework to capture multi-dimensional context of medication changes documented in clinical notes. We define specific contextual aspects pertinent to medication change events (i.e. Action, Negation, Temporality, Certainty, and Actor), describe the annotation process and challenges encountered while creating the dataset, and explore models based on state-of-the-art transformers to automate the task. The resulting dataset, Contextualized Medication Event Dataset (CMED), consisting of 9,013 medications annotated over 500 clinical notes, will be released to the community as a shared task in 2021-2022.

Introduction

An accurate medication history is foundational for providing quality medical care, allowing healthcare providers to better assess the appropriateness of current treatments, detect potential medication-related pathologies or symptoms, and direct future treatment options. Although medication information is captured in various sources of clinical data, in practice, providers often rely on structured medication orders due to easier access in electronic health record systems. However, many medication events are documented only in unstructured clinical notes\textsuperscript{1, 2}, which contain richer information but are difficult to search through especially at the point-of-care. In clinical practice, several scenarios may occur where a medication change is documented in clinical narratives but not in structured medication data. For example, if the patient already has a medication, the provider may instruct the patient to adjust the dosage or temporarily hold the medication without indicating the change in the medication order. Patient-initiated medication changes are also rarely captured in structured medication data, but would be documented in unstructured clinical narratives. Therefore, capturing medication event information from unstructured data within the patient medical record is required to achieve a full and complete picture of the patient’s medication history.

When extracting medication changes from clinical text, it is important to consider the surrounding contextual information because of the longitudinal and narrative nature of clinical documentation. Specifically, the longitudinal quality of clinical text results in documentation of events over the course of the patient’s medical history, from past and present events to future possible events. In addition, when documenting a clinical interaction with a patient, providers not only record what has occurred in the patient and the plan forward, but may also describe their clinical reasoning behind any medical decisions, including why certain treatment options were deferred. Such qualities of clinical documentation result in complex clinical events that would be insufficiently captured by extraction of medication change alone without consideration of the surrounding clinical context. This is especially true when developing a medication change extraction system to support real-world applications, such as medication timeline generation\textsuperscript{3, 4} or medication reconciliation\textsuperscript{5, 6}. For example, to generate a medication timeline, a system must extract not only the dosage adjustment action, but also place it in the correct point in time, i.e. knowledge of when the action is occurring. Similarly, medication reconciliation requires awareness of not just what medications were prescribed by healthcare providers, but also whether the patient is taking (or not taking) a medication, i.e. knowledge of patient-initiated actions.

To address the need for consideration of contextual information during medication change extraction, here we propose a conceptual framework to organize multi-dimensional context for medication events in clinical narratives, and present the resulting dataset – Contextualized Medication Event Dataset (CMED). CMED captures pertinent context for medication change events along five orthogonal dimensions (i.e. Action, Negation, Temporality, Certainty, and Actor), and

\textsuperscript{1}Equal contribution
will be released to the research community as a shared task in 2021-2022. To the best of our knowledge, CMED will be the first dataset on medication change events made available to the research community. The major contributions of this paper are:

- a dataset of 9,013 medication mentions annotated with contextualized medication change events over 500 clinical notes,
- insights into the language used by clinicians when documenting medication changes and the challenges in interpreting this language during the annotation process, and
- experimental results showing that support vector machines (SVM) and transformer-based models can partially automate this task, with error analysis providing insights into the most challenging aspects of this task.

Related Work

Previous attempts in classifying medication change events in clinical notes were driven by a variety of use cases. For example, some prior works focused only on specific medications, while others focused on specific types of medication changes but for all medications. Past works targeting specific medications include work on warfarin (labels on or stop)\(^7\), heart failure medications (labels active, discontinued, or negative)\(^9\), beta blockers (labels active, medication list, negated, discontinued, or other)\(^9\), and dietary supplements (labels continuing, discontinued, started, unclassified)\(^10\). In other works targeting medication changes but for all medications, Liu et al. focused only on medication discontinuation events\(^12\), Sohn et al. considered a greater range of medication changes (labels start, stop, increase, decrease, no-change)\(^13\), Lerner et al. also included labels that indicate sequential changes (labels start, start+stop, stop, continue, switch, decrease, increase)\(^14\), and Pakhomov et al. introduced temporal information in one of their labels (labels past, continuing, stop, start, not classified)\(^15\). Note that these works, driven by a variety of use cases, have resulted in a mixed set of labels, some of which may not cover all types of changes (e.g. labels used by Pakhomov et al. - past, continuing, stop, start, not classified\(^15\), do not differentiate between increase and decrease), or do not cover all aspects of a medication event (e.g. labels used by Sohn et al. - start, stop, increase, decrease, no-change\(^13\), cover all types of changes but do not provide temporal information).

In another body of work, attempts have been made to recognize context or assertions for medical concepts such as problems and tests\(^16\)–\(^19\). There have also been attempts at identifying negated medical concepts in clinical text\(^17, 20–23\). Although some of these works identify aspects such as certainty and negation in medical events, none of them have been applied to medication change events. Further, no previous work has attempted to identify the actor behind an event, which is especially important for medication change events due to implications for patient adherence. Thus, there is need for a more organized schema of label definitions that better contextualizes medication events.

Our work differs from previous research in several ways. First, we capture relevant contextual information on top of just identifying medication change in clinical narratives. Second, the contextual information captured is organized along multiple orthogonal dimensions. Finally, we will be releasing our annotated dataset on contextualized medication change events as part of a shared task.

Methods

Data and Annotation

For this study, we used the 2014 i2b2/ UTHealth Natural Language Processing shared task corpus\(^24–26\), which contain a total of 1,304 clinical notes over 296 patients. This corpus was selected due to its longitudinal nature, with 2-5 notes per patient, to allow potential future work in reconciling medication events extracted across different notes. To benefit from the longitudinal nature of this corpus while ensuring sufficient variation in our dataset, we first selected 44 patients from which all notes were chosen (total 199 notes), and then randomly selected 1-2 notes from each of the remaining 252 patients (total 301 notes). The resulting corpus consisted of 500 notes over 296 patients, of which 120 notes were doubly-annotated and adjudicated to measure inter-annotator agreement (IAA). Notes were annotated by a team of three annotators led by a physician. To assist the annotators, medications in the notes were pre-annotated using a medication extraction model\(^27\), and corrected if necessary by the annotators during the annotation process (i.e. incorrect pre-annotations were removed and missed medication mentions were added).
We define a medication change event as any discussion about a medication change for a given patient. The annotation process is as follows. For each medication mention, the annotator first determines whether a medication change is being discussed, and assigns it one of the following medication change event labels:

- **NoDisposition**: no medication change is being discussed, e.g. “pt is on Coumadin”, “continue lisinopril”
- **Disposition**: presence of a medication change being discussed, e.g. “Start Plavix”
- **Undetermined**: unclear if a medication change is being discussed and additional information is required to make the determination, e.g. “Plan: Lasix” – unclear if just stating a medication patient is on (NoDisposition) or starting a new medication (Disposition)

Next, for identified Disposition events, the annotator labels the clinical context for the event along five dimensions:

- **Action**: What is the change discussed? (Start, Stop, Increase, Decrease, OtherChange, UniqueDose, Unknown)
- **Negation**: Is the change being discussed negated? (Negated, NotNegated)
- **Temporality**: When is this change intended to occur? (Past, Present, Future, Unknown)
- **Certainty**: How likely is this change to have occurred / will occur? (Certain, Hypothetical, Conditional, Unknown)
- **Actor**: Who initiated the change? (Physician, Patient, Unknown)

Figure 1 summarizes the annotation process.

Some sample annotations are shown in Table 1. Note that a single medication mention can have 0, 1, or more associated Disposition events. For example, “May try amlodipine if develops cough” has 1 associated Disposition event for amlodipine (Action|Negation|Temporality|Certainty|Actor = Start|NotNegated|Future|Conditional|Physician), while “Was started on metformin at last visit but pt stopped after one week because of GI upset” has 2 associated Disposition events for metformin (Start|NotNegated|Past|Certain|Physician and Stop|NotNegated|Past|Certain|Patient). These dimensions were designed to extract the relevant clinical context for medication change events, allowing us to capture a wide variety of attributes, such as references to past events (Temporality: Past), treatments being considered but not yet decided upon (Certainty: Hypothetical), or episodes of patient nonadherence (Actor: Patient).

While defining this task, we identified certain nuances of the annotation process that led to specific guidelines in our annotation protocol, specifically, the effect of (1) surrounding contextual information and (2) external medication-specific knowledge on label assignment. For contextual information, because providers can copy-and-paste text from previous notes, a sentence that appears to be Present based on tense (e.g. “Start prednisone taper”), when found in the Past Medical History (PMH) note section, actually indicates a Past action. To balance the need for consideration of

contextual information while avoiding annotator error due to cognitive overload from having to remember the entire note, we asked annotators to consider only local context when determining the appropriate label, roughly defined as the immediate sentence containing the medication mention +/- 1 sentence and the note section. For knowledge of a specific medication’s attributes (e.g. drug class, route of administration) affecting label assignment, because some medications are only available by prescription, while others are available over-the-counter, knowledge of a specific medication’s availability can affect whether the Actor is more likely to be Physician or Patient. Similarly, some medications, such as Z-Pak, are dispensed as a set dosage pack with time-limited administration. Therefore, with that knowledge, the medication in a phrase such as “Plan: *Z-Pak*” should be annotated as Start|NotNegated|Present|Certain|Physician and Stop|NotNegated|Future|Certain|Physician. To best reflect the reality of the event, annotators were asked to annotate based on what they believe is going on, even if the assigned label depends on medical knowledge not in the text.

**System Description**

To automate the task of medication change classification, we split the task into five classification subtasks organized in a two-step process:

1. One subtask to classify each given medication mention into Disposition, NoDisposition, or Undetermined
2. Four subtasks to classify each given Disposition medication along four context dimensions: Action, Temporality, Certainty, and Actor. Negation was excluded from our experiments due to limited number of Negated instances.

For each subtask, we train a classification model based on two approaches: (1) SVM, and (2) transformer-based language models. As CMED will be used in a shared task in 2021-2022, we set aside 100 notes from our annotated data as blind data for the task. The remaining annotations in 400 notes are split into 75% for training, 5% for development and 20% for test. In addition to Negation Dimension, OtherChange for Action dimension and Unknown for all dimensions were excluded in our experiments due to the limited number of instances (<40).

**Support Vector Machines.** To explore the dataset and various dimensions, we elected to use a feature-based approach with a discriminative classification algorithm in our experiments. Our features were divided into the following classes: lexico-syntactic, window, dep-parse, note-section, and RxNorm features.

- **Lexico-syntactic.** Standard lexical features were utilized such as n-grams of whole, stemmed and lemmatized words, and part-of-speech tags.
- **Window.** We incorporated windowed lexico-syntactic features where we combined the positional information of word tokens with their lexico-syntactic features for the tokens that appear within of a window of 5 from the target medication mention in either direction. The window size of 5 was empirically determined.
• **Dep-parse.** We utilized features based on the dependency parse structure of the sentence containing the target medication, e.g. neighbors, parent and children of the medication concept in the dependency parse tree.

• **Note-section.** We experimented with a rule-based note section classification model that classifies each sentence based on the section headers and location of the sentence within the note.

• **RxNorm.** We leveraged features derived from RxNorm for the target medication such as Anatomical Therapeutic Chemical class, ingredient etc.

Experiments were performed using SVM with a linear kernel and one-vs-all classification strategy as implemented in scikit-learn. As initial experiments with different kernels (linear, polynomial and radial basis function) showed comparable performance, we chose linear kernel for all of our experiments. We used scispaCy for sentence segmentation and extraction of lexico-syntactic and dep-parse features. RxNorm features were extracted using the RxNorm public API. To deal with skew in class distribution, we adjusted the class weights to be inversely proportional to class frequencies.

**Transformer-based Language Models.** We experimented with state-of-the-art Bidirectional Encoder Representations from Transformer (BERT)-based language models, with the models pretrained on general-domain (BERT-base) and in-domain (ClinicalBERT) datasets. We formulated each of the five tasks as a sentence classification task by providing the surrounding sentence of the annotated medication as the context. In this process, we employed the pre-trained transformer to obtain a distributed representation, 0.2 dropout, and a fully connected layer of size 5 with softmax activation to make the classification for each of the five subtasks. We used the transformers package to tune our models with the train and development splits, and present our results on the test split.

We evaluated our two system approaches with the following experiments on the 20% test data, (1) SVM, (2) BERT-base and (3) ClinicalBERT. We present the micro and macro precision, recall, and F1 scores in the Results section. We also present a majority baseline on the training dataset with majority label for each dimension being chosen as the prediction for comparison against our model.

**Results**

*Inter-annotator agreement and dataset statistics*

Overall, our annotators achieved high IAA based on Cohen’s kappa. On determining whether a medication change was being discussed (Disposition vs NoDisposition vs Undetermined), IAA was 0.88 on 2,495 annotated medication mentions. For the 367 instances of agreed Disposition events, Action, Negation and Temporality had the highest IAA at 0.87, 0.83, and 0.94, respectively, while Certainty and Actor had lower IAA at 0.75 and 0.72, respectively.

The resulting dataset, CMED, consists of 9,013 annotated medication mentions over 500 clinical notes. As CMED will be used in a shared task in 2021-2022, we only report detailed statistics on the training dataset in this paper. The training dataset consists of 7,230 annotated medication mentions over 400 notes, with distribution for specific labels presented in Table 2.

Table 2: Label distribution for the training dataset
As observed in Table 2, less than 20% of medication mentions have an associated Disposition event. Further, a substantial percentage (7.7%) of medication mentions could not be resolved into Disposition or NoDisposition events due to the lack of sufficient information. Within the Action dimension, Start and Stop account for over 64.3% of Disposition events, UniqueDose for 20.2%, and titration events (Increase and Decrease) for 13%. Labels in the Temporality dimension reveal that over half of Disposition events occur in the Past (52.7%), which is reflective of the longitudinal and narrative nature of clinical notes.

Labels in the Temporality dimension reveal that over half of Disposition events occur in the Past (52.7%), which is reflective of the longitudinal and narrative nature of clinical notes. For Certainty, 16.6% of Disposition events are discussed in a Hypothetical or Conditional context. The prevalence of Past events as well as Hypothetical and Conditional events further confirms the need for contextualized medication event information. For Actor, as expected, the majority of medication changes in clinical text are initiated by healthcare providers (90.4%). Finally, Unknown in all dimensions, Negated in Negation dimension, and OtherChange in Action dimension are rare labels, each with less than 40 instances in the dataset.

### System Results

Table 3 shows the results of (1) majority baseline, (2) SVM, (3) BERT-base, and (4) ClinicalBERT against the test dataset. While SVM provides a reasonable baseline, ClinicalBERT yields the best results across all five subtasks.

### Discussion

**Annotator disagreements**

The lower IAA in Certainty can be attributed to the unclear language in physician documentation, for example:

- “This was discussed by her neurologist who suggested starting with cholesterol medication and aspirin. She is here to discuss this further.”
- “We might suggest that she be started on Cisapride 10 mg qd”
- “It might be worthwhile to reduce his atenolol from 75 to 50mg once daily to see if this helps his Sx.”

Hedging language is common in clinical documentation to express the uncertainty inherent in medical decision-making. Reflecting this, different terms expressing varying degrees of certainty are used to indicate a prescribed intervention. For example, terms such as try, recommend, or advise are more definitive, while consider, suggest, or may benefit from require some interpretation to decide whether the action has actually taken place (Certain) or is only being discussed (Hypothetical). Although we attempted to address hedging language in the annotation guidelines, these disagreements reflect the inherent subjectivity in interpreting clinical language given the complexity and ambiguity in certain aspects of clinical documentation.

Disagreements along the Actor dimension were mostly found in references to past events, e.g. “Improved breathing with spiriva, mistakenly stopped Advair”, where the subject who initiated the action is unspecified and was interpreted...
differently by different annotators. Another interesting kind of disagreement was due to shared decision-making in clinical care, where both the patient and physician contribute to medical decisions and treatments, e.g. “Discussed changing from Avapro to losartan for cost issues but he is uninterested and does not want to rock the boat.”

**Error Analysis**

We conducted error analysis on the best performing model (i.e. ClinicalBERT) and identified three major categories of errors: (1) medication mentions with multiple annotations, (2) multiple medications within the same sentence, and (3) medication mentions that require context beyond the immediate sentence to determine the label. Examples for each of these error categories are shown in Table 4.

**Table 4:** Common error categories with examples, across five classification subtasks for the ClinicalBERT model.

<table>
<thead>
<tr>
<th>Error Category</th>
<th>Example</th>
<th>Medication</th>
<th>Ground Truth</th>
<th>Prediction</th>
</tr>
</thead>
<tbody>
<tr>
<td>Medication mentions with multiple annotations</td>
<td>In addition, 8 days prior to admission, pt’s regular lasix dose was increased from 80 to 120 mg for four days, then reduced back to 80 mg.</td>
<td>lasix</td>
<td>Increase</td>
<td>Decrease</td>
</tr>
<tr>
<td>Multiple medications within the same sentence</td>
<td>We could change his statin from Mevacor to Lipitor to increase the HDL.</td>
<td>Mevacor, Lipitor</td>
<td>Stop</td>
<td>Start</td>
</tr>
<tr>
<td>Limited context</td>
<td>P: He will restart glyburide 5 mg q.d. when his blood sugar is greater than 200.</td>
<td>glyburide</td>
<td>Conditional</td>
<td>Certain</td>
</tr>
</tbody>
</table>

A significant percentage of errors occur due to medications having multiple event annotations. For example, in “In addition, 8 days prior to admission, pt’s regular lasix dose was increased from 80 to 120 mg for four days, then reduced back to 80 mg.” the medication lasix has two labels for the Action dimension (Increase & Decrease). Since our current classification setup only allows for one prediction per medication mention, the model predicts only a single label Decrease for the Action dimension, leading to an error. Although medication mentions with multiple annotations form a small fraction of our overall dataset (1.2%), this error category accounts for a large percentage of errors across all dimensions (33% of Action errors, 23% for Temporality, 22% for Certainty, and 32% for Actor). One way to address this is to reformulate our task from a sentence classification task to a multi-label classification task.

Next, we observed that multiple medications present within the same sentence lead to errors as the model is unable to differentiate between the target medications. For example, “We could change his statin from Mevacor to Lipitor to increase the HDL.” contains two medications, Mevacor and Lipitor, that each have an Action label of Stop and Start, respectively. However, since they share the same context (i.e. sentence), the model predicts both the labels as Start. To resolve this, the system needs to more precisely identify the context for each medication mention. This can be achieved by reformulating this task as a named entity recognition task.

Finally, we observed a number of errors due to the limited context of a single sentence being available to the model for prediction. For example, in Table 4, the strike-through text “when his blood sugar is greater than 200” was not fed into ClinicalBERT. Hence the model made the correct prediction (Certainty: Certain) under the limited context given (“P: He will restart glyburide 5 mg q.d.”). While improved sentence segmentation will help this instance, a more general solution such as sequential sentence classification is likely to improve this error category.

**Limitations**

We acknowledge certain limitations to our work, specifically, those due to the nature of the underlying corpus and those that can be attributed to our annotation guidelines.

CMED is built on top of the corpus used in the 2014 i2b2/UTHealth Natural Language Processing shared task. Since this corpus was selected for the purposes of the 2014 i2b2 shared task and therefore focused heavily on diabetes and heart disease patients, it is not representative of a typical patient population. Further, the corpus is limited to a single data warehouse i.e. Partners HealthCare Electronic Medical Records. Reproduction of our work on more diverse corpora is needed to better understand the effectiveness and applicability of our schema.

The current task focuses primarily on the identification and classification of contextual information for medication
change events. Medication mentions that do not discuss change are all grouped under a single label, i.e. NoDisposition, including descriptions of medication status (e.g. “currently taking lisinopril”), explicit directions to continue an existing medication (e.g. “continue metformin”), documented allergies to medications (e.g. “sulfa (rash)”), and other incidental mentions of medications. Depending on the specific use case and application, there may be value in further teasing out these different types of NoDisposition events. Further, although the current schema captures coarse temporality information of medication change events, extraction of more specific temporal references (e.g. “at last visit”, “x 10 days”) is needed to place these events in a more precise point in time. Finally, there may be additional contextual information that could contribute to improved understanding of medication changes but was not included in our annotation schema, such as the magnitude of change (i.e. what is the degree of change?) and the reason behind the change (i.e. why was this change introduced?). Such information was excluded from our current effort because of difficulties in defining a set of discrete labels to capture all possible values. Future work can be undertaken to provide such information through an extraction task built on top of CMED.

Applications and Future Work

Medication change events classified under the proposed schema can be directly leveraged in several real-world applications. Various visualizations and dashboard displays have been proposed to improve the usability of EHR systems, many of which include a medication timeline based on structured medication data. Future research can be undertaken to apply analytics developed on CMED to such applications. For example, Present and Certain actions identified from clinical narratives under our schema can be incorporated into such medication timelines to further enrich them for a more comprehensive representation of a patient’s medication history. These same events can also be presented alongside structured medication data to surface potentially missed or incorrect medication information in the structured data for purposes of medication reconciliation. Separately, patient-initiated actions captured under our schema can be used to supplement pharmacy prescription filling data towards improved understanding of medication nonadherence. Figure 2 shows an example of how such extracted multi-dimensional medication events may be used at the point-of-care, allowing users to control the information flow depending on their needs and specific use case.

Figure 2: Prototype visualization incorporating extracted medication change events into structured EHR data showing all Present Certain events associated with the medication hydralazine.

CMED was purposefully generated on a longitudinal corpus (2014 i2b2 corpus with 2-5 notes per patient) to allow future work in tracking events for a specific medication over time, to support applications such as medication timeline visualization and summarization systems. To better support such applications and also more fully utilize the clinical context captured in CMED, additional research is necessary in several directions. First, 7.7% of medication mentions in CMED were classified as Undetermined, which can potentially be classified as either Disposition or NoDisposition.
tion given additional information. Further research in incorporating other sources of medication information (e.g. structured medication orders) is needed to better understand and characterize Undetermined events. Second, although temporal information is captured in the current schema, additional research is needed for applications that need temporal alignment or to place events in a more precise point in time. Third, the current schema classifies medications at an instance level, meaning that a single medication change occurrence that is documented multiple times in a patient’s medical record will result in multiple instance-level events. Therefore, further work in concept normalization and coreference resolution is needed to resolve instance-level events in and across clinical narratives. Finally, to make CMED more useful in real-world settings, more work needs to done to identify the contradictions between different events recorded for the same medication and resolve them.

Conclusion

We introduce CMED, a dataset capturing contextual information – Action, Negation, Temporality, Certainty, and Actor – for medication change events documented in clinical notes, consisting of 9,013 annotated medication mentions over 500 notes. We describe our annotation guidelines, discuss specific nuances observed during the annotation process, and explore state-of-the-art transformer-based models to automate the task. As the first dataset on medication change events to be made available to the research community, CMED provides the necessary first step towards improved understanding of medication events in clinical narratives. We hope this effort will encourage future research and exploration into leveraging medication information from clinical narratives, and also contribute to other use cases that require consideration of contextual information for clinical events.

Abstract

Women at high risk for breast cancer may benefit from enhanced screening and risk-reduction strategies. However, limited time during clinical encounters is one barrier to routine breast cancer risk assessment. We evaluated if electronic health record (EHR) data downloaded using Fast Healthcare Interoperability Resources (FHIR) is sufficient for breast cancer risk calculation in our decision support tools, RealRisks and BNAV. We accessed EHR data using FHIR for six patient advocates, and downloaded and parsed XML documents. We searched for relevant clinical variables, and evaluated if data was sufficient to calculate risk using validated models (Gail, Breast Cancer Screening Consortium [BCSC], BRCAPRO). While only one advocate had sufficient EHR data to calculate risk using the BCSC model only, we identified variables including age, race/ethnicity, mammographic density, and prior breast biopsy in most advocates. EHR data from FHIR could be incorporated into automated breast cancer risk calculation in clinical decision support tools.

Introduction

Breast cancer is the most common cancer among women in the United States, with approximately 280,000 new cases and 40,000 deaths from breast cancer each year.1 While breast cancer mortality has declined over the past three decades because of improved detection and therapeutic advances, this decline has begun to plateau, particularly among racial/ethnic minorities.2 The identification of women who could benefit from enhanced breast cancer screening and preventive measures could further improve breast cancer mortality. Women at high risk for breast cancer, defined as an estimated 5-year risk of invasive breast cancer ≥1.67% and/or lifetime risk ≥20%, are eligible for chemoprevention with anti-estrogen agents, which reduce the risk of invasive breast cancer by approximately 50% to 65%.3,4 In addition, multiple national medical organizations recommend more intensive screening with annual mammography and consideration of supplemental breast MRI or ultrasound among high-risk women5-11. However, rates of chemoprevention uptake remain low12, with barriers that include concerns about potential side effects of treatment, insufficient knowledge about breast cancer risk assessment and chemoprevention among patients and providers, and time constraints during clinical encounters13-16. There is therefore a clear unmet need for interventions to facilitate accurate breast cancer risk assessment and enhance shared decision-making about breast cancer screening and risk-reducing measures.

We have developed the web-based decision support tools RealRisks and Breast cancer risk NAVIgation (BNAV) for patients and primary care providers, respectively, that calculate an individual patient’s estimated breast cancer risk using validated models17-18 and include interactive educational modules on breast cancer risk assessment, genetic testing, screening, and chemoprevention19-22. RealRisks is patient-facing and available in English and Spanish, while BNAV is provider-facing. Through these interventions, we aim to improve accuracy of patients’ breast cancer risk perception, enhance breast cancer screening and chemoprevention knowledge, and inform decisions regarding genetic testing, screening and risk reduction. One barrier to seamless integration of RealRisks and BNAV into clinic workflow is the requirement for manual input of patients’ personal and family history for individualized breast cancer risk calculations. Current breast cancer risk models incorporate information including patient age, race/ethnicity, breast density (assessed during mammography), reproductive history, prior breast biopsy (and pathologic diagnoses), and family history. Automation of patients’ breast cancer risk calculations using data extracted from the electronic health

843
record (EHR) could allow for more rapid, routine risk assessment. In addition, automated presentation of patients’ relevant medical histories to patients and providers could facilitate shared decision-making regarding therapeutic decisions such as recommendations regarding chemopreventive agents and lifestyle modification for risk reduction.

Fast Healthcare Interoperability Resources (FHIR) is a standard and application programming interface (API) created by the Health Level Seven International (HL7) health-care standards organization for the exchange of electronic healthcare information across platforms, particularly to support automated clinical decision support. To facilitate faster, logical, and consistent data exchange among healthcare applications, FHIR defines and organizes data elements into “resources,” such as “Condition,” “Procedure,” and “FamilyMemberHistory,” that are easily identified and understood by recipient applications. Multiple widely-used EHR vendors, including Epic and Cerner, support FHIR in order to comply with national regulatory requirements for interoperability from the Centers for Medicare and Medicaid Services (CMS) and Office of the National Coordinator for Health Information Technology (ONC). FHIR has previously been evaluated as a potential method of automatically populating documentation and registries in clinical trials, which might allow for streamlined identification of potential candidates for enrollment and more seamless clinical trial data sharing. FHIR therefore might also facilitate automated breast cancer risk calculation.

Utilizing a unique multidisciplinary team composed of biomedical informaticists, software developers, and medical oncologists from Columbia University Irving Medical Center in New York, NY, we evaluated whether the FHIR standard could support automated breast cancer risk calculations in RealRisks and BNAV as well as presentation of relevant patient medical history to patients and providers to facilitate shared decision-making.

Methods

Clinical Variables of Interest for Risk Calculation

Our primary objective was to find clinical variables within patient data downloaded from the FHIR API to allow for future automation of breast cancer risk calculation in RealRisks and BNAV. RealRisks and BNAV use two validated risk models, the Gail and Breast Cancer Screening Consortium models, to estimate a patient’s breast cancer risk, and the BRCAPRO tool to estimate a patient’s risk of carrying a deleterious mutation in BRCA1 and/or BRCA2, which are associated with up to an 80% lifetime risk of developing breast cancer. The clinical variables required for these models are summarized below (Table 1). While there are differences across models in the types of variables required, variables generally fall into one of five categories: 1) Demographics, 2) Reproductive factors, 3) Family history of breast cancer, 4) Breast pathology, and 5) Breast imaging.

Table 1. Summary of variables required for breast cancer risk calculation according to the Gail, Breast Cancer Surveillance Consortium (BCSC), and BRCAPRO models.

<tr>
<td><strong>Breast Imaging</strong></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Mammographic density (BI-RADS)</td>
<td></td>
<td></td>
<td>X</td>
</tr>
</tbody>
</table>
Of note, the BCSC model requires classification of pathology results into: 1) Prior biopsy, unknown diagnosis; 2) Non-proliferative lesion; 3) Proliferative changes without atypia; 5) Proliferative changes with atypia; 6) Lobular carcinoma in situ, as well as classification of mammographic density into the four BI-RADS categories: 1) Almost entirely fatty; 2) Scattered fibroglandular densities; 3) Heterogeneously dense; 4) Extremely dense.

In addition, a secondary objective was to find additional relevant medical history within patient data downloaded from the FHIR API that could be presented within RealRisks and BNAV with the goal of facilitating shared decision-making about chemoprevention and other risk-aligned preventive options. The variables of interest are summarized below (Table 2). These variables were chosen for their potential to guide choice of chemoprevention (for example, menopausal status, history of thrombosis or endometrial cancer, osteoporosis), discussion of testing for hereditary cancer syndromes (family history of non-breast cancers including pancreatic and prostate), and recommendation for other non-chemoprevention risk-reducing measures (for example, alcohol use, body mass index [BMI]).

### Table 2. Summary of variables of interest to facilitate shared decision-making about breast cancer prevention.

</table>
We invited six patient advocates to access RealRisks and allow for their EHR data to be downloaded using our RealRisks SMART on FHIR add-on. We used FHIR versions Second Draft Standard for Trial Use (DSTU2), Release 3 Standard for Trial Use (STU3), and Release 4 (R4), and only accessed data from medical providers utilizing the Epic EHR. In order to locate clinical variables within FHIR, we downloaded data from the following FHIR resources: “Patient,” “CarePlan,” “DiagnosticReport,” “Condition,” “MedicationStatement,” “Procedure,” “Observation” (Smoking History, Vitals, Labs), “FamilyMemberHistory,” and “DocumentReference” (Consolidated-Clinical Document Architecture [CCDA] documents). These resources consisted of documents formatted via XML.

### Data Parsing

We automatically parsed patient birthdate, race, and ethnicity from the FHIR “Patient” resource. The remainder of data from the FHIR API was downloaded the form of XML documents, which we parsed to have a tree structure using the lxml package (version 4.5.2) in Python (version 3.8.3). Two file types, “Patient Health Summary” and “Encounter Summary,” as well as many components contained in these files (such as patient allergies, medications, problems, test results, and coded diagnoses) were identified and separated for information extraction. Keywords related to the variables of interest were searched using regular expression and then exported.

### Results

We successfully accessed EHR data for all six patient advocates. We automatically populated patient birthdate, race and ethnicity from the FHIR “Patient” resource into the RealRisks application. The RealRisks patient-facing window for risk calculation using the BCSC model (Figure 1) incorporates automatically populated variables alongside variables that were manually populated by the study team at time of patient RealRisks account creation.

![Figure 1](image-url)  
*Figure 1.* Example of a RealRisks patient-facing window for risk calculation using the BCSC model. Birthdate, race, and ethnicity (on the left) are automatically populated from the FHIR “Patient” resource. Family history of breast cancer in a first-degree relative was not auto-populated, and was documented as “unknown.” When family history is not available in the EHR, patients can enter this data by interacting with the pedigree generating function in RealRisks. On the right, variables including personal history of breast cancer or surgery, mammographic density, and prior breast biopsy were manually populated by the study team at the time of RealRisks account creation, and the patient is given the option to request changes in the current version.

We then parsed the “Patient Health Summary” and “Encounter Summary” XML files for each of the six advocates. While each patient had one “Patient Health Summary” file summarizing key clinical data, a single patient could have multiple “Encounter Summary” documents, with each file representing a single encounter (such as office visit, hospitalization, imaging study). For example, one patient advocate had 153 “Encounter Summary” files representing 153 separate encounters in Epic. The contents of these files are summarized below (Table 3).
Table 3. Contents of “Patient Health Summary” and “Encounter Summary” XML files downloaded from FHIR. A component would be present in the document if the patient has relevant records.

Shown below are available FHIR data for breast cancer risk calculation and additional relevant clinical variables for each patient advocate and in total (Table 4). Among those variables required for risk calculation, variables with documentation in the majority of advocates were age (100%), race/ethnicity (67%), history of benign breast biopsy and number of breast biopsies (67%), and mammographic breast density (67%). Only one-third of advocates had documentation of family history including first- or second-degree relative with breast cancer and relative with ovarian cancer, male breast cancer, or bilateral breast cancer, and none had documentation of Ashkenazi descent or reproductive factors including age at menarche and age at first live birth. While one (17%) had documentation of a history of atypical hyperplasia, no patient advocate had available breast pathology reports. One advocate (Patient Advocate #1) had sufficient data from the FHIR XML files to calculate risk using the BCSC model, but no patient advocate had sufficient data to calculate risk using the Gail model or BRCAPRO.

Among relevant (but not required) clinical variables, all advocates (100%) had documentation of blood pressure as well as height and weight for calculation of BMI. Half of advocates had breast ultrasound reports, and one had a breast MRI report. The remainder of variables had documentation in one or no advocate. For example, while one advocate had documentation of menopausal status, none had age of menopause or number of live births documented. No advocate had a genetic testing results report or a genetic counseling note.

Table 4. Available FHIR data for relevant clinical variables for each patient advocate and in total. An X denotes that documentation of a variable was found in XML files for that individual “Continued”.

Discussion:

We evaluated whether the FHIR standard could support automated breast cancer risk calculations in RealRisks using data downloaded for six patient advocates. While only one patient advocate had sufficient information for risk calculation using the BCSC model and none had complete information for risk calculation using the Gail or BRCAPRO models, we found that the majority of advocates had documentation of age, race/ethnicity, prior breast biopsy, and mammographic density. We also found additional data, including vital signs (blood pressure, BMI) and coexisting medical conditions, that would be relevant to patient-provider discussions and decision-making regarding chemoprevention and risk-reducing measures.

To our knowledge, our group is the first to investigate the use of the FHIR API to enhance and automate breast cancer risk calculation. Our current project represents our initial attempts to locate relevant patient data in downloads from the FHIR API, and even with a small sample size of only six patients, demonstrates that data for variables including breast pathology, breast imaging, vital signs, and race/ethnicity can be successfully found in FHIR downloads. We previously demonstrated that there was moderate agreement between information on breast cancer risk extracted from the EHR compared to patient self-report30, and also found that while self-report identifies more women who are potentially eligible for chemoprevention or genetic testing for hereditary breast and ovarian cancer (HBOC) based upon family history, more specific information on breast pathology or mammographic density can be obtained from the EHR30,31.

In this study, certain categories of patient data, particularly gynecologic history, family history of cancer, and history of genetic counseling and testing, were documented less frequently than other data types or not at all. This is consistent with our previous finding that family history is better represented in self-report than EHR data, but also highlights the limitations of using EHR data alone in risk calculation, with the potential for missing or inaccurate data12,34. The presence of information is dependent on documentation by providers in the EHR, which often does not include regular documentation of pertinent negative history (for example, that a patient does not have a family history of breast cancer) and also varies based upon individual providers’ scope of practice. Some missing data can also be explained by current gaps in FHIR coverage. For example, FHIR DSTU2 does not support sharing progress notes, and gynecologic history and family history are often present free-text in progress notes and not in structured data. FHIR R4 is anticipated to provide this coverage, but R4 support for progress notes was not available at the time of our study. However, an important consideration is that much of the information required for adequate and accurate risk assessment, if present, is dispersed throughout patients’ medical charts, recorded by multiple providers in different places such as progress notes and mammography reports and in both structured and unstructured form35. Finding such data requires approaches that search for free-text within notes and other documents, in addition to structured data such as billing codes.

One potential solution for automated risk calculation in our RealRisks and BNAV decision support tools is to incorporate both self-reported data and data automatically populated using the FHIR API, with the goal of harnessing the strengths of each approach. We plan to update RealRisks to automatically populate the necessary patient information for risk calculation, with a screen that shows this data to patients with a request to review and modify data before running the risk assessments. This will allow for patients to add any missing data and correct erroneous data, with the goal of making the process faster and more accurate. If feasible, an ultimate goal is to store this semi-automated, patient-corrected risk information and return to the EHR for ongoing use by providers; given that our work is still in early stages, we have not yet implemented this. In future, we also plan to develop a screen for both patients and providers to review automatically populated additional medical history that would be relevant to shared decision-making about breast cancer risk reduction with chemoprevention, testing for susceptibility genes, screening and other preventive strategies. While a personalized approach to prevention or early detection of breast cancer has emerged as a highly promising strategy, several barriers exist including the time required to conduct risk assessment of each women in a population36. Presenting a summary of auto-populated relevant history to the provider could save
time during patient encounters and enhance discussions and recommendations about personalized screening and prevention options, which could overcome some barriers to increasing the uptake of underutilized breast cancer prevention services.

We are currently evaluating RealRisks and BNAV in a randomized controlled trial among women with high-risk breast lesions (atypical hyperplasia, lobular or ductal carcinoma in situ); patients and their providers will be randomized to have access to these tools plus standard educational materials versus standard educational materials alone, and the frequency of chemoprevention informed choice will be compared at six months[77]. Given that the majority of participating sites in this trial use Epic, we anticipate that we will have access through the RealRisks SMART on FHIR add-on to many participants’ EHR data, and therefore we plan to implement our automated risk calculation method described above to evaluate usability among a larger cohort of women. In particular, this trial will allow us to evaluate the accuracy of the EHR data pulled from FHIR through comparison with breast cancer risk data that is manually entered by the study team at time of patient enrollment. In addition, our data parsing during this initial study was more time-intensive given that we sought to locate data within the downloaded data files, but we will next use natural language-processing methods to parse unstructured data from progress notes, particularly to automatically extract family history.

Strengths of our study, as stated above, include its innovative approach to meet the unmet clinical need of automating breast cancer risk calculations utilizing FHIR data, as well as our creation of a multidisciplinary team including medical oncologists, biomedical informaticists, and software developers to best inform our study questions and approach. A major limitation is its small sample size of only six patients, of whom all were patient advocates known to the study team; this likely introduced bias into the type of data variables that would be found (or missing) in the downloaded files, and therefore might limit the generalizability of our findings. However, this study represented an initial analysis of the feasibility of using FHIR to obtain breast cancer risk factors from the EHR, and further evaluation of our methods using a larger population in a prospective clinical trial will overcome these limitations.

**Conclusion:**

We were able to identify relevant patient data in FHIR that could be incorporated into automated breast cancer risk calculation in the RealRisks and BNAV decision support tools. We will next evaluate an automated risk calculation method incorporating patient EHR data from FHIR as part of an ongoing prospective clinical trial among patients at high risk for developing breast cancer.

Abstract

Early detection and mitigation of disease recurrence in non-small cell lung cancer (NSCLC) patients is a nontrivial problem that is typically addressed either by rather generic follow-up screening guidelines, self-reporting, simple nomograms, or by models that predict relapse risk in individual patients using statistical analysis of retrospective data. We posit that machine learning models trained on patient data can provide an alternative approach that allows for more efficient development of many complementary models at once, superior accuracy, less dependency on the data collection protocols and increased support for explainability of the predictions. In this preliminary study, we describe an experimental suite of various machine learning models applied on a patient cohort of 2442 early stage NSCLC patients. We discuss the promising results achieved, as well as the lessons we learned while developing this baseline for further, more advanced studies in this area.

Introduction

Lung cancer is the most common cause of cancer related mortality in the world. Globally in 2018, more than 2 million new cases were diagnosed and more than 1.8 million deaths due to lung cancer occurred1, where the main risk factor for the development of the disease is tobacco. In recent years, while mortality in men has decreased slightly due to smoking cessation, mortality in women has increased and has practically doubled due to its later incorporation into smoking habit2. Non-small cell lung cancer (NSCLC) accounts for approximately 80% of all lung malignancies. The diagnosis of lung cancer in early stages remains a challenge and often occurs incidentally in the study of other diseases3. Approximately 70% of patients are diagnosed in locally advanced stages (stage III) or metastatic disease (stage IV)4, which contributes to low survival rates. Of note, survival declines progressively with increasing clinical stage. Overall survival at 5 years in NSCLC is around 10–15%5. Early stage NSCLC (stage I-II) patients are typically treated with complete surgical resection of the tumor. However, even after the entire resection of the tumor, 30–55% of patients will develop disease recurrence within the first 5 years of surgery6. This encouraged research into applying survival analysis methods and machine learning models to identify patients with high risk for recurrence to help in personalizing surveillance plans for these patients.

Predictive approaches for identifying tumor recurrence in NSCLC patients utilize different types of techniques such as statistical analysis of patient Electronic Health Records (EHRs), machine learning models and patient self-assessment feedbacks. The simplest form of these methods is the self-assessment techniques which rely on continuous patient self-evaluation and reporting after successful treatment7. This technique traditionally requires patients to perform self-assessment in terms of symptoms, physical abilities and other metrics, and report these metrics to hospitals through previously specified means e.g. mobile applications, and online forms8. It then notifies the physician when certain patterns appear in the patient recorded metrics8. Due to the simplicity of the approach, it cannot provide early predictions of the tumor recurrence, and it relies on patients compliance to reporting which is not guaranteed9.

On the other hand, statistical survival analysis methods and supervised machine learning models are able to provide early predictions for the tumor recurrence based on the patient characteristics and previous treatments history. One of the simplest forms of the statistical analysis tools is nomograms10, which are a graphical representations of equations that predict medical outcome. Nomograms use a points-based system whereby a patient accumulates points based on levels of his or her risk factors, where the cumulative points total is associated with a prediction. More complex techniques such as the Cox hazard model can provide a time-based analysis of the patient hazards e.g. tumor recurrence.
The Cox hazard model is one of the most widely used techniques in predicting recurrence and other prognosis factors in NSCLC patients. Despite its popularity, however, the Cox hazard model operates strictly with multiple assumptions, e.g., feature independence, linear relations, etc., which are not always guaranteed. It also cannot consume heterogeneous data such as medical imagery, genetic arrays, etc. These two limitations are addressed in supervised machine learning models such as random forests, support vector machines, neural networks, etc., which operate using different techniques that make them suitable for modeling complex relations on heterogeneous data.

Supervised models were used in different studies to predict NSCLC recurrence from patients' EHRs, where different studies have shown that they provide superior predictive accuracy compared to classical survival analysis methods, such as the Cox hazard model. However, these studies traditionally only examine a limited set of supervised machine learning approaches, and they also rely on differently structured patient records due to the different data collection protocols. These two factors make it difficult to perform a more representative comparison between the survival analysis methods and the different supervised machine learning models. Therefore, it is essential to establish rigorous means for comparison between the different supervised predictive models and statistical survival analysis techniques on unified patient EHRs structure to understand the differences between these techniques, and establish informative baselines for the task of predicting NSCLC recurrence.

In this work, we study the problem of predicting recurrence in NSCLC patients where we discuss our first-steps towards building an efficient and accurate prediction approach within the CLARIFY project — a European project focused on monitoring health status and quality of life after the cancer treatment (cf., https://www.clarify2020.eu/). Based on the previously discussed developments and challenges in relation to predicting recurrence in NSCLC patients, we started our development by assessing the performance of the basic supervised machine learning models in NSCLC recurrence prediction to establish a baseline benchmark.

In this study, we provide the outcomes of our assessment of the basic supervised machine learning methods on patient cohort of 2442 early stage NSCLC patients, where we evaluate these models on a binary classification task with the objective of classifying patients with successful treatments into one of two categories: tumor recurrence or disease-free survival. We also discuss the challenges associated to the application of these methods in terms of model accuracy, data quality, and utilized evaluation protocols.

Related Work

In the following, we discuss other works related to our study where we categorize these works into two categories: survival analysis methods and other machine learning supervised and unsupervised methods.

- **Survival analysis methods.** Survival analysis methods such as the Kaplan–Meier and Nelson–Aalen estimators, the proportional hazards models, etc., are the most common approach for predicting prognosis, relapse and other clinical outcomes of lung cancer patients. For example, (author?) used the Cox hazard to predict long-term mortality/survival after lung cancer resection in patients older than 65 years on Medicare data for lung cancer resections. These models were also used in more specific survival analysis studies which focused on patients' survival in relation to specific bio-markers and chemotherapy drug configurations. Similarly, study conducted by Wen et.al. in 393 North American patients with NSCLC used Cox proportional hazard model to investigate associations between functional genetic variants of autophagy-related genes and radiation pneumonitis as well as clinical outcomes after definitive radiotherapy. The multi-variable Cox model enabled them to predict radiation pneumonitis, local recurrence-free survival, progression-free survival, and overall survival of NSLC patients.

On a similar note, (author?) used survival analysis methods in their study to examine the causes of death of long-term survivors of lung cancer where they utilized the Surveillance, Epidemiology and End Results (SEER) database (1988–2008). They conducted a survival analysis using a Kaplan–Meier estimator and conducted a multivariate analysis using a Cox proportional hazard where the study concluded that cardiac as well as non-malignant pulmonary condition contributes considerable proportion of deaths in long-term lung cancer survivors.

- **Supervised machine learning models.** Multiple studies of non-small cell lung cancer (NSCLC) postoperative recurrence have utilized supervised machine learning model to predict the probability of tumour recurrence and other
### Table 1: Analysis of the characteristics of the patient cohort examined in our study in relation to tumor recurrence. The summation of the total percentages of the sub characteristics can be less than 100 for some of the examined features due to missing data values of this type of data for some patients EHRs.

Related factors[^10]. For example, (author?)[^20] have studied the associations between age, comorbidity, and other patient factors and treatment of postoperative NSCLC recurrence where they used a logistic regression to predict the postoperative prescribed treatment type – active or palliative. Supervised methods is able to operate on different types of data such as images, sequence and structured tabular data, therefore, they were utilized in different studies to consume heterogeneous data types. For example, they have been used for survival prediction of NSCLC patients from a combination of clinical and micro-array data[^15]. They were also used to model PET/CT images in order to predict early stage NSCLC patients survival[^21].

### Patient Cohort Analysis

Our study uses electronic health records (EHRs) of patients which are collected and stored by Spanish Lung Cancer Group (SLCG) which is a multi-disciplinary group focused on finding better treatments for lung cancer. In the following, we discuss the patient cohort examined in our study and the features and characteristics extracted from the patient EHRs.
• **Patient cohort.** Our study is conducted on a cohort of 2442 early-stage (stage I or II) NSCLC patients where 1275 (52.2%) of these patients had tumor recurrence after successful treatment. The mean age of the patients in our dataset is 65.6 years with little difference between recurrence (65.9) and disease-free survival (65.4) patients. Males represent around 74% of the patient cohort while 85% of this cohort are current or previous smokers. All the examined patients are diagnosed with stage I and stage II NSCLC where patients are split between the two stages with a 54.6% for stage I and 45.4% for stage II. In terms of the TNM staging system, the vast majority of patients have been diagnosed with M stage and N stage of 0 (92% and 76.3% respectively) while the T stage diagnoses has a more even split. The mean tumor size was 34.6mm, where patients who suffered a recurrence had a slightly larger mean tumor size (36.0mm) compared to disease-free survival surviving patients who have a mean tumor size of 33.2mm with a similar range for both. The ECOG performance status of the patient cohort is mostly divided between the statuses 0 and 1 with approximately 57% and 38% respectively while other ECOG statuses 2, 3 and 4 are associated with approximately 5% of the patients only. Table 1 provides a more detailed view of the characteristics of our patient cohort in relation to patient tumor recurrence and disease free survival.

• **Feature analysis.** The electronic health records of our patient cohort contain a different set of patient information and features such as the patient’s demographics, diagnosis, bio-markers, treatments and follow up information. Patient history includes gender, smoking habits, familial cancer history and comorbidities. Diagnosis features detail information on the tumour classification, histology, etc, at time of diagnosis along with the symptoms the patient suffered. The bio-marker features record the results of any bio-marker analysis performed on the patient during the course of their treatments. The treatment records of a patient include the details of any chemotherapy, radiotherapy or surgical procedures the patient underwent during their treatment. Chemotherapy features include the drugs used (including any maintenance drugs), the start and end dates of the treatment and the patients response to the chemotherapy. Radiotherapy features include the area radiated, the dose and the fractioning. Surgery features contain the type of surgical procedure, resection degree, the response and the post-surgical TNM staging values.

• **Patient labelling.** In order to label patients as having relapsed (i.e., positive cases for training the machine learning models) we rely on 2 feature groups in the SLCG dataset. The primary source for labelling comes from the patients’ progression records. If a patient has a progression record with status "Progression" or "Relapse" they are labelled positive. A secondary source for labelling comes from the patients’ follow-up records. If a patient has a follow-up status of "Alive with disease" or a follow-up status of "Dead" with cause of death "Lung cancer" they are also labelled as positive. All other patients are considered negative examples for the purposes of training our models.

• **Patient consent.** The patient data used in this study was collected under the provisions of the Law 14/2007 on Biomedical Research at all times along with the confidentiality of the data of patients according to the requirements of the law 15/9 [54] on Protection of Personal Data and Implications of EU General Data Protection Regulation 2016/679 (GDPR), applicable from 25 May 2018, Directive 95/46/EC.

The data collected was identified with a code. Access to patients’ personal information was restricted to the study doctors/investigators, the ethical clinical research committee of Puerta de Hierro-Majadahonda University Hospital and specialized authorized personnel to verify the study data and procedures, always keeping the confidentiality of the latter in accordance with current legislation. Only clinical data regarding the disease were used for subsequent analysis by the technical partners of the consortium, no personal data that could reveal the patients’ identity was used. The signature of the informed consent for entry into the study is revocable since the patients can withdraw their consent at any time so that we stop using their personal data or their own samples for this research; this revocation can be done simply by notifying the investigator. The entry in this study was totally voluntary so in case of revocation or refusal to enter the study the patient would continue to be clinically treated by their doctor whether or not participating in the study.

**Methods**

In this section we discuss the data preparation and preprocessing step, analysis of the features included in the investigated patients EHRs and the learning models that we use in our study.

• **Data preprocessing.** We have applied a set of data preprocessing operations on the patients’ EHRs to be consumable by our learning models and to decrease feature sparsity. We have fixed some corrupted date values where the date contains an invalid day or month value by replacing these values with a a placeholder value 1. We have also filled some
empty boolean fields with expected default values. For example, empty comorbidities annotations were assumed absent. This has been executed carefully with manual expert support to enrich the patient features extracted from their EHRs.

We have then formulated the patient records in a tabular dataset form, where we convert each patient record into a row of features. In this step, we have one included numerical and categorical feature values and we have excluded free text annotations and date values. We have attempted to preserve the order events in the patient row values by using different indexed columns for the same event which are indexed based on their order.

• **Data censorship.** In our study, we use the patient records to the full of their length to decide whether the patient had a tumour recurrence where we use all the available follow-up data points to detect recurrence. On the other hand, when build the patient features, we censor the patient data features using two criteria defined by experts to ensure that the learning models are only trained on features which are extracted from events successful treatment. First, if the patient had chemotherapy and radiotherapy treatments and did not have a surgery, we only consider the patient’s features prior to the first successful chemotherapy (the chemotherapy which results in absence of tumor). Secondly, when the patient have a successful surgery, we only consider features prior to this surgery and including the surgery detail.

• **Learning models.** In this study, we use a set of four supervised machine learning models: Random Forest (RF), Multi-Layer Perceptron (MLP), Support Vector Machine (SVM) and Logistic Regression (LR). In the following, we provide a short description of each of these models and how they work:

  * Random Forests are supervised machine learning models which uses a large number of small decision trees called estimators to produce predictions, where aggregates the prediction of these estimators to produce a more robust overall prediction. Random Forests can provide explanations for their predictions based on its decision trees (estimators) feature weights.

  * Multi-Layer Perceptrons are artificial neural networks composed of multiple neural layers, where each layer is composed by an affine transformation followed by an element-wise non-linear operation. In our implementation, MLPs use stochastic gradient descent to optimize the log-loss on the training data.

  * Support Vector Machines are supervised machine learning models which performs binary classification by learning a linear decision boundary by optimizing a margin-based loss function.

  * Logistic Regression is a machine learning model which assumes a linear relation between the input features and the output predictions. The predictions of the logistic regression model are easily interpreted in terms of the coefficients corresponding to each of the input features contributing to the final model prediction.

• **Model training pipeline.** We trained the previously mentioned models on the patient EHRs using a multiphase-procedure as illustrated in Fig. 1 where we perform the data preprocessing and censorship as previously discussed. We then train the models using a k-fold cross-validation strategy, where models’ hyperparameter tuning process is executed using the hyperparameters optimization framework optuna across at least 10 trials per model class. Further discussion on the model training and evaluation process is included in the Results section.

Results

In this section, we discuss the setup of our experiments where we describe the details of our evaluation protocol, metrics and the outcomes of our evaluation.

• Evaluation protocol. We cast the problem of assessing risk of tumour recurrence for a patient as a binary classification task which answers the question: whether a patient will have a recurrence or not. We execute our task on a cohort of 2242 patients where we use a 5-fold cross validation strategy. The 5-fold cross validation strategy is an evaluation technique where we split the patient cohort into 5 different random splits and evaluated our learning model on the five different splits independently. In each split evaluation, we use the other splits as training data and we evaluated our model on the specified splits. This technique produces a generalized view of the model predictive accuracy on the whole patient cohort with no data leakage between the training and testing cohorts.

• Metrics. We report the evaluation results of our examined models using a range of conventional binary classification metrics such as accuracy, precision, recall and the F1 score. We also use ranking metrics such as the average precision (i.e. the area under the precision-recall curve) and the are under the ROC curve (AUC-ROC).

• Model hyperparameter tuning. Our experiments were focused on four models as described in the methods section: Random Forest (RF), Logistic Regression (LR), Multi Layer Perceptron (MLP), and Support Vector Machine (SVM). The hyperparameters for these models were chosen using a hyperparameter search procedure executed using the hyperparameter optimization framework optuna. For each model, we execute a set of 10 trials to find the optimal hyperparameter configuration where each trial corresponding to a single hyperparameter configuration chosen from a predefined search space. We then choose hyperparameters corresponding to the best performing configuration as the
Figure 3: One of the best performing Logistic Regression model’s coefficients. As a linear model, LR is interpretable through its coefficients that are tuned to give weights to the input features. Top chart presents features yielded by model as relevant (coefficients > 0) which contributes the most to recurrence prediction, while the bottom one non-relevant for prediction (coefs <= 0) which contributes the most to predicting disease-free survival.

model best hyperparameters for each of the examined models.

• Evaluation results. Table 2 shows the results of our computational experimental evaluation of the four examined models using a 5-fold cross validation evaluation strategy. The results show that the random forest model achieved the best results in terms of all the used evaluation metrics where it achieves 0.69, 0.71, 0.74, 0.72, 0.67 and 0.68 scores in terms of accuracy, precision, recall, F1 score, average precision and the are under the ROC curve metrics respectively. However, the results also show that the margin between the metric scores of the random forest model and the other examined models in not significantly large, where the standard deviation of the metric scores of all the models is 0.02, 0.02, 0.03, 0.02, 0.01 and 0.02 in respect to the accuracy, precision, recall, F1 score, average precision and the are under the ROC curve metrics scores respectively. The results also show that all the examined model have consistent results through the different 5-fold cross validation runs where the reported standard deviation of the their reported metrics is always less than 0.05.

In the Fig 2 we demonstrate plots of the ROC and precision recall curves of the examined models. The ROC curve shows that all the examined models a better predictive accuracy than random the random baseline with marginal differences between the performance of all the models. On the other hand, the precision-recall curve demonstrate some disparities between the model performance especially in terms of the models precision in relation to changes of the model’s recall. For example, the logistic regression and SVM model suffer from a significant decrease of precision when the model’s recall is less than 0.2 in comparison to other models.

• Feature importance analysis. In Fig 3 we provide an example of model feature prioritization, where demonstrate the highest and lowest coefficient values learnt by the logistic regression model and their corresponding features. These coefficients represent the weight of contribution of their corresponding features towards the recurrence/survival predictions. The top part of figure demonstrates the features with the highest coefficient which contributes the most to
predicting that a patient would have a recurrence. For example, the highest contributing feature to predicting recurrence is have a stable disease at the end of the last successful chemotherapy treatment. Other major contributing features include smoking, previous cancers, comorbidities such as hepatitis and COB disease, and large tumor size at diagnosis represented by the T stage. The bottom part of Fig. 3, however, demonstrates the features with the lowest coefficient (negative values) which contributes the most to predicting that a patient would have a disease-free survival. The figure shows that the most significant features in this category are outcomes of the last successful surgery e.g. TNM stages and resection grade, and the final response to last successful chemotherapy treatments.

Discussion

The main goal of this work has been to assess the suitability of off-the-shelf machine learning models to the task of predicting relapse in early stage non-small cell lung cancer patients. To that end, we have used data on a comprehensive patient cohort from the Medical Oncology Department of Hospital Universitario Puerta de Hierro Majadahonda in Madrid, Spain. While the standard methods used in this context (such as models based on Cox proportional hazard analysis) were reported to produce competitive results, they do have their limitations.

First, they use purely statistical, local features based on frequency for the predictions, and thus they cannot, by definition, use complex, long-range relationships between the particular data elements. This is an aspect some readily-available binary classification machine learning models such as neural networks may address better, as they can naturally model non-linear boundaries between the classes of relapsing and non-relapsing patients.

The Cox models also cannot work with heterogeneous data (e.g. patient data together with biomedical database and publication data), even though such data are more likely to provide a truly comprehensive representation of the patients and their disease. This is an aspect models based on extensible and semantically integrated machine learning data sets, which we plan to incorporate in the next stages of this work, can address more naturally than purely statistical models.

Furthermore, using predictive models based on machine learning allows for rapid prototyping and easy experimentation with a broad range of possibly complementary models, as shown in this preliminary work.

While a rigorous clinical validation of the model predictions is a part of our future work, our experiments have demonstrated the feasibility of the machine learning-based approach in the context of relapse prediction. All explored models significantly outperformed a naive baseline in standard machine learning metrics, and thus established a solid non-trivial stepping stone for further experiments in this area.

Perhaps the most important lesson learned was the crucial role of clinical data preprocessing with direct involvement of the oncologists, who were instrumental in defining the scope of features applicable for training the machine learning models. They were also essential for devising specific strategy for labelling positive and negative patient examples that is a must for optimal and clinically-relevant model performance. We believe the strategy is generally applicable across similar datasets and clinical needs. However, there is certainly lot of space for improvement in terms of data cleansing and conversion of qualitative values of patient features into quantitative data that are more suited for the machine learning models. This aspect would require a dedicated publication on its own and is a part of our future work.

Another critical aspect we intend to address in future research is the clinical validation of the predictive models. One would ideally like to compare the performance of the models with a human baseline, which is, however, possible only in a prospective study we are currently performing. In these settings, the models will be trained on retrospective data and tested on prospective patients, which will let us assess the capability of the models to predict high risk scores of patients who did indeed relapse, and low scores of patients who did not, in the follow-up period. This will allow for much more realistic assessment of the machine learning models, and overcome the main limitation of the presented preliminary work.

Funding

This paper is part of the CLARIFY project that has received funding from the European Union’s Horizon 2020 Research and Innovation Programme under grant agreement No. 875160. It has also been funded by the Insight Centre for Data Analytics at National University of Ireland Galway (supported by the Science Foundation Ireland grant 12/RC/2289_2).

Abstract

Background. A key to a more efficient scheduling systems is to ensure appointments are designed to meet patient’s needs and to design and simplify appointment scheduling less prone to error. Electronic Health Records (EHR) consist of valuable information about patient characteristics and their healthcare needs. The aim of this study is to utilize information from structured and unstructured EHR data to redesign appointment scheduling in community health clinics. Methods. We used Global Vectors for Word Representation, a word embedding approach, on free text field “scheduler note” to cluster patients into groups based on similarities of reasons for appointment. We then redesigned an appointment scheduling template with new types and durations based on the clusters. We compared the current appointment scheduling system and our proposed system by predicting and evaluating clinic performance measures such as patient time spent in-clinic and number of additional patients to accommodate. Results. We collected 17,722 encounters of an urban community health clinic in 2014 including 102 unique types recorded in the EHR. Following data processing, word embedding implementation, and clustering, appointment types were grouped into 10 clusters. The proposed scheduling template could open space to see overall an additional 716 patients per year and decrease patient in-clinic time by 3.6 minutes on average (p-value<0.0001). Conclusions. We found word embedding, that is an NLP approach, can be used to extract information from schedulers notes for improving scheduling systems. Unsupervised machine learning approach can be applied to simplify appointment scheduling in CHCs. Patient-centered appointment scheduling can be achieved by simplifying and redesigning appointment types and durations that could improve performance measures, such as increasing availability of time and patient satisfaction.

Keywords
Word Embedding, Clustering, Electronic Health Records, Appointment Scheduling, Healthcare Processes

Introduction

Appointment scheduling in health care is complex. Dynamic patient’s medical, physiologic, and mental state can lead to uncertainty in patient flow1. In acute health care systems, triaging is applied to evaluate acuity and meet demands. However, in non-acute or outpatient settings, triage scheduling is not the most effective way of scheduling. Outpatient settings should consider various factors such as: the number of services, the number of providers, the patient arrival process, the number of appointments, service times, and provider punctuality to design their scheduling systems2, 3. Our project goal is to redesign appointment scheduling to meet the needs of patients. In our previous study to improve access to care for underserved populations, we partnered with seven Community Health Centers (CHCs) which are ambulatory care settings providing primary and mental care for underserved populations and are designed as safety nets for these populations4, 5. We focused on discovering population needs, barriers to accessing healthcare, and strategies to reduce access barriers. We utilized Electronic Health Records (EHRs) covering a wide range of different information, consisting of both unstructured narrative text as well as structured data. We found redesigning appointment scheduling is one intervention that could potentially improve access to care. In this paper, we propose a patient-centered appointment template redesign by leveraging EHR data from our partner clinics.

Many appointment scheduling methods have been developed to address issues such as demand uncertainty, urgent care, and no-shows aiming at improving access to care and clinic service quality6. Other studies aimed at open access scheduling which allows patients to see a provider on the same day of requesting an appointment7. One general conclusion of these studies is that simplifying appointment types is an essential principle in implementing open access scheduling8,9-10. Simpler appointment types can reduce complexity in scheduling, leading to less error and better access to care11. A well redesigned scheduling scheme based on patient characteristics can improve utilization of medical
resources\textsuperscript{12}. In these studies, decreasing the number of appointment types or simplifying the appointment types in scheduling systems was recognized as a key step towards successful implementation. However, in these studies, there are no in-depth discussions on the appropriate ways to simplify appointment types.

Through our introductory literature review, we found that previous work in redesigning appointment scheduling did not propose patient-centered appointment structure for optimizing scheduling systems. Few studies focused on improving appointment scheduling based on patient characteristics, but these proposed scheduling systems were designed to accommodate health care settings like emergency departments, radiology departments, and inpatient settings rather than helping community health centers or outpatient settings. In this paper, we utilize real-world encounter data in community health clinics to identify appointment needs of populations they serve. We discuss how to leverage patient’s encounter data including reasons for seeking care to construct patient-centered appointment scheduling. We utilize a natural language processing approach, “word embedding”, to extract significant information from patient records. We use extracted information to cluster patients into groups based on similarity of their reasons for seeking health. The patient clusters are critical input in redesigning appointment types and durations that are simpler and more efficient without adding additional burden on clinics. Clinic managers and other stakeholders are encouraged to use the findings of this study to restructure their health care systems. This approach can also be a roadmap for developing automated appointment scheduling tools for ambulatory care settings.

**Methods**

Natural Language Processing (NLP) has been widely used to enable computers to understand free text and use the information derived from free texts\textsuperscript{13}. NLP includes wide range of computational techniques used by machines to comprehend human-like language processing\textsuperscript{14}. Word embedding is one of the featured learning techniques in NLP where words, phrases, or sentences are mapped to vectors of numbers\textsuperscript{15}. Word embedding can be used to derive semantic relationships between words using deep learning algorithms\textsuperscript{16}. Many studies in areas, such as sentiment analysis, information retrieval, and information extractions have applied word embedding\textsuperscript{16}. The source of free text data in our project is “patient reason for seeking health”. This field is entered by schedulers into the EHR systems. The objective of this study is to utilize word embedding to extract information from reasons for appointments, and then aggregate the similar reasons into single concepts. Those concepts are used to create new appointment types and durations. Figure 1 shows analysis engines used for redesigning appointment scheduling templates.

**Figure 1.** Analysis engines used for redesigning appointment scheduling templates. Unstructured data were used in Notes, MedTagger, WORD2VEC, and Validation steps. Structured data were used in Clustering, Validation, and Redesign steps.

**Data collection and preprocesing (figure 1, steps: Notes, MedTagger):** We collected EHR data from an urban community health clinic which included patient, visit, and provider characteristics. The field, “schedulers’ notes”, was the main data points to extract information. A scheduler note documents a patient’s reason for seeking care at the clinic. For example, when patient calls the clinic and asks for an appointment, the scheduler enters the patient explanation into the EHR system. We used schedulers’ notes to cluster patients based on the similarity of reasons for seeking healthcare. Schedulers’ notes are free text fields with many abbreviations; therefore, any attempt to extract information should include resolving issue of abbreviations. MedTagger, a library developed by Mayo Clinic, contains a suite of programs indexing based on dictionaries\textsuperscript{17}. We used the MedTagger\textsuperscript{18} dictionary list to expand the abbreviations to their full forms, for example “DM” is transformed to “diabetes mellitus”.

**Text mining (figure 1, step: WORD2VEC):** There are various word embedding models that map words to vectors (word2vec) of real numbers. These methods are generally categorized into two methods of matrix factorizations and shallow window-based models. Matrix factorization methods capture the statistical information about the corpus. Approaches, such as latent semantic analysis (LSA)\textsuperscript{19} capturing the term document frequencies or Hyperspace Analogue to Language (HAL)\textsuperscript{20} capturing the term-term frequency are two examples of matrix factorization methods.
The problems with these methods are that the most frequently used words contribute a disproportionate amount to the similarity measure, for instance co-occurrence with words such as “the” or “a” has a large effect on the similarity measure despite a lack of semantic relatedness. The skip-gram and continuous bag-of-words (CBOW) models are two of the most widely used word2vec approaches that use neural network structures in learning word representations. We used the Global Vectors for Word Representation (GloVe) method to represent each text column with their real-valued vectors. The GloVe model addresses the shortcomings of the earlier models. GloVe captures the benefits of count data while simultaneously capturing the meaningful linear substructures prevalent in modern log-bilinear prediction-based methods. We used the GloVe pre-trained vectors on a 6 billion token corpus from 2014 Wikipedia to construct a 50-dimensional vector for every word in the text that appeared in the pre-trained model. We normalized vector for words without representation in the pre-trained vector model; more specifically, we assigned the average of words appeared in the body of our sample to words without representation. We then averaged all the vectors for the words in the sentence to calculate the final representation of each sentence. For each patient encounter in the EHR, there is a scheduler note in free text format. We ran the word2vec algorithm on each encounter note. Each encounter was converted to a row with 50 columns representing the 50-dimensional vector that is derived from the note.

**Clustering (figure 1, step: clustering, validation):** The data were then fed into an Agglomerative clustering algorithm. Agglomerative clustering is a bottom-up hierarchical clustering approach by merging pair(s) of clusters in which clusters generated in earlier step might be nested within the ones generated later. This approach does not necessarily neglect the small clusters; hence, it is useful for the discovery of the smaller groups. To find the optimal number of clusters, we started with 2 clusters and stepwise increased the number of clusters to 20. In each run, we compared the results of clustering by analyzing the profile within each cluster. Attributes such as age, gender, and provider specialty were used to objectively validate the appropriate number of clusters. We also evaluated the clusters by reading 100 notes per cluster to see whether clustered notes are aligned with human judgment. We found the optimal number of clusters is between 10 to 12. We chose 10 as our final number of clusters for this study.

**Appointment type and duration redesign (figure 1, step: redesign):** In this step, the goal is to optimally give new appointment duration to each of the new 10 appointment types, i.e. the 10 clusters. We assumed that the clinic capacity and demand do not change. We investigated how standalone simplification of appointment types and durations could potentially impact performance measures, such as number of patients seen per year and patient satisfaction defined as patient time spent in-clinic. Patient time spent in-clinic is the difference between patient arrival and departure times and includes the sum of waiting time to see the provider, time with the provider, and time spent for check-out and payments. Proposed appointment durations were calculated based on the capacity that the clinic must accommodate daily. The sum of provider hours allocated to see patients per day was defined as daily clinic capacity. For example, if the clinic had two providers on a given day who each allocates 4 hours to see patients, the total capacity of the clinic on that day is 8 hours (i.e. 480 minutes), or 240 minutes per provider.

We used the distribution of current appointment durations per cluster to determine the most effective appointment durations for each cluster. For each cluster, we started by assigning the median current appointment durations to proposed durations (figure 2), then we increased it step by step by 1 percentile to the maximum. We then used the capacity and demand of the clinic to calculate performance measures in each step.

**Performance measures in the proposed appointment system:** Performance measures were:

1) Number of patients seen per year. The difference between current durations and proposed durations was calculated as time available to see more patients. We then calculated the number of additional patients that can be seen in the proposed system by dividing the time available to see more patients by new appointment durations per cluster. To normalize this measure, we calculated the number of additional patients that the clinic can see in the proposed scheduling system by year.

2) Provider time with patient. It was measured as total appointment duration (minute(s)) per provider.

3) Predicted patient time spent in-clinic. The time patients spent in-clinic, which includes in-clinic waiting time plus time spent seeing the provider, was calculated as the difference between arrival time and departure time recorded in the EHR data. We used current appointment durations, arrival time (AM vs PM), gender, provider specialty, number of provider(s) available in the day of appointment, day of week, and patient age as independent variables and in-clinic time as the dependent variable to develop a multivariate linear regression model. We used the regression model to predict time spent in clinic using the proposed appointment durations. Pairwise t-tests were calculated to test for significant differences between current and proposed systems.
We fit the current daily demand to the current daily capacity using the proposed types and durations. We found the most effective duration for each cluster by maximizing number of patients per year and provider time with patient while minimizing overall patient time spent in-clinic (figure 4).

Results

We collected 17,722 encounters of an urban community health clinic in 2014. The dataset included deidentified patient ID, day and time of encounter, patients’ arrival and departure times, age, gender, provider ID and specialty, appointment type (102 unique types recorded in the EHR), and appointment notes (or schedulers’ notes). The dataset included 7,061 unique patients in 2014. Following data processing, NLP implementation, and clustering, appointment types were grouped into 10 clusters using patients’ needs in the current scheduling systems (shown in table 1).

Table 1 and figure 2 were used to determine the most accurate number of clusters. Our proposed scheduling system has 10 types of appointments (noted as clusters). Table 1 shows examples of free texts that were aggregated into one concept. Cluster 1 seems to be appointments that are assigned to patients with complex issues. Cluster 2 represents acute female complications or patients with behavioral health needs. Cluster 3, which is the largest in terms of number of reasons, consists of acute care encounters that need to be scheduled as soon as possible. Clusters 6 and 7 are assigned to patients with chronic pain problems and other chronic problems. Clusters 8 and 9 are predominantly for pregnant, reproductive health and other female complications. Cluster 10 is for wellness and other childcare patients.

Figure 2 illustrates the distribution of current appointment durations per each cluster. Appointment durations typically range from 10 to 60 minutes. Cluster 1 has the highest durations, and this is aligned with the visit reasons shown in table 1, because it is given to complex patients. Cluster 10 has the lowest durations as it is given to well childcare.

Table 1. Cluster profiles and examples of reasons grouped into clusters.

The overall clinic patient gender distribution was 63% to 37% for females and males respectively. Table 2 provides a breakdown of age and gender profiles for each cluster. Cluster 1 represents younger patients from both genders. Cluster 10 shows that 95% of patients are younger than 13 years old, and it represents a pediatric population. Clusters 8 and 9 consist of predominantly female patients. Cluster 3, that was determined to be acute care based on table 1, represents all ages and genders. The gender and age profile of each cluster seems to be in agreement with examples of reasons for visits in table 1.

Figure 3 shows percentages of appointments within a cluster that were scheduled with various provider specialties. Cluster 2 is a mix of behavioral health and all other specialties. Cluster 3 (acute care) patients were scheduled with all types of specialties. Cluster 10 patients are predominantly scheduled with pediatricians.
Figure 4 shows scheduling performance measures per several potential durations for new appointment types. Performance measures are the percentage reduction in average patient in-clinic time, ratio of patients seen in a new practice compared to the current practice, and ratio of provider time spent with patient compared to their capacity. For example, if we consider the value of the 65th percentile of all durations within a cluster to the new appointment duration for that cluster, we would see an 11% increase in patient time in the clinic, a 35% increase in number of patients accommodated, and a ~30% decrease in provider time with patients. The results in figure 4 include iterations from the 65th to 80th percentiles. We did not see changes outside this range, so they are not included in the figure. We chose the 75th percentile duration of appointments within each cluster as the new proposed appointment duration, because it can reduce average patient in-clinic time by 10%, increasing the overall number of patients to be seen by 9%, without significantly affecting provider time spent with patient.

Figure 4. Performance measures by iterations. Nth iteration means assigning the Nth percentile of appointment durations within a cluster to the cluster.

Table 3 shows comparisons of the current scheduling system and the proposed scheduling system. Average appointment duration in the current scheduling system is the average of current durations by cluster. Averages of appointment duration in proposed (i.e. 75th percentile duration of appointments within each cluster) scheduling system are higher for clusters 1, 2, 4, 7, 8, 9, and 10, and lower for clusters 3, 5, and 6 compared to the average(s) of current durations (p-value<0.0001). The time patients spent in-clinic per visit is calculated based on the EHR patient’s arrival and departure times. Predicted time spent in-clinic was calculated using a linear regression model trained using the current scheduling. Table 3 shows the proposed scheduling system could open space to see overall an additional 716 patients per year, which is about 10 percent more patients. Figure 5 shows distributions of patient time spent in-clinic per visit. Our results suggest that the new scheduling systems and appointment duration could decrease patient in-clinic time by 3.6 minutes on average (p-value<0.0001).

Discussions

We studied the possibility of using patients’ reasons for seeking health along with patient, visit, and provider characteristics to design new appointment types and durations for community health centers. Our study has three major findings. First, word embedding, that is an NLP approach, can be used to extract information from schedulers notes for improving scheduling systems. Second, unsupervised machine learning approach can be applied to simplify appointment scheduling in CHCs. Third, patient-centered appointment scheduling can be achieved by simplifying and redesigning appointment types and durations that could improve performance measures, such as increasing availability of time and patient satisfaction.

In this work, we expanded utilization of word embedding trained models by applying it on scheduler notes in primary care settings. We found word embedding trained on EHR scheduler notes using MedTagger, and GloVe can capture semantics of medical terms, and the results are aligned with human judgment (shown in table 1).

The Institute of Medicine defines health care quality as "the degree to which health care services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." One of the domains of health care quality is efficiency. Our study found simplification of scheduling based on patient, provider, and clinic characteristics could improve efficiency. In this work, we designed a methodology to simplify appointment types and times because complex schedule templates could lead to mismatching patient problems to incorrect solutions. Simplifying appointment types and times is one of the requirements of transitioning from traditional access models to advanced access models. The approaches in this study could simplify appointment scheduling to match daily supply and demand. We found simplifying scheduling templates could improve overall clinic performance, such as improving provider productivity, decreasing patient in-clinic waiting time, and improving clinic accommodations. Our methodology is significant because improved overall performance could be achieved without additional supply, more resources, or extended hours.

Patient-centeredness is another domain of health care quality that is achieved by meeting patient needs and preferences. In this study, we designed an infrastructure for patient specific resource allocation. Patients with different reasons for seeking health, age, and gender have different resource requirement. Our proposed appointment scheduling template clusters patients into classes based on reasons for seeking health. Timeliness and patient satisfaction are other aspects of a good health care delivery system. Our study found that simplified scheduling can reduce in-clinic time that could consequently lead to improved timeliness and satisfaction.

Our study has few limitations. First, our patient encounter data lacked clinical information such as diagnoses, procedures, lab results, and clinicians’ notes. In any future work these features can also be used to design stronger patient specific resource distribution. Another limitation of this study was that our dataset did not include information about in-clinic patient journeys, such as step by step activities and timestamps from the moment that a patient checks in to departure of patients, and information about daily staffing of medical assistants and nurses. Those factors could be predictors of in-clinic waiting time. Another limitation of the methodology is computationally resource intensive.
nature of agglomerative clustering, especially when it comes to large data. Other clustering or unsupervised learning methods might be explored. One limitation of word embedding model such as GloVe is that words must be seen in the training data in order to have an embedding. There are various methods to deal with out of vocabulary (OOV) words such as subword embedding, <unk> replacement, random initialization, etc.

Future work in this area might focus on four objectives. First, expansion of abbreviations by utilizing more comprehensive dictionaries that would include less commonly used abbreviations. Second, other unsupervised clustering methods such as deep learning or reinforcement learning might be able to extract more relations between notes which would lead to more precise clusters. Third, researchers might use the findings of this study to either implement the algorithms in current EHR interfaces or design a new interface for a decision support system. Future research in this area could also evaluate the effectiveness of the proposed algorithms in real world clinical practice. Forth, EHRs contain a longitudinal data and information on previous patients’ encounters that can be considered to augment this redesign approach.

Potential Medical Applications. One of the steps of moving from traditional appointment scheduling to optimized open access scheduling is to simplify appointment types and times. Ambulatory care settings can leverage methodologies and findings of this paper to achieve optimized open access scheduling. Previous studies did not discuss the most appropriate ways to simplify appointment types. These previous studies mainly offered appointment types such as “new”, “established”, “acute”, and “postoperative” as decreased number of appointments. A key advantage of the methodology presented in this paper is that the simplification of the appointment template not only helps clinics implement advanced open access scheduling system, it is also patient-centered and patient specific. The proposed appointment scheduling templates are designed based on reasons patients are seeking health care. Another potential medical application of this study is to utilize the unsupervised machine learning approach presented in this paper to design automated appointment scheduling tools for healthcare settings. These tools can be in the form of online appointment scheduling or automated phone call scheduling. These potential tools ask patients why they need appointments and the system finds the most appropriate appointment type and time for the patient. Methodologies presented in this paper can also be applied on both scheduler and clinician notes to find care needs and gaps for patients and design interventions to close the gaps.

Conclusion

A key to a more efficient scheduling systems is to ensure appointments are designed to meet patients’ needs, and to design and simplify appointment scheduling which is less prone to error. In this paper, we presented approaches for redesigning appointment scheduling based on patient characteristics, needs, and desires. We used EHR data to investigate the relationship between patient characteristics and reasons for visit to help providers redesign healthcare systems that can meet the needs of patients. We applied word embedding and unsupervised machine learning methods to design more effective and efficient appointments in ambulatory care settings. We found that simplifying appointment types and times can help healthcare systems achieve improved access and patient satisfaction without adding additional resources.

Abstract

The COVID-19 pandemic required rapid implementation testing at large scale. We describe our approach to creating an efficient and highly scalable end-to-end testing and reporting workflow. We utilized a combination of consumer-driven workflows, a consistent ordering and data collection EMR user interface, an EMR independent entry point for affiliated providers, and rapidly evolving automation of screening, registration, patient identification, curbside specimen management, and prioritization logic. Our agile approach allowed us to transition from people-driven processes and gain efficiencies utilizing previously developed informatics infrastructure, new solutions and emerging consumer digital tools. We supported over 1,000,000 tests with >200 prioritization logic changes without requiring education or changing the provider ordering workflows, handled patient-driven screening, data collection, and ordering of up to 9 patients/minute while decreasing curbside specimen collection from more than 39 to less than 17 minutes per patient. The approach supported texting consumers and standards-based reporting to public health agencies.

Introduction

The development and implementation of efficient testing strategies for SARS CoV-2 has been key to the public health response and care of patients impacted during the COVID-19 Pandemic. This report describes our informatics approach to the rapid scaling of standardized guided screening and ordering processes, prioritization, specimen collections, lab processing, and results reporting. Intermountain Healthcare is an integrated not-for-profit health system with more than 41,000 employees who serve the needs of people across the intermountain west, primarily in Utah and Idaho. The system includes clinics, a medical group integrated by 2,400 physicians and advanced practice providers, affiliate networks comprising 3,800 physicians, hospitals, homecare, telehealth and health insurance plans. The organization provided COVID-19 testing services to affiliated providers, to public health agencies, to business entities, as well as to patients being cared for by the health system.

An ongoing challenge during the pandemic has been limited testing supplies, equipment, lab capacity, and the associated rapid evolution of testing criteria. National and local guidelines rapidly shifted who should be tested, tests to be used for which clinical scenarios; this was compounded with the supply chain challenges and local evolution of the equipment available and improving turnaround times of the different tests. This resulted in the need to apply strict but changing criteria to testing. We needed to be able to provide intuitive guidance to the shifting testing criteria in electronic and paper-based ordering.

With Intermountain Healthcare’s unique geography, there was a need to create a consistent ordering workflow which would facilitate specimen collection throughout the states of Utah and Idaho, allow high-throughput testing in our centralized laboratory while also leveraging regional and external labs when testing capacities varied due to supply chain shortfalls. In addition, as Intermountain Healthcare provides care for a wide variety of clinical scenarios, we needed to ensure that the appropriate prioritization was assigned to the appropriate patient scenario, so that a critically ill patient might have the most rapid turnaround time in order to qualify for therapeutic intervention, and also to maintain our community responsibility to provide rapid turnaround testing to a large volume of the population in the outpatient setting.

Due to the rapidly changing environment of testing supply availability and changing epidemiology, our team was initially tasked with creating a stable, front-facing workflow which would automatically flex ordering criteria, require and document the U.S. Department of Health and Human Services Ask On Order Entry (AOE) questions, calculate

872
specimen prioritization, expedite lab processing, and patient resulting at a volume and rapidity never previously experienced in healthcare.

Ordering

In the face of such a rapidly changing environment, we aimed to surface clinical decision support within the providers’ natural workflow. The recommendations for testing would then either allow the healthcare team to proceed with COVID-19 testing based on the most up to date Infectious Disease recommendations or defer testing and recommend other management. The decision support would allow us to have a stable ordering interface for providers, without depending on providers to re-learn the rapidly changing testing guidelines via other lagging asynchronous methods (email, PDFs, department meetings, etc).

Beyond hosting our ordering criteria, AOE questions and prioritization within our Electronic Medical Record (EMR), Intermountain Healthcare also services many affiliated providers who partner with Intermountain for collections and testing, but who don’t normally access our EMR. We needed to create an easy, reproducible method for affiliated providers to meet the required elements mentioned above.

Expanded Screening

As the urgency of the pandemic increased, it became clear that a provider visit was not required for basic screening for testing eligibility in non-critically ill patients. There was a desire to use unlicensed individuals (ex. Medical Assistants) for screening via a COVID-19 phone hotline. We were challenged with the question of devising a simple method of showing the ordering criteria and facilitating registration, insurance gathering, ordering, and scheduling, in a manner sustainable by a standing-order protocol. By achieving this workflow, we hypothesized we would have the ability to dramatically increase our offerings to our community patient populations without jeopardizing patient safety.

Specimen Collection

Due to the risk of healthcare worker infection from COVID-19 specimen collection, by virtue of a nasopharyngeal swab being an aerosol generating procedure, Intermountain strategically decided to host all outpatient collections at specific curbside testing locations. This allowed the process to maximize safety and optimize personal protective equipment resources. The curbside collection sites would both collect samples ordered by other healthcare teams, and also provide on-site screening for eligibility of testing for patient walk-ins. At the peak of testing, Intermountain Healthcare maintained 26 curbside collection locations throughout the states of Utah and Idaho. Any inefficiency in the process of on-site registration, insurance collection, ID verification and specimen collection would be a large rate-limiting part of the pandemic response.

Lab

In early March 2020, Intermountain Central Laboratory began COVID-19 testing with the ability to process and result approximately 300 tests/day. At that time, there were only a few labs in Utah able to process COVID-19 tests. Due to extremely limited supply and large demand, each lab had variable capacity to perform tests on a given day. Each lab had multiple different order codes, depending on type of COVID-19 test available based on location and testing instrument. In the first deployment of testing, if Intermountain Central Lab ran out of capacity on a given day, the lab personnel would need to manually cancel and reorder all tests with the external lab order code, which was highly inefficient. In order to maximize efficacy we needed to devise a system of rapidly flexing the specific test order code available to Intermountain ordering providers depending on the day of availability without changing the providers’ ordering workflow in a noticeable manner, thereby relieving the lab personnel of the need to manually cancel and reorder thousands of tests in a given day.

Reporting

As important as it is to provide interventional healthcare after infection in a nascent pandemic, facilitating a convergence with public health measures to prevent further community spread of infection remains essential to a comprehensive response. Therefore, we needed to support public health reporting on an extraordinarily broad and rapid scale, while not hindering our management of actively infected patients. While Intermountain was already a recognized participant in Electronic Case Reporting (eCR) several challenges still existed, which required nimble collaboration and innovation between Intermountain, state and federal data systems to ensure timely contact tracing and other essential public health measures.
Beyond reporting innumerable data regarding patient presentation and test results to public health entities, the burden of immediately reporting test results and counselling directly to the patient remains elder to all other measures. While our initial processes were quickly deployed people-driven results callbacks, the pivot to technology-based direct reporting of results to patients was urgent in our evolution.

**Methods**

**Ordering Process**

At the beginning of the pandemic SARS-CoV-2 by PCR tests (COVID-19 tests) were in short supply. It was important to preserve these valuable resources and prioritize COVID-19 tests for different patient populations.

In such a rapidly changing environment regarding testing criteria, epidemiology and recommendations, we made the strategic decision to host Clinical Decision Support within the normal ordering workflow. Selecting a COVID-19 testing order triggered a universal COVID-19 screening data intake form, which flexed the criteria logic face up, telling the healthcare team if the patient qualified for testing based on their answers on the intake form. If the patient met testing criteria, the healthcare team could proceed and order the test. By channeling all COVID-19 testing via this intake form, we were able to ensure continuity of practice across a wide geography and variable clinical environments, ensure data reporting was performed on each COVID-19 test, and leverage the various data points for internal and external review regarding trends within the pandemic on a real-time basis.

![COVID-19 Screening Form](image)

*Figure 1.* Universal COVID-19 screening data intake form. Caregiver input of discrete data were used in Decision Support algorithms, ensured continuity of practice, enabled agile changes during the pandemic, ensured data reporting on each COVID-19 test, and leveraged the various data points for internal and external review regarding trends within the pandemic on a real-time basis.
Furthermore, once we created this framework of ordering design, it was simple to quickly change the testing criteria on a compressed delivery timeline. Additionally, the change to ordering logic would be immediately reflected in active patient workflows. For illustration, initially the only criteria which would allow a patient to have a COVID-19 test based on CDC guidelines was presence of 1. Fever OR 2. Cough OR 3. Shortness of Breath. This rapidly expanded, and as Intermountain remained aligned with the State of Utah and Federal testing guidelines, we were able to leverage our technical tools to deliver and facilitate information to the end-user regarding the most up to date criteria in a stable and actionable workflow. Once the intake form was established, we were able to utilize the universal criteria as the basis for standing order protocols. Our ability to leverage unlicensed staff to screen patients for COVID-19 testing became easily facilitated because the entire organization was following a set list of criteria for patient testing. We created order sets including a standing order, and auto added the correct diagnosis code based on clinical testing indication provided within the intake form, to ensure appropriate data reporting, billing and coding.

For affiliate provider ordering, we created an affiliate website which displayed the ordering criteria currently accepted at Intermountain Healthcare. A lab requisition in the form of a fillable PDF was provided, with the option to e-mail or fax the form to a universal inbox. The unlicensed staff of the COVID-19 hotline would monitor the inbox and enter the orders into our EMR using the standard intake form, attributing the ordering physician as the affiliated physician. The patient would then present to one of our curbside collection sites for specimen collection.

Rules Based Ordering and Prioritization Logic

As previously described, beyond simply providing access to a large volume of testing, there remained a clinical imperative to balance our testing prioritization between our acute inpatient patient populations and our community health directive. To put it simply, a critically ill intubated ICU patient with potential for novel therapeutics was deemed to need a quicker result compared to an otherwise healthy individual in the community getting screened due to close contact with a COVID-19 case. As we investigated various options to calculate prioritization and its associated workflow, the options initially evaluated included 1. Manual printing of order form, with lab personnel calculating patient priority by hand; 2. Making the ordering providers note the patient priority as a part of ordering workflow; 3. Automated calculation of prioritization using Boolean-based logic, and printing prioritization directly on lab order label for lab personnel to read when scanning the specimen. After evaluating each option, we elected to choose option 3. This choice allowed us to flex testing instrument order code and prioritization in a dynamic fashion, while never changing the ordering interface for providers. Depending on the patient presentation and available data, we were able to change the patient prioritization algorithm on a daily or hourly basis depending on direction from lab and infectious disease leadership without any change in the clinical healthcare team’s workflow.

Laboratory Specimen Prioritization

Boolean logic-based prioritization algorithm was developed to flex the appropriate type of test and test prioritization after the intake form was completed. Clinical Informatics huddled with lab, Infectious Disease, and Clinical Operations leadership every day and decided on prioritization adjustments which were synchronously implemented. While this methodology was efficient for the frontline clinical workflow, it required significant work from the Clinical Decision Support team to flex the logic based on internal and external lab availability on a daily basis. In order to smooth this process, an external lab configuration webpage was developed as a user interface, which allowed the lab leadership to directly choose which prioritization levels would send to internal or external lab sites. By placing the prioritization algorithm order codes directly in the hands of the lab leadership, they were able to change a simple UI with one click. This modification would instantly change the order code and lab assignment placed by the decision support algorithm for all COVID-19 orders of a certain priority throughout the Intermountain EMR. This allowed our system to remain extraordinarily nimble while handling rapidly increasing volumes of collections and testing across a two-state geography.

In addition, in order to further develop lab efficiency, we facilitated the ability of the lab to directly scan the specimen sample’s (e.g. saliva) barcode directly into the Lab information system, rather than typing the number into the system. This simple fix was exponentially advantageous in increasing lab capacity and decreasing lab turn-around time.

Curbside Collections

As we streamlined the screening and ordering workflow, attention then shifted to the community collection process. In order to optimize the registration, identity (ID) verification, and collection process, we developed a novel workflow
leveraging EMR agnostic text messaging/emailing with a JavaScript app hosted in our EMR at the time of collection check-in.

For the automatic text message/email, we utilized PubSub\textsuperscript{2} to identify all future orders, regardless of ordering location (ex. pre-procedural vs. COVID-19 hotline vs affiliate ordering vs. Primary Care Provider (PCP) ordering), and then sent a text message and an e-mail to patients within 60 seconds of their order completing within our EMR. The message would contain a visit ID, a link to a scannable QR code, and also had an optional link for self-scheduling an arrival window to level-load patient volumes at the collection sites. The numerical visit ID/QR Code contained no protected health information and was a meaningless number if attempted to be scanned outside of Intermountain’s EMR.

Again, the simplicity of this solution was that every COVID-19 outpatient order generated within Intermountain Healthcare would generate a patient text message and email (as long as the patient had previously agreed to receive electronic communications), creating a consistent patient experience regardless of the specific use case for COVID-19 testing. We were able to split the patient cohorts of messages into their respective “reason for test” as indicated by our COVID-19 ordering intake form. Therefore, all the pre-procedural testing patients could have unique information sent to them specific to pre-procedural testing requirements vs. message content for general symptomatic patient education.

At the time of arrival to the curbside collection location, the patient presented their visit ID or QR Code to the healthcare team. By virtue of the patient having a text message/email containing this information, the curbside team knew with a glance that the patient registration, insurance, and ordering had already been completed. Prior to the implementation of this solution, the curbside collection team would re-verify the patient registration, insurance, and order placement on all patients, even if the patient stated they had a previously placed order by another healthcare team. Once the curbside healthcare team had confidence that the generation of a visit ID/QR Code reliably indicated complete patient registration, insurance capture and order placement, their efficiency markedly increased.

To maximize the impact of visit ID/QR code, we coupled this deployment with a de novo web module to facilitate patient check-in at the curbside collection locations. The website asked the healthcare team to enter the visit ID/QR code. This was accomplished by 3 different options: 1. typing in the visit ID number; 2. scanning the QR code with a barcode scanner; 3. if the patient had not received their visit ID/QR code, the web module would also allow the healthcare team to search by patient name and date of birth. Once entered, the web module would display required patient demographics for verification, contact information, insurance information for optional verification, and presence of previous consent for treatment on file. There were fields for entering workflow-specific comments (ex. Vehicle type) as well. For the final step of the workflow, the healthcare team would click the “Print” button. This would cause automatic printing of specimen order labels, printing of lab order requisition, print the typed patient comments directly onto the lab requisition for vehicle identification, complete and document a verbal consent to treat if needed, create the new central lab encounter, auto-activate the order for lab processing, and auto-generate a patient/parental/minor work and school excuse letter accessible within our EMR and patient portal. By distilling approximately 10 different steps into a single clickable button, efficiency of curbside collections was transformed, and the patient experience of collections improved dramatically.

Patient Self-Directed Screening Questionnaire

Despite these significant advances in ordering processes, on-site collection workflows, and lab processes, there remained an appetite for improving the patient experience of screening even further. We initially had leveraged a standalone chat-bot style screening tool on our patient-facing website, which would indicate to the patient whether or not they met testing criteria. However, after completing the screening, the patient would still need to interact with a member of a healthcare team (COVID-19 phone hotline, Video Visit, PCP, on-site curbside team) in order to generate an order. This step of verbally interacting with a member of the healthcare team to generate the order was unsurprisingly a large rate-limiting step. COVID-19 hotline wait times were often long and onerous. The development of an asynchronous technology-based patient-facing screening algorithm which would then map into our existing processes was highly desirable.

After several months of evaluating different options, our team released our build of an innovative patient-facing technology-based solution. A web survey tool was used to develop a questionnaire to gather patient inputted testing criteria, demographic, insurance data, offer self-scheduling options, and then automatically generate a true COVID-19 testing order within our EMR. Patients seeking COVID-19 testing were now able to go directly to our online patient self-directed screening questionnaire. If they met criteria for testing, the patient would enter their
demographic information, their insurance information, reserve an arrival window, and a true order would be generated within our EMR. The patient would then receive their visit ID/QR code via text and email within 60 seconds of completing the questionnaire.

Several key factors were leveraged for the creation of this workflow. Patient matching remains a challenge for validated and unvalidated patient registration experiences. Our workflow proposed to match patients to pre-existing records in the database using previously established algorithms. If a patient could not be matched, then a new patient record would be created.

Direct mapping of patient-entered insurance information into our Revenue Cycle software was a completely new workflow in our healthcare system. There was risk of patients choosing the wrong health insurance plan, intentionally or unintentionally. In our questionnaire, we queried the patient on several points of insurance information (unchanged, new insurance, new patient to Intermountain, no insurance) If a patient self-reported they had no health insurance, we also desired to map that to the appropriate Health Resources and Services Administration (HRSA) account for state billing. To mitigate the risk of inaccurate information mapped directly to our EMR, we created a new pandemic insurance profile in Revenue Cycle. This allowed our rules to copy pre-existing insurance information to the pandemic profile, enter new insurance to the pandemic profile, or map the HRSA account to the pandemic profile for the uninsured patient. By specifically calling out a pandemic profile, which was only populated by the patients’ use of our online screening tool, when the patient presented later for a normal non-testing related visit, the registration staff would know to re-verify insurance information.

The self-scheduling of arrival windows allowed patients to view all sites available with open time slots across the Intermountain and Idaho geography. Once the arrival window was reserved, we included an option for cancellation/rescheduling in the confirmation email, which allowed patients to be nimble in their needs while also not artificially limiting site capacity.

Reporting

As previously discussed, reporting results to patients as quickly as possible, and also reporting to public health entities was essential. Reporting to public health entities was facilitated via Electronic Lab Reporting. For delivery of results directly to patients, a people-driven process of results callbacks was the initial step. Although Intermountain Healthcare had a pre-existing robust patient portal for facilitating multiple aspects of the patient’s healthcare experience, we found that a large portion of our testing population were new patients to our healthcare system. Registering for patient portal access to view their test results initially required several steps which were challenging to a de novo patient in a contactless environment, therefore we implemented a results callback team which would call each patient with their test results. Predictably, this was an unsustainable process as the testing volumes exponentially increased. Operations decided to focus calling to only positive test results, however, even that volume became tangibly difficult to sustain with the surge in case counts. We pivoted to the concept of light identity authentication for viewing test results outside of our patient portal. While consulting closely with legal and compliance regarding patient privacy and confidentiality, we proposed a workflow of sending a unique, personalized link via text message, which when accessed by the patient, with verification of DOB, would then show the patient their result with appropriate education and guidance. Implementation of the viewing of test results after light-authentication went live in December 2020.

Results

Provider Ordering Workflow

With our novel ordering, prioritization, and lab configuration website, we have sustained >200 changes to prioritization and test codes without ever changing front-facing provider ordering workflows for over 6200 providers.

Shift from COVID-19 hotline phone screening online patient-directed screening and ordering

The capacity of our online patient-directed questionnaire to handle high volumes of screening was stable and reproducible. Maximum velocity of orders received so far has been 9 patients/minute. With the shift in order generation from requiring a patient phone call discussion with the healthcare team to our online patient-driven questionnaire, the COVID-19 hotline wait times were markedly improved. At the peak of testing demand in Fall 2020, COVID-19 hotline wait times often exceeded 1-2 hours. On 12/18/20, one day immediately prior to launching our online patient-driven questionnaire, 62% of phone calls were answered in less than 60 seconds, with a 13% abandonment rate. On 01/07/21, two weeks after deployment of our online patient-driven questionnaire, 91.2% of
Phone calls were answered in less than 20 seconds, with a 0% abandonment rate. Relative volume of inbound calls concomitantly decreased without changes in overall testing volume.

**COVID Hotline – Trends by Week (Inbound calls)**

Info, Registration, Results, Spanish Lines

![Graph of COVID Hotline Trends](image)

**Figure 2. Volumes of inbound phone calls to COVID-19 hotline from November 2020 to February 2021**

Continuous Improvement Curbside Collection time studies

After implementation of our online patient-driven screening/registration/insurance/scheduling on December 19, 2021, our on-site curbside collection patient cycle times decreased by 59%. Pre-implementation, the average patient time on site was 39.83 minutes. Post-implementation, the average patient time on site was 16.35 minutes. Our operational goal was < 20 minutes. Direct patient feedback often remarked on the improved positive experience, noting that the streamlined testing system was “fast, easy to access, with timely results.”

![Graph of Curbside Collection Times](image)

**Figure 3. On-site patient cycle times from December 2020 to January 2021**
Lab Experience time studies

In March 2020, Intermountain Central Laboratory began COVID-19 testing with the ability to process and result approximately 300 tests/day. After successful implementation of the above described measures and optimization of workflows and capacity, currently as of March 2021, Central Lab has the capacity to process and result approximately 10,000 tests/day. In summer 2020, with volumes of approximately 3000/day, often outpatient PCR turnaround times would take 4-5 days, whereas currently >97% of outpatient PCR tests are completed in less than 24 hours. As of March 10, 2021, Intermountain Central Laboratory had resulted > 1,100,000 COVID-19 tests.

Cost per test

Clinical Informatics teamed with all other partners in operations to reimagine how we could make testing more affordable, scalable, and accessible at all points of the patient experience. Digitization and automation were key contributors to decreasing the cost per test by 30.8% resulting in an estimated monthly cost avoidance of more than 2 million dollars.

Discussion

In summary, our results demonstrate how an agile, motivated, innovated Informatics team, tightly linked to operational workflow can transform healthcare. Critical to our success was the need for creativity, decisive choices, and a team mandate to never stay anchored in hubris, but to rather continually assess the problem to be addressed and create new, innovative solutions. While our team rapidly pieced together several workflows to create a highly efficient functional system, this complexity offered multiple points of failure and required constant monitoring.

Our key core functions included consumer facing data collection, stable healthcare workflows and unified screening approach for >6200 providers and screening personnel, automated flexing of ordering codes and prioritization, easily transmissible data for public health reporting, providing community testing without jeopardizing turnaround times for critically ill patients. Our testing processes truly transformed with the digitization of automated online patient-directed screening, order placement, Visit ID/QR code for collections check in, and text-message based delivery of test results.

Conclusion

There were several key points we learned: 1) Keep ordering process simple with a stable user interface; 2) Create discrete data elements of symptoms/exposure/risk; 3) Evaluate lab capacity and create automated prioritization scheme; 4) Partner with laboratory services to determine workflow, and push prioritization as a visible part of normal workflow (ex. Print priority on specimen label); 5) Adjust prioritization PRN; 6) Collaborate with operational
partners on a daily basis; 7) Use technology to improve the patient experience and create gains in testing capacity; 8) Maintain a workflow for non-tech savvy patients to mitigate possible service inequities.

These eight key points illuminate the components necessary to implement an agile, EMR agnostic, strategically delivering high-efficiency solutions for respiratory virus testing in a pandemic.

Abstract

Clinical notes are an efficient way to record patient information but are notoriously hard to decipher for non-experts. Automatically simplifying medical text can empower patients with valuable information about their health, while saving clinicians time. We present a novel approach to automated simplification of medical text based on word frequencies and language modelling, grounded on medical ontologies enriched with layman terms. We release a new dataset of pairs of publicly available medical sentences and a version of them simplified by clinicians. Also, we define a novel text simplification metric and evaluation framework, which we use to conduct a large-scale human evaluation of our method against the state of the art. Our method based on a language model trained on medical forum data generates simpler sentences while preserving both grammar and the original meaning, surpassing the current state of the art.

Introduction

Making medical information available for patients is becoming an important aspect of modern healthcare, but the frequent use of medical terminology makes it less accessible for patients/consumers. There is a trade-off between promoting more “patient-friendly” medical notes\(^1\) and the efficiency of clinicians who often prefer writing in shorthand. This is an opportunity for automation, as Natural Language Processing (NLP) and Natural Language Generation (NLG) techniques have the potential to simplify medical text and thereby increase the accessibility to patients while maintaining efficiency.

Text simplification in the general domain has improved greatly with the introduction of new deep-learning methods borrowed from the field of Machine Translation\(^2\). However, the challenges in medical text simplification are particularly focused around explaining the abundant terminology, much of which is in Greek or Latin\(^3\). This is why most efforts in the field are concentrated around the use of a mapping table from complex to simple terms\(^4, 5\). While the task of language simplification is not new, there are very few datasets specifically built for it\(^6\). In the case of medical text simplification, the community has not yet been able to use a common benchmark due to data access constraints\(^7\). Perhaps, the only resource that comes close is a medically themed subset of Simple Wikipedia\(^4, 7\). In the context of clinical notes, medical accuracy and safety are of utmost importance, which makes consistent evaluation a strong requirement for sustainable improvements in the field.

We present a medical text simplification benchmark dataset of 1250 parallel complex-simple sentence pairs based on publicly available medical sample reports. Furthermore, we propose a novel approach to lexical simplification for the medical domain, which uses a comprehensive ontology of medical terms and their alternatives, and a novel scoring function that combines language model (LM) probabilities and word frequencies into one unified measure. We conduct a human evaluation to validate our method and find that unbounded, left-to-right LMs trained on medical forum data achieve the best results on our benchmark dataset. Finally, we make the source code for our method, and all materials necessary to repeat the human evaluation, available on GitHub\(^8\). While evaluated in the medical domain, this approach can be abstracted into other domains by utilising an appropriate alternative ontology and suitable language model training data.

Our contributions are the following: a dataset of simplified medical sentences, a new approach for text simplification, an evaluation framework for text simplification, and a model that generates simpler, grammatically correct sentences with their original meaning preserved.

Related work

**General text simplification.** Initial efforts on automatic text simplification use Phrase-based Machine Translation (PB-MT) methods driven by the availability of two resources: the open-source framework Moses and the Simple English Wikipedia dataset. These early PB-MT systems perform well, but remain too careful in suggesting simplifications. Later work provides extensions that address some of these issues — deletion and Levenshtein distance based ranking. Stajner et al. (2015) provide an insight into how much of an effect the size and the quality of the training data has on the performance of the MT systems.

Machine translation algorithms trained on parallel monolingual corpora, such as the Newsella parallel corpus, have shown great promise in recent years, combining, ideally, lexical and syntactic simplification. Nisioi et al. (2017) use the OpenNMT package to simultaneously perform lexical simplification and content reduction. Sulem et al. (2018b) show that performing sentence splitting based on automatic semantic parsing in conjunction with neural text simplification (NTS) improves both lexical and structural simplification.

**Medical text simplification.** A complex vocabulary is typically the main hindrance to understanding medical text, and is therefore the main target for simplification. Fortunately, there are numerous medical ontologies containing multiple ways of expressing the same medical term, often including an informal, layman alternative. Using these ontologies to replace complicated words with more common ones is a recurring theme in medical text simplification. Abrahamsson et al. (2014) show a preliminary study on a method that replaces specialised words derived from Latin and Greek with compounds from everyday Swedish words, and achieve encouraging results on readability. Shardlow et al. (2019) use existing neural text simplification software augmented with a mapping between complex medical terminology and simpler vocabulary taken from the alternative text labels of SNOMED-CT. Their simplification method has an increased understanding among human evaluators based on a crowd-sourced evaluation process. Van den Bercken et al. (2019) use a neural machine translation approach that is aided by a terminology-mapping table that decreases the medical vocabulary in the (complex) source text.

Despite these efforts, the field still lacks a benchmark dataset based on real medical data as well as accessible open source medical baselines; the exception being the small, medically themed subset of Simple Wikipedia provided by Van den Bercken et al. (2019). The main drawback of this corpus is that it tends to simplify sentences by omitting some of the information, which is not a viable method in the context of clinical notes. Medical data is highly sensitive and even its use for research purposes is strictly regulated and often difficult. Therefore a new medical data resource is bound to have a great impact and move the field forward, as it has happened in the past.

**Dataset**

The MTSamples dataset comprises around 5,000 sample medical transcription reports from a wide variety of specialties uploaded to a community platform website. However, publicly available annotations are limited to only include high-level metadata, e.g. the medical speciality of a report.

We create a parallel corpus of clinician-simplified medical sentences on the basis of the raw MTSamples dataset. We pre-process the entire original dataset by tokenising all sentences and expanding abbreviations based on a custom list of common medical ontologies compiled by clinicians. We then review and exclude sentences that have too little context (i.e. are confusing or ambiguous to a clinician) or grammatically incorrect. Finally, three clinicians (native British English speakers) create a new version of each sentence using layman terms, ensuring consistency of both structure and medical context and accuracy. Only one simple sentence is generated for each original sentence for which simplification is possible. The resulting dataset contains 1,250 sentence pairs, of which 597 (47.76%) have been simplified. The remainder have been left unchanged because they could not be further simplified. The average number of tokens in the original sentences is 66.96, and in the simplified sentences 68.60.

We divide the data into a 250 sentence development set and a 1,000 sentence test set.

Medical ontologies

Recognising concepts and subsequently linking with a medical ontology are common medical NLP tasks necessary for higher level analysis of medical data\textsuperscript{24}. Many semantic tagging systems use the labels (text representations) defined as part of the ontologies to recognise possible instances of the entities in the text. Typically, every concept has a primary official label as well as at least a few alternative labels. Ideally these labels should be interchangeable; thus, they can be used to replace more complicated labels with layman alternatives.

In order to maintain good coverage of both medical terms and layman terminology, we select three state-of-the-art medical ontologies for creation of our phrase table. SNOMED-CT is one of the most comprehensive medical terminologies in the world, and is also available in different languages. As of the January 2019 release, it comprises 349,548 medical concepts, covering virtually all medical terminology used by clinicians. We also include the Consumer Health Vocabulary (CHV), the purpose of which is lexical simplification\textsuperscript{25}, and the Human Phenotype Ontology (HPO), which is a standardized vocabulary of phenotypic abnormalities encountered in human disease, and also contains a layer of plain language synonyms\textsuperscript{26}.

We create a vocabulary of medical terms (named entities) based on the labels of concepts from these ontologies — approximately 460,000 labels from 160,000 concepts. For example, the concept label “Otalgia” has alternative labels “Pain in ear” (Snomed), “Earache” (CHV), and “Ear pain” (HPO). To produce it, we align the ontologies using the union-find algorithm\textsuperscript{27} and discard duplicate labels, as well as those without alternatives, as they cannot contribute to the simplification process.

Lexical simplification

Lexical text simplification looks to identify difficult words and phrases and replace them with alternatives based on some measure of simplicity. Word frequency over a large amount of text is often chosen as this measure and has been used to both identify and replace candidates\textsuperscript{4}. The probability score of a sentence based on some language model has also been used to rank candidates\textsuperscript{28}. Additionally, in the medical domain, terminology words are often assumed to be the main target of lexical simplification\textsuperscript{4, 5}. We propose a new approach to medical lexical text simplification, which uses a vocabulary based on a medical ontology (see Section ) to identify candidates. It then ranks each alternative using a linear combination of word frequency and the sentence score produced by a language model. After completing the replacement and ranking steps for each medical term (of one or more words) in an input sentence, the process is repeated until no further changes are suggested. Figure 1 shows a high-level view of the algorithm.

Candidate ranking

The main task of lexical text simplification is to make the overall sentence simpler, so a ranking function should aim to provide the simplest replacement for each entity. However, this introduces a second challenge – maintaining correct grammar after the replacement. A good ranking function should therefore optimise for both the simplicity and grammaticality of the result.

Word frequency is a strong indicator for simplicity\textsuperscript{29} as it directly measures how common a given word is. However, there are different approaches to how it is utilised for multi-word expressions. Common approaches include taking the average\textsuperscript{5}, the median, or the minimum word frequency. We choose the minimum, under the assumption that the least frequent word in the sequence drives the overall understanding of the sequence. For example, consider the candidates

\begin{figure}
\centering
\includegraphics[width=\textwidth]{simplification_algorithm.png}
\caption{A flow diagram of the simplification algorithm.}
\end{figure}
otalgia of ear, and earache. An average or median frequency would score option 1 as simpler because of the very common word of, whereas the minimum word frequency would score option 2 as more frequent. To calculate the word frequencies (WF) for a given set of candidate labels, we use the wordfreq python package which provides word frequency distributions calculated over a large general purpose corpus.

\[
P(w) = \frac{C(w)}{|W|}
\]

where \(C(w)\) is the number of times the word occurs in the corpus and \(|W|\) is the number of words in the corpus. Given a sequence, such as heart attack, composed of words \(w_1 \ldots w_k\) we calculate its word frequency score, \(WF\), as

\[
WF(w_1 \ldots w_k) = \min_{i=1}^{k} \ln (P(w_i) + \epsilon)
\]

As we seek to combine this probability with language model scores, it makes sense to convert it to a logarithmic scale to avoid computational underflow. For the same reason, we introduce Laplace smoothing through the addition of the constant \(\epsilon (10^{-10})\).

Language models have made impressive strides in recent years, showing that they are capable of generating complex syntactic constructions while maintaining good grammar and coreference. We argue that the latter quality makes them a good predictor of grammatical correctness. Given that lexical simplification relies on the replacement of a recognised span from the sentence with a simpler one from a vocabulary, language models can be used to determine a score for how well a new term conforms to the grammar of the sentence.

To calculate this score we train a language model on a dataset of 160,000 original, top-level posts (1.8M sentences), scraped from the Reddit’s AskDocs forum. This dataset contains sentences which are largely medical and therefore will have the necessary vocabulary, while its language style is predominantly layman since the top post in a thread is usually written by a non-expert looking for medically-related information.

Given a sequence of words \(w_1 \ldots w_n\) and a language model, we can estimate the likelihood of the sequence as the log-probability of each word occurring given all preceding words in the sentence:

\[
\ln \hat{P}(w_1 \ldots w_n) = \frac{1}{n} \sum_{i=1}^{n} \ln P(w_i|w_{i-1}, \ldots, w_1, \langle s \rangle)
\]

where \(\langle s \rangle\) is the start symbol and \(n\) the number of tokens in the sequence. We normalise by the number of tokens \(n\) to account for replacement terms of different length, e.g. dyspnoea and shortness of breath. The language model gives a signal for how appropriate and grammatically correct the replacement term in the given sentence is. Table 1 shows both the language model \(LM\) and frequency \(WF\) scores for the term replacements of myocardial infarctions. In our example, the \(LM\) scores heart attacks (notice the plural) above heart attack given the context Patient had multiple.

Given the frequency score \((WF)\) of a replacement term \((T_i)\) and the language model score \((LM)\) for its corresponding replacement sentence \((S'_i)\), we define the final score as a linear combination of the two:

\[
\text{Score}(T_i) = \alpha LM(S'_i) + (1 - \alpha) WF(T_i)
\]

We then select the term with the highest score. The parameter \(\alpha \in [0, 1]\) acts as a regulariser and can be fine-tuned on a separate dataset. When \(\alpha = 0\), the score is entirely driven by \(WF\). When \(\alpha = 1\), the score is entirely driven by \(LM\). We select suitable \(\alpha\) values on the development set.

Simplification algorithm

A comprehensive vocabulary often results in overlapping candidate spans. For example, in the sentence Patient has lower abdominal pain, the following 5 spans match an entity: lower, abdominal pain, abdominal, pain, and lower.

\[\text{http://pypi.org/project/wordfreq/2.2.1}\]

\[\text{https://www.reddit.com/r/AskDocs/}\]

abdominal pain. In the case where two or more spans overlap or one is subsumed by the other, the algorithm takes a greedy left-to-right processing approach. It ranks the spans in order from left to right, prioritising longer spans and ignoring all spans that have any overlap with an already processed span. Additionally, it is fairly common for a sentence to contain more than one non-overlapping medical terms. For example, consider the artificial sentence: *Patient has a history of myocardial infarction, tinnitus, otalgia, dyspnoea and respiratory tract infection.*, which has multiple, non-overlapping spans suitable for replacement. When constructing candidate sentences to score, replacing only one complex term while leaving the rest of the sentence unchanged yields a sub-optimal score. The optimal approach would be to perform an exhaustive search of all possible combinations within the sentence. Given $n$ terms, and $r$ replacements per term on average, exhaustive search would require $r^n$ combinations, i.e. exponential in the number of terms in the sentence. Rather than introduce this computational cost, we instead consider each term independently of the others. After simplifying all of them, we repeat the extract-and-replace process (see Figure 1) until no further change occurs, i.e. until convergence (see Table 2). This reduces the time complexity to $n \cdot t$, where $t$ is the number of iterations to reach convergence. We cap the number of iterations $t$ at 5, as our experiments show only 1 out of 1000 sentences to ever reach this many iterations. In practice, we find that most sentences converge after one iteration, with a median of 1 iterations and an average of 1.19.

Experimental setup

As described in Section , our method requires a language model to score alternative terms. To assess the best model for this purpose we train three different language models. Next, we fine-tune $\alpha$ for each of them and proceed to measure their respective success against the human-generated reference. The language models we select are:

- **ngram** — a trigram language model built with KenLM\(^6\) and trained on Reddit AskDocs;
- **GPT-1** — a neural language model\(^33\) trained on Reddit AskDocs;
- **GPT-2** — a neural language model\(^32\) pretrained only on generic English text. We don’t fine-tune this model to evaluate whether general-purpose language models are better at choosing layman alternatives.

In order to evaluate our approach, we compare it against three methods from the literature:

- **NTS** — Nisioi et al. (2017)\(^15\) train an encoder-decoder on Simple Wikipedia, which contains a proportion of medical sentences;
- **ClinicalNTS** — Shardlow et al. (2019)\(^5\) augment the system by Nisioi et al. (2017)\(^15\) with a medical phrase table, which is the current state of the art for clinical text simplification;
- **PhraseTable** — a simple term replacement system based on the phrase table from Shardlow et al. (2019)\(^5\), which we consider our baseline.

The $\alpha$ parameter introduced in Equation 1 regulates the ratio of the language model and the word frequency score used for scoring a replacement term. A held-out development set of 250 sentences is used for tuning the $\alpha$ parameter for each of our models. For this purpose we use the automatic metric SARI\(^28\), as it intrinsically measures simplicity by comparing the model output against both the human reference and the input sentence. We perform grid search on the $\alpha$ space (0 to 1) for each model (see Figure 2) and select the top $\alpha$ to be used in the final evaluation.

\(^6\)https://github.com/kpu/kenlm
Traditional evaluation metrics

There are three general evaluation approaches for simplification that have been tried in the past:

- **BLEU score**\(^{34}\) is one of the standard metrics of success in machine translation and has been used in some cases for simplification\(^{35}\) as it correlates with human judgements of meaning preservation.

- **SARI** is a lexical simplicity metric that measures the appropriateness of words that are added, deleted, and kept by a simplification model\(^{4,15}\).

- Human evaluation, either through dedicated annotators or crowd-sourcing, indicating whether the generated sentences are considered simpler by the end users.

Both SARI and BLEU are intended to have multiple references for each sentence to account for syntactic differences in the simplified text. As we only have one simplified reference for each original sentence, these metrics are likely to be somewhat biased to a particular way of expression. Therefore, conducting a human annotation process can bring additional reassurance to the evaluation process.

Human annotation

We design a human evaluation process in the form of a crowd-sourced annotation task on Amazon Mechanical Turk (MTurk)\(^{36}\). The goal of the task is to determine whether a simplified sentence is better than the original. Celikyilmaz et al. (2020)\(^{37}\) identify the two most common ways to conduct human evaluation on generated text: (i) ask the annotators to score each simplified sentence independently with a Likert scale\(^{1}\), (ii) ask the annotators to compare sentences simplified by different models. We experiment with both methods and decide to opt for the latter, which produces more consistent results, as also shown by Amidei et al. (2019)\(^{38}\). For this purpose, we create sentence pairs from each original sentence (marked as A) and either a sentence simplified by the model or the gold simplification provided in the dataset (marked as B). We use the following four categories:

1. Sentence A is easier to understand.
2. Sentence B is easier to understand.
3. I understand them both the same amount.
4. I do not understand either of these sentences.

Often, the simplified sentence generated by the models is identical to the original sentence. To save annotation resources we annotate such pairs only once and extrapolate the annotation to all models. MTurk provides little control over the reading age and language capabilities of the annotators, so we have to account for some variability in the annotation. Therefore, all sentence pairs are annotated 7 times by different annotators. In total, the annotations comprise 20,965 sentence pairs derived from 2,995 unique ones. Finally, we use the option of selecting only “master” annotators\(^{7}\) for the task, as it is difficult to judge the quality of the work of particular annotators. We choose turkers

---

\(^{7}\)Master annotators are annotators whose work has not been rejected by task requesters for some period of time.
Table 3: Human judgement counts for sentence pairs from the test set for all models and the reference human sentences. S: the generated was simpler; F: the original was simpler; E: both of equal complexity; N: cannot understand either; U: was not changed by the model/human reference; SG: simplification gain as defined in Equation 2. Bold indicates best model. Scores in SG are significant ($p < 0.05$)

without medical experience, as opposed to medical professionals, because they are a good representation of the end users of such system. We assume that the human reference should both succeed more often and fail less often than any of the models. We measure the quality of the models with a Simplification Gain $SG$ that we define as the difference between successes $S$ (option 2.) and the failures $F$ (option 1.), normalised by the total number of pairs, $T$:

$$SG = \frac{S - F}{T}$$ (2)

Results

We count all judgements of the same category for each model and the human reference, and present the results in Table 3. Additionally, based on these counts we calculate the simplification gain $SG$ as described in Equation 2. We can make the following conclusions based on this data:

- the human reference is very rarely more complex than the original, which makes a considerable difference in its Simplification Gain, as opposed to most of the models, which seem to be prone to this kind of error (see columns F and SG);
- based on the Simplification Gain in SG, the GPT-1 model yields the best performance. We believe this is due to: (i) having access to the entire context (as opposed to n-gram), which makes it cautious about simplification, and (ii) being more focused on medical terminology due to its training set (as opposed to GPT-2);
- the methods we compare against have a negative Simplification Gain, meaning the number of failures exceeds the number of successes. General-purpose NTS is less eager in its simplification (column U in Table 3), which could be explained by the divergence between its training set (Simple Wikipedia) and our test set (Clinical Notes). Both ClinicalNTS and PhraseTable overcome this by applying a medical phrase table (see Section 6 for more details), which triggers more medical replacements. ClinicalNTS has higher Simplification Gain overall compared to general purpose NTS, which is to be expected, but still fails more often than succeed;
- A possible explanation for the high number of successes of NTS and ClinicalNTS lies in their aggressive removal of phrases, which makes them easier to understand, but at a considerable loss of information. Both systems use a model trained on Simple Wikipedia, which very often simplifies sentences by removing words or phrases. For example, the original sentence: “It has normal uric acid, sedimentation rate of 2, rheumatoid factor of 6, and negative antinuclear antibody and C-reactive protein that is 7.” is simplified into “It has normal uric acid.”

We also report the scores for the most commonly used automatic metrics in the field, BLEU and SARI, though we stress that these scores are unreliable due to (i) their limitations as shown by Sulem et al. (2018) — they only use surface level syntactic features, and (ii) they perform better with multiple references and we only have one. The NTS baseline is still performing poorly in most metrics except for BLEU, which is likely due to its conservative approach resulting in a large number of unchanged sentences that likely overlap with the reference sentences.

To test the impact of convergence, we perform an ablation study on all our models. We take all the sentences that require more than one iteration to converge (around 10% of the dataset) and perform the same human annotation described in Section . Our results show that convergence improves **SG** for all models except GPT-2 by reducing the number of miss-simplified sentences. Empirically we find that the GPT-2 tends to increase the length of the sentence at each iteration, falling into a loop typical for language models.

**Grammaticality and meaning preservation**

Asking end users to rank two sentences in order of simplicity is not enough to judge whether a generative model is performing well. A model should be penalised if the simplified sentence is grammatically incorrect or if it has altered the meaning of the original sentence. To test these two criteria, we take a random sample of 1250 simplified sentences from all models from the test set. We ask a linguist to assign one of three grammaticality categories: no errors (G1), minor errors (G2), and major errors (G3). We then ask a clinician to mark sentences from the same sample where the meaning has changed in any way.

Table 5 summarises our findings. It clearly shows the contributions of a good language model in both preserving grammar and meaning. Our method, which is informed by language models, scores highest in both criteria. NTS, which uses a language model decoder, is quite successful in preserving grammar but less successful in preserving meaning. This is likely due to its training set, which encourages the model to remove complex phrases to simplify a sentence. ClinicalNTS and PhraseTable, which rely on a hard-coded phrase table of medical substitutions, score lower both in grammaticality and meaning preservation.

**Conclusion**

In this paper, we present a novel approach to medical text simplification in an effort to empower patients with valuable information about their own health.

First, we address the lack of high quality, medically accurate, and publicly available datasets for evaluating medical text simplification by creating such a dataset with the help of medical professionals. Second, we propose an evaluation framework for assessing the quality of simplification algorithms in the medical domain, including an experimental setup for crowd-sourced human evaluation and a metric, which we call Simplification Gain, to compare the outcomes. Third, we use the knowledge stored in state-of-the-art medical ontologies to construct a comprehensive ontology of alternative medical terms, and we develop a method for simplifying medical text by extracting and replacing medical terms with layman alternatives. To rank the alternatives, we define a scoring function that takes into account both the frequency of the replacement term and how well it fits into the sentence. Our experiments, using crowd-sourcing, show that our method is capable of simplifying complex medical text while retaining both its grammatically and meaning.

We show that our method surpasses the state-of-the-art systems in medical text simplification, improving on grammaticality and meaning preservation of the simplified sentences. These aspects are particularly important in the context of medical text simplification, where factual correctness is paramount.

First-line drug resistance profiling of Mycobacterium tuberculosis: a machine learning approach

Stephanie J. Müller, PhD1, Rebone L. Meraba, MSc1, Gciniwe S. Dlamini, MSc1, Darlington S. Mapiye, PhD1
1IBM Research Africa, Johannesburg, South Africa

Abstract

The persistence and emergence of new multi-drug resistant Mycobacterium tuberculosis (M. tb) strains continues to advance the devastating tuberculosis (TB) epidemic. Robust systems are needed to accurately and rapidly perform drug-resistance profiling, and machine learning (ML) methods combined with genomic sequence data may provide novel insights into drug-resistance mechanisms. Using 372 M. tb isolates, the combined utility of ML and bioinformatics to perform drug-resistance profiling is demonstrated. SNPs, InDels, and dinucleotide frequencies are explored as input features for three ML models, namely Decision Trees, Random Forest, and the eXtreme Gradient Boosted model. Using SNPs and InDels, all three models performed equally well yielding a 99% accuracy, 97% recall, and 99% F1-score. Using dinucleotide frequencies, the XGBoost algorithm was superior with a 97% accuracy, 94% recall and 97% F1-score. This study validates the use of variants and presents dinucleotide features as another effective feature encoding method for ML-based phenotype classification.

Introduction

Despite decades of research and pharmaceutical advancements, tuberculosis (TB) continues to affect more than 20% of the global population1. Only 30 countries account for nearly 90% of the TB cases observed worldwide, with many of these being low- and middle income countries (LMIC)1. While pharmaceutical interventions such as new anti-TB drugs remain a focus area to eradicate TB, the continuous development of drug resistance by Mycobacterium tuberculosis (M. tb) strains poses the greatest challenge in attempts to curb the epidemic.

Drug-susceptibility testing using phenotypic methods such as laboratory-based culture are both laborious and time-consuming, sometimes requiring up to three months for confirmation of drug-susceptibility of the M. tb isolate. In addition, the infrastructure and technical skills needed to perform phenotypic testing is often limited in LMIC countries which also tend to be most in need of these capabilities. To circumvent these long waiting times - during which drug-resistant M. tb continues to spread within communities - several genotypic assays have been developed for rapid screening of isolates for drug-resistance mutations2,3. Although such genotypic assays improve the turnaround time, they are limited in the mutations they screen for, thereby reducing their ability to comprehensively detect drug resistance. As a result of this design, these assays are unable to either detect mutations in other genes of the isolate, discover novel mutations arising in the bacterial community, or exclude the potential resistance to non-target M. tb drugs as caused by other mechanisms4,5.

Numerous studies have applied traditional bioinformatics methods to explore the M. tb genome and identify single nucleotide polymorphisms (SNPs) or insertions and deletions (InDels) associated with drug resistance6–8. Briefly, these studies categorized genetic variants according to those that are associated with resistance to a drug and those that are not, followed by classification using these phenotypic labels. This approach is useful for drugs such as Rifampicin (i.e Rifampin) in which resistance is conferred by a few variants with large effect size. However, its performance is reduced on drugs for which resistance is conferred by a large number of variants, possibly spanning multiple genes. Advances made in machine learning and sequencing techniques in the last decade have provided a greater platform from which to investigate and leverage the “hidden” patterns within genomic data, thereby providing an alternative to phenotypic drug resistance profiling8,9. To facilitate this, several machine learning approaches have been applied to genomic data from M. tb isolates to predict drug resistance6,9,10.

In this study, the application of machine- and statistical learning models and genomic features is presented with the aim of developing a clinically applicable model to detect extreme first-line multi-drug resistance (MDR) i.e isolates simultaneously resistant to the four first-line anti-TB drugs. We hypothesize that the predictive performance for anti-TB drugs that define extreme MDR to first-line drugs can be improved using a comprehensive set of genomic variants.
coupled with tree-based machine learning algorithms capable of incorporating and encoding them.

**Materials and Methods**

**Data collection and pre-processing**

A total of 372 *M. tb* isolates sourced from Walker *et. al* were included in this study. Here, machine learning and statistical methods were used to identify features stratifying isolates from two extreme MDR phenotypes, namely first-line drug resistance and first-line drug susceptibility. A total of 186 samples resistant to all four first-line anti-TB drugs (Rifampicin (RIF), Isoniazid (INH), Ethambutol (EMB), and Pyrazinamide (PZA)), and 186 samples susceptible to the same four anti-TB drugs were used as input to the workflow.

![Generalized workflow used in this study](image)

**Figure 1:** Generalized workflow used in this study

Using a customised bioinformatics workflow (Figure 1), all isolates were subjected to quality control, in which paired-end raw sequencing reads in FASTQ format were trimmed using Cutadapt (v. 1.18) with a Phred score of 20. The trimmed sequences were aligned to the *M. tb* H37Rv reference genome (Genbank: NC000962.3) using BWA-mem (v. 0.7.17). Samtools (v. 1.9) was used to convert Sequence Alignment Map (SAM) files to Binary Alignment Map (BAM) format. Subsequently, Picard Tools (v. 2.18.23) was used for BAM file sorting, marking of duplicate reads, adding of read groups, and indexing. SNPs and InDels were called using the Genome Analysis ToolKit (GATK, v. 3.8), followed by annotation using SNPEff (v. 4.3.1). Missense SNPs and frameshift InDels were extracted using SNPSift (v. 4.3.1).

**Variant prioritization**

Variants present in 16 *M. tb* genes with known drug resistance mutations to the four first-line anti-TB drugs were prioritized for this study, namely, rpoB for RIF resistance, abpC, fabG1, inhA, katG, ndh for INH resistance, embA, embB, embC, embR, iniA, iniC, manB, rmlD for EMB resistance, and pncA and rpsA for resistance to the drug PZA. This selection was based on the reported involvement of these genes in the occurrence of drug resistance in *M. tb*. SNP and InDel mutations not appearing in at least 99% of the 16 candidate genes were removed from further analyses. The remaining mutations were used to generate a feature matrix which served as input for training of three ML classifiers.

**Dinucleotide frequencies**

Dinucleotides are comprised of the 16 unique combinations of four nucleotides AT, AA, AC, AG, TT, TA, TC, TG, GT, GA, GC, GG, CT, CA, CC, and CG. To calculate dinucleotide frequencies, reads spanning the 16 target genes were extracted using genomic coordinates retrieved using Mycobrowser. For each sample, extracted reads were synchronized using Fastq-pair followed by assembly into contigs using the default parameters of the SPAdes assembler. Contigs are continuous sequences produced when the optimal overlap of input reads is obtained. Low read overlap, and sequence contamination may result in poor construction of a single contiguous sequence, thereby rendering either no contig or multiple shorter contigs. Samples producing a single contig and samples producing multiple contigs were selected and used further in the analysis to compute dinucleotide frequencies, where in the latter group, the longest contig was selected as recommended in Douglass *et al*. Samples producing no contigs in at
least one of the genes were excluded from further analyses as the cost of reducing the sample size was considered to be less detrimental than the cost of other measures aimed at maintaining the sample size, such as data imputation.

For a random subset of samples from each phenotype, contigs in FASTA format were submitted to the BLAST\textsuperscript{21} database via the PATRIC\textsuperscript{22} website. This was to confirm that the contigs produced co-located with the genes from which the reads were extracted. Lastly, the 16 dinucleotide frequencies of the contig sequences belonging to the genes of interest were calculated as described by Dlamini \textit{et al.}\textsuperscript{23}. To account for frequency-bias due to variable gene and contig lengths, dinucleotide frequencies were normalised across the genes for each sample to produce relative frequencies.

\textit{Data visualization}

Principal Component Analysis (PCA) and t-distributed Stochastic Neighbor (t-SNE) were used to investigate separation of the data based on the two phenotypes. Both PCA and t-SNE may be used to reduce the dimensionality of highly sparse datasets, while maintaining the variation within the information captured in the original dataset. In addition to performing dimensionality reduction for the purposes of visualisation, PCA was performed on the feature matrix of SNPs and InDels to investigate the potential confounding effect of lineage on resistance to anti-TB drugs, as described by Gan \textit{et al.}\textsuperscript{24}. This was completed by excluding all lineage specific mutations reported in Walker \textit{et al.}\textsuperscript{4}.

\textit{Classification}

Three ML algorithms, namely, Decision Trees\textsuperscript{25} (DT), Random Forest\textsuperscript{26} (RF), and the eXtreme Gradient Boosted algorithm\textsuperscript{27} (XG) were investigated for their ability to classify the dataset into two drug resistance phenotypes, using either variants (SNPs and InDels) or dinucleotides as features. Data were classified using a binary label $Y$, with 0 used to denote drug susceptible samples, and 1 used to denote drug resistant samples. For each feature workflow, the data was randomly split into 80\% training data and 20\% test data in a stratified manner to maintain phenotype distributions. Five-fold cross-validation was performed through a randomized grid search using Scikit-learn’s RandomizedSearchCV\textsuperscript{28} to optimise the parameters of each model. Predictions were made on the held-out test set using the optimised parameters for each model. Lastly, the performance of the three models was assessed using accuracy, recall, and F1-score and 95\% confidence intervals were estimated using bootstrapping\textsuperscript{29}.

Two sets of analyses were conducted using dinucleotide features: a composite analysis (in which dinucleotide frequencies for all genes were used simultaneously as features), and a per-drug analysis, in which the classification models were retrained and tested on the subset of dinucleotide features encoding the set of genes linked to resistance of each drug. For resistance to RIF, each of the three models were trained using the dinucleotide frequencies calculated on the contig spanning the \textit{rpoB} gene. Likewise, for INH resistance, the dinucleotide frequencies calculated for all samples across the \textit{ahpC}, \textit{fabg1}, \textit{inhA}, \textit{katG}, and \textit{ndh} genes were selected, and used in model training and testing. This same process was completed for resistance to EMB and PZA, respectively, using the gene sets described previously. This analysis was performed with the goal of furthering our understanding of the mechanisms driving classification within one drug as compared to the others.

\textit{Results and Discussion}

\textit{Data collection and pre-processing}

\textit{Features}

The variant-based feature set consisted of 54 features and 372 observations, containing 186 resistant and susceptible samples each. For the dinucleotide features, contig construction was attempted for each of the 16 genes of interest and for all 372 samples. Of the 372 samples, samples producing no contig for one or more of the 16 target genes were removed from the analysis and the subset of samples producing at least one contig per gene was retrieved. This process reduced the sample size from 186 samples with resistant and susceptible phenotypes each, to 153 resistant and 182 susceptible samples, respectively. A randomly chosen set of contigs were visualized in the PATRIC database, confirming that the contigs constructed for the genes did indeed span the intended genes. In addition, more than
30% of the samples produced multiple, short contigs for the embR gene, and thus, this gene was removed from all further analyses. Therefore, the final feature dataset for dinucleotide frequencies was comprised of 335 observations (samples) and 240 features (16 dinucleotide frequencies for 15 genes).

**Data visualization**

Using variants as features, PCA and t-SNE of the 16 target genes showed a lack of multiple clusters due to a poor separation of the *M. tb* isolates by lineage (Figure 2). As expected, given the absence of the 42 lineage-defining mutations that were reported by Walker *et. al*\(^4\), these findings suggest that the samples are from a single lineage. Moreover, the lack of multiple clusters with a clear discrimination between the two phenotypes confirms that lineage is not a confounder of *M. tb* drug resistance. Relative frequencies of dinucleotides as features representing the 15 genes showed no discernible pattern of resistance classification (Figure 3).

**Figure 2:** (A) PCA and (B) t-SNE of variant features for 16 genes

**Figure 3:** (A) PCA and (B) t-SNE of dinucleotide features for 15 genes

**Classification**

When using variants as features, the XG model was trained using default parameters, while DT and RF models were trained using optimised hyperparameters. When using dinucleotide frequencies as features, all three models were trained using default values for the hyperparameters as these hyperparameter configurations yielded optimal cross-validated results.

For all three ML models, classification by drug resistance phenotype showed that using variants as features resulted in
fewer incorrect predictions (Figure 4) as compared to using dinucleotides as features (Figure 5). Although marginal, the use of variants as features performed better than using dinucleotide frequencies (Table 1). When considering the use of variants as features for phenotype classification, all models performed equally well with an average accuracy of 99%, recall of 97%, and F1-score of 99%.

When using dinucleotide features, the XG algorithm outperformed the DT and RF models, with an average accuracy of 97%, recall of 94%, and F1-score of 97% (Table 1). This may be attributed to either the input features, the existence of additional resistance-associated mutations, or the co-occurrence of resistance to multiple drugs within the genes of interest. Alternatively, it may be that the feature encoding methods used in this analysis are capable of encoding additional features associated with drug resistance.

**Table 1:** Classification results: average performance of the three models with their 95% confidence intervals

A subset of important features driving the drug resistance prediction was extracted for each model. For the approach
using variants as features, the Ser315Thr mutation in the katG gene and Ser450Leu mutation in the rpoB gene were consistently identified as the top two features across all three models (Table 2). These results are similar to those reported by Walker et al., where these mutations were identified to confer resistance to INH and RIF, respectively. Similarly, in a whole genome sequencing study performed to detect genomic markers of *M. tb* drug resistance, the most common mutations observed for INH and RIF resistance were katG (Ser315Thr) and rpoB (Ser450Leu), respectively\(^30\). Furthermore, when the evaluation of genotype MTBDRplus for rapid detection of drug resistant TB was performed among resistant clinical isolates, the same mutations were dominant\(^31\).

The drug composite analysis using dinucleotide features encoding for similar samples revealed the AT dinucleotide in the iniC gene to be the top feature driving the phenotype classification for all three models (Table 2). This feature was closely followed by the TA, and AT dinucleotides in the rpoB gene driving classification using the DT, and RF models, respectively. While iniC harbours mutations linked to EMB resistance, rpoB is well-known for its mutations conferring resistance to Rifampicin\(^4\). Mutations in the fabG1 gene have also been associated with resistance of *M. tb* to INH\(^32\).

When analysing the dataset per drug, phenotype classification using dinucleotides from the rpoB gene responsible for RIF resistance performed relatively well, with a mean accuracy of 88%, 94%, and 94% for the DT, RF, and XG models, respectively (data not shown). Classification of samples into their respective phenotypes using features from the five genes associated with INH resistance also performed relatively well, with a mean accuracy of 90%, 94%, and 96% for the DT, RF, and XG models, respectively. Lastly, models built using dinucleotide features from genes linked to either PZA or EMB resistance performed worse than those built for RIF or INH (results not shown). Additionally, the TA dinucleotide in the pncA gene was found to consistently be the top performing feature driving phenotype classification using dinucleotide features from the gene set responsible for PZA resistance. Using dinucleotides from genes linked to EMB resistance, the AT dinucleotide in the iniC gene was the most important feature driving phenotype classification using the DT and XG models, while the GC dinucleotide in the manB gene was the most important feature when using the RF model.

While we are unable to validate these findings using laboratory methods at this time, it may be hypothesised that classification using dinucleotide features built using genes conferring EMB resistance in isolation may be weaker, but when analysed with features for the genes associated with the other three first-line drugs, classification using EMB features may be strengthened, as seen by the dominance of the iniC gene as a top feature (Table 2).

As shown by this study, the use of two different genomic feature encoding methods may enable the identification of different drug resistant genes. The analyses conducted has shown that although the genetic determinants of resistance to RIF and INH are well defined and understood, the full catalogue of mutations encoding resistance to other first-line drugs is not yet fully understood. Therefore, these findings demonstrate and support that rapid diagnostic tests relying on detecting mutations conferring resistance to RIF and INH are highly sensitive and specific but those targeting other drugs require further optimization if they are to replace conventional drug susceptibility testing.

Some limitations to this study include the potential error in phenotypes as drug susceptibility testing for some drugs have been shown to have low reproducibility and high variance, assuming that resistance for each drug and feature space were independent. Additionally, all variants in the genes included in this analysis were considered as equally important during model development, limiting our knowledge of strain hypervirulence\(^33\).

Whilst the effects of small sample sizes on ML algorithms are well-documented, the final models performed fairly well despite the limited dataset. This may, in part, be attributed to the type of algorithms (tree-based methods) that were implemented, whose complexity could be controlled in order to minimise over-fitting. In addition to the choice of algorithm, the feature set that was used to fit the models also contributed to the models’ performance. In situations where the dataset is limited, it is necessary to utilise knowledge-based features that are known to have a direct influence on the prediction task. In this study, this manifested in two ways. Firstly, it was through the focus on the 16 genes that have been implicated in drug resistance in the four first-line drugs. Secondly, and specifically for the variant-based analysis, it was through the additional employment of hand-crafted, expert-informed variant features that were extracted from the 16 genes of interest.

Conclusion

In this study, three ML models were evaluated for their ability to classify the phenotype of *M. tb* samples as being resistant or susceptible to the four first-line anti-TB drugs. These models used two different feature encoding methods. The use of variants (SNPs and InDels) as features performed slightly better than the models constructed using dinucleotide frequencies as features. Furthermore, a review of the model features that drove the classification results for the variant-based analysis revealed a set of known important features, thereby confirming the utility of this feature encoding approach. In contrast, the important features driving classification using dinucleotide features provided unexpected results, with the AT dinucleotide in the iniC gene (associated with EMB resistance) being the top performing feature. This study therefore demonstrates the potential use of different genomic variation encoding methods combined with machine learning in clinical workflows to robustly predict anti-TB drug resistance. The results obtained in this study demonstrate the potential of phenotypic drug resistance profiling through encoding underlying genomic variation into features that can be used to develop machine learning models capable of discriminating *M. tb* isolates with extreme forms of resistance.

Abstract

We developed a prognostic model for longer-term outcome prediction in traumatic brain injury (TBI) using an attention-based recurrent neural network (RNN). The model was trained on admission and time series data obtained from a multi-site, longitudinal, observational study of TBI patients. We included 110 clinical variables as model input and Glasgow Outcome Score Extended (GOSE) at six months after injury as the outcome variable. Designed to handle missing values in time series data, the RNN model was compared to an existing TBI prognostic model using 10-fold cross validation. The area under receiver operating characteristic curve (AUC) for the RNN model is 0.86 (95% CI 0.83-0.89) for binary outcomes, whereas the AUC of the comparison model is 0.69 (95% CI 0.67-0.71). We demonstrated that including time series data into prognostic models for TBI can boost the discriminative ability of prediction models with either binary or ordinal outcomes.

Introduction

Traumatic Brain Injury (TBI) is one of the leading causes of death and disability in the United States. There are nearly 2.8 million new TBI cases every year in the US (1). It is estimated that the general trend of worldwide TBI cases will continue to increase and be a growing significant health problem, particularly, for low- and middle-income countries (2). Accurate and early prediction of outcomes in TBI patients can help in clinical management as well as in optimizing resource allocation within the health system (3).

Even though not all TBI cases result in death, different forms of disability are common in complex TBI cases, and simple mortality predictions do not account for the long-term health consequences associated with TBI. Therefore, any practical TBI prediction model should consider outcomes other than mortality (2). The Extended Glasgow Outcome Scale (GOSE) is a functional TBI outcome measure of the severity of TBI and is often used in prognostic models (4). GOSE rates patients in eight categories, from death to upper good recovery, and has been commonly dichotomized into mortality (versus survival) or unfavorable (versus favorable). In this research, we develop a model to predict the GOSE outcome of TBI patients.

Prior studies have developed and evaluated models to predict mortality or severity of TBI patients. A systematic review shows that many prognostic studies suffer from methodological issues. For example, the sample size may not be sufficient: 75% of studies have less than 500 subjects (2,3,5). Two of the most widely used prediction studies for TBI patients are the International Mission on Prognosis and Analysis of Clinical trials in Traumatic Brain Injury (IMPACT) (6) and Corticosteroid Randomization After Significant Head injury (CRASH) (7). The covariates in these models are primarily based on the clinical, physiological, and lab data that are collected at the time of admission, which does not take into account the evolution of the primary injury, and the development of secondary brain injuries.

Regression models, such as logistic regression, to predict disease occurrence (diagnosis) or disease outcome (prognosis), are standard approaches to build a prediction model (8). However, machine learning (ML) algorithms are gaining acceptance for use in the clinical domain especially as the increasingly large and rich data sets such as Electronic Health Records (EHR) data are growingly available (9). On the other hand, recent data suggests that ML algorithms do not necessarily outperform regression models for prognosis of TBI cases, especially when the number of predictors is not high.

In our study, in addition to clinical and laboratory data collected at the time of admission to the Emergency Department (ED), we use time series data obtained from the first few days in the ICU. Recurrent neural networks (RNN) are well known to achieve strong results in many applications with time series and sequential data (10). Two common RNN structures, the Long Short-Term Memory (LSTM) and Gated Recurrent Unit (GRU), can capture the long-term temporal dependencies in variable-length samples. GRUs are getting more attention since they can maintain the effect of LSTM units while they are simpler. A study showed that GRUs can outperform LSTM units both in terms of CPU time and generalization (11).

One of the limitations in working with clinical time series data is missingness. Approaches to handle missing values in time series data include, but are not limited to, deletion, mean imputation, and autoregression (12). A case study shows that when the missing rate is high, excluding incomplete data negatively impacts the performance of prediction models compared to alternative scenarios of imputation (13). In this work, imputing time series missingness and training the model are done simultaneously. GRU-D is a recently developed recurrent unit for managing the missingness that optimizes the model performance by imputing missing data while simultaneously learning the model parameters (14).
In this paper, we describe an attention-based RNN with new recurrent units known as GRU-D. Our study differentiates from others according to the following characteristics.

- The model combines the temporal features during the ICU stay (e.g., a sequence of vital signs) and non-temporal features such as age and sex.
- The model handles missing values in the time series data and learns from the missingness patterns. Training and imputation occur simultaneously. It uses GRU-D units that benefit from a decaying mechanism for imputation of missing values among time series data.
- The most important features for predicting the longer-term outcomes in acute TBI patients are identified.

Materials and methods

Source of data

This study was based on data from the prospective, multicenter Transforming Research and Clinical Knowledge in Traumatic Brain Injury (TRACK-TBI) study (15). The TRACK-TBI study collected detailed clinical data on TBI patients from 18 different academic Level I trauma centers across the US. TRACK-TBI enrolled 2996 participants across the spectrum of TBI severity.

For this analysis, we included a total of 110 clinical variables that were collected at the time of arrival to the ED, discharge from ED, and during the ICU or hospital stay. During ICU stays, measurements were recorded as frequently as every hour, providing extensive time-series data for those variables. Of the total 110 variables, 59 were static variables (demographic or one-time-recorded measurements in ED), and 51 were time-series variables that were recorded during the patients hospitalization. The GOSE was measured at six months after injury and was used as our primary outcome variable for this analysis. Table 1 shows the summary statistics for clinical variables in the dataset.

Study participants
We included all adult participants with GOSE scores available and those that are admitted to the ICU. Non-adult participants and those who withdrew consent are excluded from the analysis. Out of 2996 participants, 902 met the mentioned criteria and are included in the analysis. Only the first five days of ICU data are used in this study. Figure 1 shows the exclusion criteria and the number of subjects that are left after applying each criterion.

Figure 1. Flowchart showing study participant selection

Missing data
Large amount of missing values in clinical time series data is common (16). To tackle sporadic measurements in the ICU, we discretized the observation time window into fixed-length time intervals. As shown in Figure 2, some variables might have missing values after discretizing the time window, while others have more than one value in a timestamp. We replaced the value of each variable in each timestamp with the average of recorded measurements in the corresponding interval. In order to handle the missingness, we utilized a modified version of Gated Recurrent Units which will be discussed later.

From all static variables, those with more than 20 percent missing data were excluded from the analysis. For imputing the missing static data, we used a Multivariate Imputation with Chained Equations (MICE) approach. In this approach, a series of predictions are used to impute the missing values of each variable. This is done iteratively until the imputed data does not change significantly (17).

Model Development
In this study, a deep RNN model was developed to predict TBI patients’ functional outcome at six months, post injury. As the output of the model (GOSE) is an ordinal variable, we follow the same procedure presented by Chen et al. (18) to handle the ordinal output in a neural network. We transformed a classification problem with $K$ ordinal categories to $K-1$ binary classifications. To do so, we used a special type of output encoding. The $i^{th}$ element of the encoded binary output shows whether the original output is larger than the $i^{th}$ ordinal level. In other words, if a data point belongs to the $i^{th}$ category, the first $i-1$ binary variables of the encoded output vector are 1 and the rest are 0. As an example, if GOSE value is 3, the corresponding vector is $(1,1,0,0,0,0,0)$. We use the sigmoid function as the activation function of the output node, and a squared error loss function is used.
Figure 2. Distribution of recorded measurements across different variables over time for a single patient. The plot on the left shows that different variables have different frequencies of measurement. For example, blood pressure is taken hourly, but urea lab is taken at most once a day. The plot on the right illustrates how values are aggregated over 10-hour intervals.

The model consists of two parts. In the first part, time series data for the first five days of ICU is fed to an RNN which is elaborated on later. The output vectors of RNN at each time step go through an attention layer which takes a weighted sum of its input vectors. The attention layer output is concatenated with the static values and passed through a hidden dense layer before the output dense layer. Figure 3 shows the structure of the prediction model.

Figure 3. The deep RNN structure for predicting the output. Temporal features are fed to the GRU units and static features are connected to the output through a hidden layer. An attention layer is also used on top of the sequential part of the model.

In this model, we used a modified GRU unit presented by Che et al. (14) which is called GRU-D. They showed that the missingness pattern among variables in time series can provide useful information. They modified the GRU unit in such a way that it captures the missingness information and, at the same time, imputes the missing data. In this research, we used the GRU-D units for RNN cells in our model to predict the GOSE among TBI patients.

In the clinical domain, variables tend to be close to a default number when they are unobserved for a long time (14). This would mean that missing values in time series would fade gradually to a default value (e.g., the empirical average of the variable). GRU-D enjoys a decay mechanism for input variables and hidden states to address the mentioned properties. Two types of decay variables are used in GRU-D, input decays ($\gamma_x$) and hidden state decays ($\gamma_h$). The general formulation of decay vectors is as follows:

$$\gamma_t = \exp\{-\max(0, W_\gamma \delta_t + b_\gamma)\}$$

(1)

where $\delta_t$ shows how far the last observation of each variable is from time $t$. $W_\gamma$ and $b_\gamma$ are the parameters of the model which must be learned. Corresponding to each variable, a masking vector, $m$, is defined in such a way that is 1 if the variable is observed and otherwise is 0. To impute the input values of the time series, the following formulation is used.

$$\hat{x}_t^d = m_t^d x_t^d + (1 - m_t^d)(\gamma_x^d x_t^d + (1 - \gamma_x^d)\hat{x}_t^d)$$

(2)
In Equation (2), indices $d$ and $t$ indicate $d$-th variable and $t$-th time slot, respectively. $\hat{x}_t^d$ is the imputed value of the input variable and would be used in the traditional GRU equations. $x_t^d$ is the input time series data. $\gamma_t^d$ is the input decay calculated by Equation (1). $\hat{x}_{t'}^d$ is the last observed value of $d$-th variable at time $t'$. $\bar{x}_t^d$ is the empirical average of $d$-th variable over all time steps and observations.

To fully capture the missingness information, a decaying mechanism for the hidden states is utilized. Before modifying each hidden state using traditional GRU equations, a new decayed hidden state is calculated as follows:

$$\hat{h}_{t-1} = y_{ht} \odot \hat{h}_{t-1}$$

(3)

Instead of $x_t$ and $h_{t-1}$, we use $\hat{x}_t$ and $\hat{h}_{t-1}$ in the update functions of the GRU-D.

To avoid our model overfitting on the training data, we used some tools to regularize the model. We utilized dropout after each layer of the model (both recurrent and feed-forward layers) to randomly drop some of the nodes. We also applied a L2-regularizer on the hidden layer weight parameters. L2-regularizer applies penalties on the layer weight parameters. These penalties are summed into the loss function and hence, avoids weight parameters taking large values.

For comparison purposes, we developed a regression model using static data. In this model, only the variables used in the IMPACT prediction model (6) are included, which are age, motor score, pupillary reactivity, hypoxia, hypotension, glucose, and hemoglobin. To build the model, we first converted the values of each variable to the IMPACT score, and then developed an ordinal logistic model on those scores. The IMPACT model originally was developed on patients with moderate and severe TBI (GCS ≤ 12), and a dichotomized GOS score based on favorable and unfavorable outcomes. To have a fair comparison with IMPACT, we also developed, trained, and validated our model under the same conditions. In order to dichotomize the GOSE score, an outcome is unfavorable if GOSE ≤ 4, otherwise it is considered favorable.

The output of the prediction is an ordinal variable, and generally three types of performance metrics are used to assess ordinal classifiers: accuracy, misclassification error, and rank association (19). All these three measurements are used in this study to compare the models. Accuracy (ACC) simply calculates the proportion of correct classifications. To take the misclassification into account, we also used Area Under the Curve (AUC), F1 score, and Mean Squared Error (MSE). MSE measures the degree of error between true and predicted labels. To calculate this error, we assigned a number to each class of GOSE score from one to eight. Since the class sizes are imbalanced in the output variable (Table 1), we used weighted average of MSE (AMSE) and weighted average accuracy (AACC) across all classes (20).

Another criterion measures the association between true ($y$) and predicted ($\hat{y}$) labels using a rank order correlation statistic called Kendall’s correlation coefficient ($\tau_b$) (21). Based on this criterion, values of $\tau_b$ are in the interval of [-1,1]. Larger values of $\tau_b$ indicate better association between two ranking vectors (predicted and true output values) and hence better prediction. However, this measurement has a drawback since it does not consider the predictions individually and only takes into account the ranking of the prediction and true values as two vectors.

To tune the model hyperparameters, we used a Bayesian Optimization (BO) method presented in (22) to find the best set of hyperparameters for the model. BO is a strategy for optimizing black-box objective functions that are expensive to calculate. To evaluate the performance of the models in each iteration of BO, a 10-fold cross validation is implemented which splits the data to training, testing, and validation sets. The proportion of different GOSE levels was preserved among all training, testing and validation sets. To assess the performance of models, the same 10-fold cross validation approach was utilized, and the metrics were evaluated on the testing data.

In order to interpret the proposed model, we utilized Shapley Additive Explanation (SHAP), a unified framework for interpreting predictions via feature importance (23). SHAP unifies methods like LIME (24) and DeepLIFT (25) under the additive feature attribution umbrella. An additive feature attribution method formulates the outcome of a prediction model in the form of $f(x) = \theta_0 + \sum_{i=1}^{n} \theta_i x_{i}'$, in which $f$ is the prediction model, $\theta_i$ is the attribution assigned to each feature and $x_{i}'$ is a simplified input showing whether the $i$-th feature is missing. To implement the method, we used the SHAP python package written by the authors of the original paper.

**Results**

A total of 902 participants and 110 variables met the inclusion criteria for this study. Our proposed prediction model was trained on the training data and its performance was measured on the test set based on different metrics. The results are shown in Table 2. The values represent the mean and the standard error of mean for a 10-fold cross validation.

We also analyzed the importance of time series data in the prediction task. To do so, we first only added the static data to the model and eliminated the recurrent part of the model (i.e., GRU-D units). We then trained another model which only incorporated the time series data. This model lacked the static inputs of the main model, so it only had the GRU-D units fed by time series data. The results of this analysis are shown in Table 3.

Figure 4 illustrates the important features that contributed to the outcome prediction of two sample patients with different outcomes. The important features were derived based on the magnitude of the SHAP values. Figure 5 shows the top important features derived using SHAP values. To assign a single value to each temporal feature, we took an average over all data for the first 120 hours of each patient. Figure 6 illustrates the time series values of three numerical variables among top features for favorable and unfavorable outcomes over the first five days of ICU stay. The missing values in the time series data were imputed using the linear interpolation.

Figure 4. Important features contributing to the outcome prediction of two patients. Patient A had a favorable outcome with GOSE eight, and patient B died after six months (i.e., GOSE equals one). Features indicated with red and blue colors contribute to the unfavorable and favorable outcomes, respectively. Patient A is a 24 years old male with both reactive pupils at ED, while patient B is a 42 years old female with only one reactive pupil at ED.
Figure 5. Top important features based on the absolute value of SHAP. Each point represents a patient, and the horizontal axis indicates the SHAP value of each feature for a patient. Negative and positive SHAP values imply the contribution to an unfavorable and favorable outcome, respectively. The color of each point represents the value of a feature for a patient. Feature names that start with “Daily” correspond to time series variables.

Figure 6. Time series values for different lab measurements over the first five days of ICU stay. Solid lines show the average and dashed lines are three standard errors. Favorable and unfavorable outcomes are separable for all three measurements.

Discussion

The main objective of this study is to predict 6-month outcome for the TBI patients admitted into the ICU. Prior studies using the TRACK-TBI dataset developed a clustering approach for identifying TBI cohorts (26) and implemented a linear regression model to predict the post-concussive symptoms among mild TBI patients (27).

Comparison of model performance and relevance

The comparison between the RNN model and IMPACT shows that the RNN model with time series data performs better based on all metrics. When all population is included and the outcome consists of all eight levels of GOSE, the AUC for both models is low (less than 0.6). One of the possible reasons for not achieving a high AUC is the implementation of a multiclass classification with eight classes. After dichotomizing the GOSE and refitting the models, the AUC for both IMPACT and RNN increases (0.69 and 0.86, respectively). However, RNN still outperforms the IMPACT on all metrics. Even though we did not include the CRASH model in our analysis, one study validated CRASH on TRACK-TBI dataset and demonstrated a poor discriminative ability (AUC of 0.49-0.50) for mild TBI patients (28).

Since the IMPACT model was originally developed on severe and moderate TBI patients, we expected a better performance for IMPACT on this population. However, compared to their performance on all populations, the RNN and IMPACT have a weaker performance. The RNN model with the binary outcome has an AUC of 0.86 on the whole cohort whereas it shows a lower AUC (0.81) on the severe and moderate TBI population. One potential reason is that TBI patients with lower acuity...
represented over half the studied cohort (555 subjects), thus by excluding these patients, training data shrinks by a significant amount.

Results in Table 3 illustrate that the time series data play an important role in the RNN model’s performance. The model trained with only time series data significantly outperforms the model trained with static data. For example, the Kendall coefficient for the model with time series data is 0.55 while this metric for the model with static data is only 0.15. The model trained on only time series data is even superior to the IMPACT model as all the metrics show a better performance. This improvement implies that training our model only with time series data demonstrates a better predictive ability in comparison with the IMPACT model.

**Interpretability of deep learning models**

To support the interpretability of the RNN model used in the work, we used SHAP to rank the features based on their contribution to the outcome prediction. The important features identified by our model highlight the validity of our model development strategy. The model found that age was one of the most important variables, which is a well-recognized observation (29) and indeed is a core component of the IMPACT prediction model. Other variables from the IMPACT model, namely motor GCS and pupillary reactivity, are also featured. Interestingly, the time series of the GCS are also featured in our model which is novel. This likely reflects the evolution of the patients’ neurological exam over time and therefore contributes to prognosis.

The inclusion of vital sign data is noteworthy. The diastolic blood pressure is a known risk factor for long-term cardiovascular health but has not been described in traumatic brain injury populations. Heart rate on the other hand may reflect shock or dysautonomia which impacts patients after TBI and may contribute to prognosis as well. The inclusion of sodium levels in our model suggests that the therapeutic intensity of treatment for elevations in intracranial pressure, which includes administration of hypertonic saline solution, is reflective of prognosis – the sicker patient is treated more aggressively. Therefore, elevated sodium as a negative prognostic marker likely represents the reality that the patient was exhibiting signs of more substantial injury requiring more aggressive therapy. However, this hypothesis would need to be formally tested as patients with the most severe injuries may develop diabetes insipidus (DI), which results in increased sodium, but DI remains relatively uncommon. Despite the limitations, it is worth highlighting that the model uncovered new and/or hypothesis-generating findings by leveraging both static and time-series data within this cohort.

The SHAP contributions of the top features cohere with their measured values, which is clearly illustrated in Figure 5. Most of the time, a consistent trend exists between SHAP contribution and measured values of each variable. Age is one of the best examples of this consistency between feature values and their SHAP contribution. As shown in Figure 5, the SHAP values decrease when the patients’ age increases, which means a patient’s age contributes more to an unfavorable outcome for older people. Figure 4 shows the SHAP contributions for patients A and B with favorable and unfavorable outcomes, respectively. Based on the SHAP scores, ED pupil reactivity contributes to the favorable and unfavorable outcomes for patients A and B, respectively, which matches the value of this feature since both pupils are reactive for patient A while only one of the pupils of patient B is reactive.

**Limitations**

One of the challenges in working with clinical time series data is that variables are not measured consistently over time. For example, vitals are recorded regularly, but mostly when patients are unstable. On the other hand, lab results are recorded only when physicians or nurses order them. As a result, clinical variables are recorded irregularly, and the measurement frequency varies between patients and is dependent on the place where the variables are taken. This frequency might be different across variables and even over time (16). However, our deep learning algorithm requires time series data to have regular time intervals. To make it possible, we discretize the observation time window into fixed-length time intervals (one-hour intervals) and aggregate all data within each interval. This method is a tradeoff between losing some information and increasing missing data. By increasing the length of time intervals, some information is lost since all available data in each interval is aggregated. Comparably, by decreasing the length of time intervals, as much data as possible is retained, but the missing data would increase since some of the intervals have no data.

Another limitation of this work is related to the amount of available data as well as external data for validation. The two notable prognostic models that are developed on large cohorts are IMPACT and CRASH. While both models are trained on data with more than 9,000 subjects, our model is trained only on 902 patients. Since the available data for this study is significantly lower than other major studies in the literature, providing more data would be beneficial for this prediction model. Furthermore, due to the lack of external data with enough time series data, we did not validate our model on an external dataset. We also acknowledge biases that may exist in the underlying data. For instance, if elevations in intracranial pressure were treated by a new medication that did not iatrogenically elevate the serum sodium concentrations, it might be expected that this laboratory value would no longer contain important prognostic information. However, if the model we present were not revised to reflect this change in practice, it could result in erroneous predictions. Methods for the
reproducibility and validation of models have yet to be standardized for clinical data science but are crucial in prognostic prediction applications.

**Conclusion**

We propose a deep RNN based model for long-term prognosis of TBI, which is trained on both static and time series data and predicts the GOSE after six months of injury. The model handles the time series missing values and utilizes the information from missingness patterns in temporal features. In summary, our results show that training the model on time series data for TBI patients can be informative and boost the performance of the predictions. Even the model that is solely trained on time series data outperforms the well-known IMPACT prediction model. Top important features are derived from the RNN model, and their values show a separable trend for favorable versus unfavorable outcomes. This study shows the magnitude of information that can be derived from time series data to prognose TBI more accurately.

Semantic Search for Large Scale Clinical Ontologies

Duy-Hoa Ngo, Madonna Kemp, Donna Truran, Bevan Koopman, Alejandro Metke-Jimenez
The Australian E-Health Research Centre, CSIRO, Australia

Abstract Finding concepts in large clinical ontologies can be challenging when queries use different vocabularies. A search algorithm that overcomes this problem is useful in applications such as concept normalisation and ontology matching, where concepts can be referred to in different ways, using different synonyms. In this paper, we present a deep learning based approach to build a semantic search system for large clinical ontologies. We propose a Triplet-BERT model and a method that generates training data directly from the ontologies. The model is evaluated using five real benchmark data sets and the results show that our approach achieves high results on both free text to concept and concept to concept searching tasks, and outperforms all baseline methods.

Introduction

Data standardisation is an important and challenging goal in the field of medicine. One of the key elements required to achieve semantic interoperability between clinical systems is the availability of common ontologies that define the concepts in the domain. Currently, the most comprehensive clinical ontology available is SNOMED CT, which contains more than 340,000 concepts and has been widely adopted in Electronic Health Record (EHR) systems worldwide. However, despite the availability and coverage of large ontologies such as SNOMED CT, there are still many challenges with adoption and implementation. These revolve around two main issues: 1) much of the source data is free text and needs to be mapped to a standard ontology; 2) existing systems use their own code systems and it is not feasible to replace them with SNOMED CT.

The first problem can be addressed by using natural language processing (NLP), whereby free text is analysed to identify relevant concepts. This process is called information extraction and it has been studied extensively in the biomedical domain. The process is typically divided in two phases: identifying the spans of text that represent relevant concepts and mapping these spans to concepts in a chosen ontology (also referred to as concept normalisation).

The second problem can be addressed by mapping between ontologies. For any ontology of considerable size these maps cannot be generated manually and require at least partial automation. This area of research is called ontology matching. Some of the most important elements that inform the matching process are the labels, synonyms and descriptions of the concepts.

Tailored solutions exist for both the concept normalisation problem and the ontology matching problem. However, these tend to be very specific to the particular use case. Instead, in this paper we propose a generalised method for searching large ontologies such as SNOMED CT, using short spans of text as input. This method can be used generically for both concept normalisation and ontology matching. A novel algorithm is presented, based on deep-learning-derived word representations, that is capable of finding good candidate concepts, even in the absence of common vocabulary. Input to the algorithm can be free text, when doing concept normalisation, or a concept from a source ontology, when doing ontology matching.

We empirically evaluate our method in a number settings — both concept normalisation and ontology matching. The results show that our method can effectively find relevant concepts, outperforming a number of comparison baselines. In addition, we show that our method is particularly suited to finding concepts where the input shares little or no common terms with the relevant concept.

Related Work

The problem of searching large ontologies has been studied in the context of data entry. Sevenster et al. proposed and evaluated an autocompletion algorithm for large medical ontologies and showed that a multi-prefix matching approach performs better than the baseline approach that only completes the entered string to the right. A modified version of this algorithm is implemented in Ontoserver, a high-performance FHIR terminology server, and it is used by default to do value set expansions. However, this algorithm doesn’t perform well on other tasks where the input strings are not partial prefixes but rather full words or short sentences. Also, the algorithm uses standard string matching so it only works well when the queries use the same vocabulary as the ontology being searched.

1 In FHIR, this is the operation used to implement auto-complete style widgets for data capture.
Searching ontologies has also been studied in the area of information extraction, specifically in the concept normalisation step where a span of text that has been identified as being relevant is mapped to a concept in an ontology. Wang et al.\textsuperscript{3} wrote an extensive literature review on clinical information extraction. An example of a state of the art algorithm specifically designed for the concept normalisation step can be found in the work of Luo et al.\textsuperscript{4}.

Finally, although not specific to ontology search, there is also relevant related work in the area of information retrieval (IR). Recently, advanced neural network methods have been developed to learn semantic representations of words and overcome the vocabulary mismatch problem of traditional IR models. Popular models that follow this trend include Word2Vec\textsuperscript{19}, GloVe\textsuperscript{22} and fastText\textsuperscript{21}. Their underlying idea is based on the distributional hypothesis in linguistics, i.e., words that are used and occur in the same contexts tend to purport similar meanings\textsuperscript{2}. Those neural networks are trained with large data resources by supervised learning algorithms. Once the training is finalised, every word located in the model’s dictionary will be encoded by a fixed length embedding vector. Then, those embedding vectors can be used as inputs to a combination function (e.g., average function) or another neural network model to derive an embedding vector of a query or a document. A limitation of these methods is that once the training is completed, the embedding vectors are static, which means that an embedding vector of a given word is always the same regardless of the context of use. Therefore, they may face issues with polysemy when a word might have a different meaning in a specific context.

Several contextualised word embedding methods based on deep long short-term memory (LSTM) architectures, such as CoVe\textsuperscript{24}, ELMO\textsuperscript{23} and FLAIR\textsuperscript{25}, have been proposed to improve the understanding of words and sentences. The main difference with the static word embedding methods is that the words’ embedding vectors are dynamically generated according to which context they have been used, i.e., surrounding words in a given sequence. Recently, transformer-based approaches like BERT\textsuperscript{17}, XLNet\textsuperscript{27}, RoBERTa\textsuperscript{20} have been proposed and achieved state-of-the-art results over most NLP downstream tasks. A key idea in these methods is that the meaning of a word in a sequence is represented by how much attention of that word attracts the other words in the sequence. Once the training of those models completes, they output a list of embedding vectors for all tokenised words of a given sequence. Then, those embedding vectors can be combined in different strategies to derive a semantic embedding vector for an input sequence.

A special feature of a search engine designed to search large ontologies is that the to-be-searched documents are concept labels, which are usually short and, therefore, sentence embedding methods are highly relevant because they can be used to compute semantic relatedness between this type of label. Recently, many sentence embedding methods, for example Doc2Vec\textsuperscript{20}, Skip-Thought\textsuperscript{10}, InferSent\textsuperscript{11}, Universal Sentence Encoder\textsuperscript{12} and the Sentence-BERT model\textsuperscript{8} have been proposed and have achieved good results in various natural language understanding tasks such as sentiment analysis, text classification, question answering and semantic textual similarity. Doc2Vec is an extension of Word2Vec that is trained with large, unlabelled text data. Skip-Thought is another extension of the Skip gram Word2Vec model that tries to predict the surrounding sentences of a given sentence. Universal Sentence Encoder trains a transformer network which augments unsupervised learning whereas InferSent trains a Siamese BiLSTM network with a max-pooling layer on top. Similar to the InferSent architecture, Sentence-BERT replaces a BiLSTM network with a BERT network and outperforms the other state-of-the-art methods on common semantic textual similarity and transfer learning tasks. These models have been trained on natural language inference data sets\textsuperscript{14, 15}, in which, an input to a learning model is a pair of sentences and the output is an inferred relation between them.

The algorithm we propose in this paper is most similar to Sentence-BERT\textsuperscript{8}. Sentence-BERT uses a Siamese architecture, and classification and regression objective functions. Our approach instead, uses a Triplet network\textsuperscript{9}, which processes three inputs in parallel, and a triplet loss function, which is a learning to rank metric for the three inputs.

**Method**

In this section we provide the details of our semantic search engine model for large scale clinical ontologies. First, we give an overview of the model and its components, and explain how to rank results for a given query. Then, we outline our training procedure, optimization objective in developing the model.

The main idea of this model is to transform every concept’s label into appropriate embedding vectors in a vector space so their locations preserve the semantic relations between concepts in the ontology. Figure 1 shows an example that illustrates this idea. The example shows that the concept Asthenia has three synonyms: “Weakness - general”, “Lassitude” and “Debility”. Due to the characteristics of synonymy, we would expect that the distance between the

\textsuperscript{2}https://en.wikipedia.org/wiki/Distributional_semantics
embedding vectors of synonyms, e.g., “Asthenia” vs. “Weakness - general”, would be smaller than the distance between the vectors of labels of concepts that are not synonyms, e.g., “Asthenia” vs. “Fatigue” or “Exhaustion”.

Figure 1: A SNOMED CT fragment for Asthenia, Feeling tired, Fatigue, Exhaustion and Energy and stamina finding. On the other hand, the concept Feeling tired is a sibling of the concept Asthenia because they both are children of the concept Fatigue. By applying the distance calculation method on the tree structure, the distance between two concepts is computed by the sum of the distances from those concepts to their lowest common ancestor. Therefore, we would also expect the distance between embedding vectors of a concept’s label to its direct parent concept’s label to be smaller than the distance of that concept’s label to its sibling concept’s label. In this example, the distance between concept Asthenia and concept Fatigue must be smaller than the distance between concept Asthenia and its sibling Feeling tired. Again, because “Lassitude” is a synonym label of Asthenia and “Weariness” is a synonym label of Fatigue, we would infer that a embedding vector of “Lassitude” is located closer to a embedding vector of “Weariness” than to a embedding vector of “Feeling tired”. The intuition of distance comparison based on synonymy and tree-based distance can be applied to all concepts in an ontology.

Label embedding with Triplet-BERT model

In order to achieve a vector space model that observes the properties described in the previous section, a Triplet-BERT model was trained to produce a semantic embedding vector for short text spans such as concepts' labels or user queries. The Triplet-BERT model is a kind of Triplet network and it was mentioned by Reimers et al. It consists of three instances of the same embedding layer containing a shared BERT network and a pooling layer (see Figure 2). It requires three text inputs, which are fed into the network at the same time, and represent three different roles: an anchor input, a positive input and a negative input. In this work, an anchor input is a user query (e.g., “Weakness - general”); a positive input is a label of a high relevant concept (e.g., “Asthenia”) to the user's query; and a negative input is a label of a less relevant concept (e.g., “Exhaustion”) to the query.

Figure 2: Triplet-BERT model architecture

The objective of a Triplet-BERT model is to train its parameters so at the end, the encoded embedding vector of the anchor input is closer to the embedding vector of the positive input than that to the embedding of the negative input. Firstly, each input is fed into a BERT network to produce a list of intermediate embedding vectors, then, a pooling layer combines these vectors to produce a summary embedding vector for a given input. Now, after receiving three embedding vectors $V_{anchor}$, $V_{positive}$ and $V_{negative}$ for anchor, positive and negative inputs respectively, the model computes distances between the embedding vector of the anchor input against the embedding vectors of positive and negative inputs. Finally, the Objective Function module compares the two distances and indicates whether the model needs to adjust its parameters through the back propagation algorithm. Once the training has completed, the embedding layer is used to produce embedding vectors for any user text query as well as concept labels in the ontology. In order to rank results for a given query, the cosine similarity metric is used to compute relevance scores between the user queries and the concepts’ labels.
Training Data Set

Deep neural network methods had been recently used to develop sentence embedding models. Due to the huge number of parameters in deep neural networks, these models require a significant amount of training data. Some common published data sets used for training sentence embedding are the Stanford Natural Language Inference (SNLI) data set\(^{14}\), the Multi-Genre NLI data set (MLNI)\(^{15}\) and the Semantic Textual Similarity (STS) data set\(^{16}\). Each entry in those data sets consists of a pair of sentences and a label that is either a relationship type or a semantic similarity score. These entries cannot be used in our Triplet network because it requires three input sentences at the same time. Therefore, we propose a method to generate a data set for training our Triplet network (see Algorithm 1) based on the aforementioned intuition about distances of concepts in an ontology’s hierarchy. The whole data set was generated from SNOMED CT and the Human Phenotype Ontology (HPO). Each entry in the data set consists of three strings following the same order: an anchor label, a positive label and a negative label. In total, the generated data set contains nearly 4 millions entries, which are then split into training, development and testing data sets with ratio of 90%, 5% and 5% respectively.

Algorithm 1: Generate training data from ontology for Triplet network

```

    parentLabel ← getRandomLabel(directParents, T)
    otherLabel ← getRandomLabel(otherConcepts, T)
    addToDataset(D, anchor=label\(_1\), positive=label\(_2\), negative=parentLabel)
    addToDataset(D, anchor=label\(_1\), positive=label\(_2\), negative=otherLabel)
    addToDataset(D, anchor=label\(_1\), positive=parentLabel, negative=otherLabel)
end
d\text{train}, d\text{dev}, d\text{test} ← splitTrainDevTest(D)
```

Training Details

**BERT network.** Transfer learning was used to fine-tune BERT parameters. In this work, we adopted BioBert-Base v1.1\(^{13}\) — a state-of-the-art biomedical language representation model, which has been widely using biomedical natural language processing tasks.

**Pooling layer.** The pooling layer is added on top of the BERT network to get an embedding vector for a given text input. Different strategies can be used to work with BERT’s output embedding vectors, however, according to Reimers et al\(^8\), the MEAN strategy achieved a better result than the others. Therefore, we chose the MEAN strategy for the pooling layer to produce a fixed size, i.e., a 768-dimensional embedding vector for the given text input.

**Distance metric.** We use Euclidean distance to compute distances between the anchor embedding vectors \(V_{anchor}\), the positive embedding vectors \(V_{positive}\) and the negative embedding vectors \(V_{negative}\).

**Objective function.** The objective of our model is to move the anchor embedding vector \(V_{anchor}\) closer to the positive embedding vector \(V_{positive}\) and far away from the negative embedding vector \(V_{negative}\). Therefore, we minimize the following objective function to tune the model’s parameters:

\[
loss = \max(||V_{anchor} - V_{positive}|| - ||V_{anchor} - V_{negative}|| + m, 0)
\]

Here, a small margin value \(m\) is used to push the distance \(||V_{anchor} - V_{negative}||\) being at least \(m\) higher than the distance \(||V_{anchor} - V_{positive}||\). Otherwise, the loss value is positive, thus its derivatives to model’ parameters are not 0, so the back propagation algorithm will update the model’s parameters. In the training phase, we fix \(m = 0.1\).
**Training settings.** Our model was trained in 5 epochs. We set a batch-size of 32, Adam optimizer with learning rate 2e-5, and a linear learning rate warm-up over 10% of the training data. The training process was done in 40 hours with one GPU with 32G RAM, using Python 3.6, Pytorch 1.6 and CUDA 10.1. The Triplet-BERT codes was derived from Sentence-BERT codes by replacing siamese network by triplet network.

**Evaluation**

In this section, we firstly describe how to evaluate the performance of our semantic search system and related evaluation metrics. Next, we present data sets used in the evaluation and finally we analyze the experimental results.

As our evaluation measure we use Hits@K. For a given query, Hits@K is 1 if the relevant concept is found in the top K results; otherwise it is 0. In our evaluation, we used Hits@1, Hits@5 and Hits@10. Additionally, in order to measure the usefulness of the list of returned results for a given query, Normalized Discounted Cumulative Gain (nDCG) and Mean Reciprocal Rank (MRR) were used. Their underlying assumption is that the higher the relevant results are ranked, the more gain the user receives. Therefore, the ideal ranking would first return the result with the highest relevance level, then the next highest relevance level, etc. nDCG@K measures the performance of a search system based on the relevance order of the K returned results against the ideal ranking order. In our evaluation, we used nDCG@1, nDCG@5 and nDCG@10.

**Data Sets for Evaluation**

For evaluation, the following five data sets were used:

- **cadec2sct**: This data set contains 2036 unique short text extracted and annotated to SNOMED CT clinical finding concepts from medical forum posts on patient reported Adverse Drug Events (ADEs).
- **note2sct**: This data set contains 4960 unique short text extracted and annotated to SNOMED CT clinical finding concepts from real patients’ narrative discharge summaries in a hospital in Queensland, Australia.
- **hpo2sct**: This data set contains 14,149 unique labels collected from 5978 phenotype concepts from the Human Phenotype Ontology (HPO), which have been mapped to concepts in SNOMED CT.
- **fma2sct**: This data set contains 13,123 unique labels collected from 5702 concepts from the Foundational Model of Anatomy Ontology (FMA), which have been mapped to concepts in SNOMED CT.
- **ncit2sct**: This data set contains 46,185 labels collected from 13,830 concepts from the National Cancer Institute’s Thesaurus (NCIt) which have been mapped to concepts in SNOMED CT.

Three of the data sets, i.e., **cadec2sct**, **note2sct** and **hpo2sct** were manually annotated by two clinical terminology experts, whereas, the other two, i.e., **fma2sct** and **ncit2sct** were taken from the Large BioMed Track in the Ontology Alignment Evaluation Initiative 2020.

The first two data sets aim to evaluate the text-to-concept searching functionality where a user runs free-text queries to search relevant SNOMED CT concepts. In the **cadec2sct** data set, clinical symptoms or diseases were described by different members with or without medical background, so the texts were not restricted to follow any standard naming rules. The entered texts were just the observation or understanding of lay people reporting adverse drug events. In contrast, in the **note2sct**, clinical entities were entered by doctors in hospital. Those texts are in free-text form, but the vocabulary is expected to be technical in nature.

The last three data sets were extracted from well-designed biomedical ontologies. Thanks to cross-ontology alignment, it is expected that the results of searching a concept’s label from one ontology will return its mapping concepts from another ontology that is found in the alignment. Additionally, these data sets can also be used to evaluate SNOMED CT concept-to-concept search when all labels of a given concept from a source ontology, such as HPO, FMA or NCIt, are used to search relevant SNOMED CT concepts.

**Models for Comparison**

As presented in section Method, the key operation in our work is how to encode a short text into an embedding vector. For evaluation and comparison purposes, the following baseline embedding methods have been implemented to build

---

3http://www.cs.ox.ac.uk/isc/projects/SEALS/oaei/

4http://oaei.ontologymatching.org/
different semantic search systems for SNOMED CT.

- **Elasticsearch BM25**: BM25 defines a weight for each term as a product of some IDF-function and some TF-function and then summarises that term weight as the score for the whole document towards the given query. In this work, a document is a collection of labels of a SNOMED CT concept.
- **Word2Vec-based Average**: This model defines an embedding vector of a given text as an average of embedding vectors, which map to text’s tokens in a pre-trained biomedical word2vec resource⁵.
- **BioBERT based CLS**: This model uses a pre-trained BioBERT⁶ to encode an input text into a sequence of corresponding embedding vectors. Then, it defines an embedding vector of a given text by embedding a vector of special tokens [CLS] according to the original idea from BERT⁷.
- **BioBERT based MEAN**: Similar to the previous model but this model computes an average of all output embedding vectors as a summarised embedding vector for a given input.
- **Triplet-BERT**: We use the fine-tuned BioBERT with MEAN strategy for the pooling layer to encode a given text into an embedding vector.

The first model is a keyword-based search engine, which does not count synonymous features in its scoring function. The second model uses a pre-trained word embedding, trained on a very large biomedical text collection. Each word in a pre-trained word2vec always has the same embedding vector regardless of the context, so this model can be considered as a context-free embedding model. The third and the fourth models are based on a pre-trained BERT network, in which a word may have different embedding vectors depending on the context of use. The two models can be considered as general contextualised embedding models. The last model fine-tunes BERT parameters over the triplet data set generated from SNOMED CT, and therefore it can be considered as a domain-specific contextualised embedding model.

**Evaluation on Concept Normalisation Task**

In this experiment, a user provides a short query string and asks the system to return relevant concepts from SNOMED CT. The query is either a clinical mention in cadec2sct and note2sct or a concept’s label in HPO, FMA and NCIt. We split the five data sets above into two groups based on the different editions of SNOMED CT used in the ground truth data. The first group consists of three data sets including cadec2sct, note2sct and hpo2sct, where the ground truth data uses clinical finding concepts from the Australian edition of SNOMED CT. The second group consists of two data sets, nci2sct and fma2sct, where the ground truth was created from concepts in the international edition of SNOMED CT.

**Table 2**: Hits@K evaluation of searching a query to all SNOMED CT concepts

Table 1 and Table 2 show the results computing Hits@K values in the two groups with K = 1, 5 and 10 for the five aforementioned methods. Our method Triplet-BERT consistently outperforms all other methods on all metrics over

---

⁵https://bio.nlplab.org/
⁶https://github.com/dmis-lab/biobert
all five data sets. We have also computed the statistical significance \textbf{p-value} for Triplet-BERT on a paired \textit{t-test} against the remaining methods. In almost all cases with various datasets and ranking value K, the computed value \( p \ll 0.05 \), which indicates strong evidence of significant differences between the results obtained by Triplet-BERT and the results returned from BM25, Word2Vec, BERT-CLS and BERT-MEAN. In Table 1 and Table 2, we highlighted cases where \( p > 0.05 \) by underlining the corresponding cell. For example, for dataset \texttt{note2sct} and \( K = 5 \), the \textbf{p-value} computed for Triplet-BERT and Word2Vec is 0.75.

On the other hand, Triplet-BERT achieved a high Hits@10 value 0.904 for data set \texttt{note2sct}, which means for a clinical mention written in the narrative of a discharge summary, the chance is about 90% that annotators can find the correct SNOMED CT concept within the top ten results that are returned. Similarly, the Hits@10 values are high for the \texttt{hpo2sct} and \texttt{fma2sct} data sets. Good results on these data sets were expected as the text in \texttt{note2sct}, \texttt{hpo2sct} and \texttt{fma2sct} data sets mainly focus on clinical finding concepts; the \texttt{fma2sct} data set mainly focuses on anatomical structure concepts, and both types of concepts are comprehensively covered by SNOMED CT.

The performance of Triplet_BERT on \texttt{cadec2sct} and \texttt{nci2sct} datasets is a bit lower than on the \texttt{note2sct}, \texttt{hpo2sct} and \texttt{fma2sct} data sets. This is likely because of the quality of the text in \texttt{cadec2sct}. Many references were written in casual language which leads to irrelevant concepts being retrieved. For example, “threw up” was annotated to 422400008 | Vomiting (disorder) |, but our system returned 282667008 | Does throw (finding) |. Additionally, the lack of context also causes ambiguity; for example, the text “damage to my muscles” was annotated to 129565002 | Myopathy (disorder) |, which means a disorder of skeletal and/or smooth muscle, but our system returned 95847005 | Injury of muscle (disorder) |, which is a child concept of the annotated concept. The second reason for lower performance was posited as lower quality of synonymous labels of NCIt concepts in the \texttt{nci2sct} data set. For example, an NCIt concept \texttt{C1212} has the following labels: “sirolimus”, “rapamycin”, “SILA 9268a”, “WY-090217”, “AY 22989”, “rapamune” and “rapa”, but only the first two labels were found by our search system. The other labels contain either numeric tokens or abbreviations that do not provide helpful information to find relevant concepts.

An interesting observation here is that without the fine-tuning of Triple_BERT, the basic BERT models did not out-perform Elastic BM25 and Word2Vec (even though one may expect them too). An explanation for this phenomenon is that the Elastic BM25 and Word2Vec mainly focus on keywords similarity, in which all stop-words had been removed from the text during indexing and searching. On the contrary, the original BERT model creates embedding vectors for all tokens of the text, including stop-words. In the case of BERT, due to the short query text and concept labels (≈1-2 tokens), BERT’s self-attention layers may not capture the context of the text’s tokens. For example, all the terms “Headache”, “head pain”, “Cephalodynia”, “Cephalalgia” and “Cephalgia” refer to the same meaning - “pain in head”. Pre-trained BioBERT computes similarity scores between (headache, cephalodynia) = 0.69; between (headache, cephalgia) = 0.73; and between (cephalodynia, cephalgia) = 0.97. The big difference in similarity scores tell us that in pre-train BioBERT, there is not enough context to embed those terms in highly similar vectors. This weakness is solved in Triplet_BERT because the model was fine-tuned from the original BERT model to push embedding vectors of those terms to be close to each other.

\textbf{Impact of Overlapping Text and Synonymy in Searching Performance}

In this experiment, we investigated the performance with respect to how similar queries are to their relevant concepts. Queries that are very similar to a relevant concept label will be easy to match, while queries that share no common terms will be harder to match. First, we define an overlapping degree as the proportion of shared tokens between query and concept label. Assuming that a query \( q \) contains a list of non stop-words: \( T_q = \{ t_{q_1}, \ldots, t_{q_N} \} \), and similarly, the concept \( c \) corresponding to the query \( q \) in the ground truth data sets contains a list of non stop-words: \( T_c = \{ t_{c_1}, \ldots, t_{c_M} \} \) of all its labels, then an overlapping degree of \( q \) against \( c \) is calculated as follows: \textit{overlapping}(q, c) = \frac{||T_q \cap T_c||}{||T_q||}. \) We divide our evaluation into two: 1) clinical findings concepts, which are often clearly expressed and have many synonym labels (\texttt{cadec2sct}, \texttt{note2sct} and \texttt{hpo2sct}); 2) all concepts types but with fewer synonym labels (\texttt{fma2sct} and \texttt{nci2sct}). We do this split to understand the impact that the synonym labels have for the different methods.

Figure 3 shows the line charts of Hits@10 values of different methods at different intervals of overlapping degrees on the two aforementioned groups. (The left hand side of the plots shows queries with many shared terms; the right
Evaluation on only clinical findings concepts with more synonym labels (cadec+note+hpo).

Evaluation on only clinical findings concepts with fewer synonym labels (fma+nci).

**Figure 3:** Evaluation of searching performance with different overlapping degrees

hand side shows queries with little or no term overlap.) As the overlapping degree goes down, the performance of all methods also decreases because these are harder queries to match. The line charts show that the Elastic BM25 method achieved high performance when the queries share many terms with their corresponding concepts. Particularly, in the range of overlapping from 0.8 – 1.0, the Hits@10 values of BM25 method was 0.943 for the cadec+note+hpo group, and 0.977 for the fma+nci group. Those values were close to the Hits@10 values of our Triplet-BERT method, i.e., 0.982 and 0.990 respectively. However, when the overlapping degree gradually decreases, the Hits@10 values of the BM25 method quickly falls to 0.0. In contrast, Triplet-BERT still maintains its performance as the overlap decreases. The reason for this is that Triplet-BERT encodes the meaning of terms; thus it is still able to retrieve the relevant concept for a query even when it shares little or no common terms. Comparison between Figure 3a and Figure 3b, shows that number of synonym labels does not have a dramatic effect on performance for all five methods considered. A point to note, though, is that when Triplet-BERT has access to queries with more synonyms (Figure 3a), it maintains better performance for very low overlap queries compared with fewer synonyms (Figure 3b). This shows that Triplet-BERT does exploit synonyms for better performance.

Let us consider some specific examples of matching with low overlap queries. A query “narrow retinal arterioles” should match 271728000 | Retinal arteries attenuated (finding). After running this query with five methods described above, we found that Elastic BM25 failed to return its correct result, whereas other methods were successful. An explanation is that the query and its corresponding concept shared only one word, “retinal”, which is 1/4 of the query length. On the other hand, because “attenuated” vs. “narrow” as well as “arteries” vs. “arterioles” are semantically similar, the other methods, which rely on the meaning of the words, are able to find the correct result. Another interesting example is the query “tooth mass excess”, which matches SNOMED CT concept 71485000 | Macroodontia (disorder). The overlap degree is 0.0. After running this query, only Triplet-BERT found the correct result.

**Evaluation on the usefulness of the searching results**

Search system are often evaluated according to the Normalized Discounted Cumulative Gain (nDCG) metric. We do the same here but first need to define the respective gain function a user receives for different types of results. Assume a user runs a query $q$. The ‘gain’ $g$ a user receives for a result list $l$ against the correct result $q^*$ is defined as follows: $g = 3$ if $l = q^*$; $g = 2$ if $l$ is a direct parent or direct child of $q^*$ in the ontology; $g = 1$ if $l$ is a grand parent, a grand child, a uncle or a sibling of $q^*$ and $g = 0$ otherwise.

Table 3 shows nDCG@1, nDCG@5, nDCG@10 and MRR values of different methods on two group datasets described in the previous section. By all metrics, Triplet-BERT method achieved the best performance. The average nDCG values produced by the Triplet-BERT is around 70%, which means the order of the returned results is highly correlated to the order of ideal results.

Now, let’s see an example to illustrate the importance of nDCG and MRR values. Assume that a user wants to find relevant SNOMED CT concepts for the query “delayed closure of fontanels”. Our Triplet-BERT method returned a
Table 3: nDCG@K and Mean Reciprocal Rank (MRR) evaluation of searching methods

<td>0.596</td>
</tr>
<tr>
<td>Triplet-BERT</td>
<td><strong>0.758</strong></td>
<td><strong>0.799</strong></td>
</tr>
</tbody>
</table>

Correct concept 82779003 | Late fontanel closure | in the first rank; the Word2Vec method returned this concept in second rank; both BERT-CLS and BERT-MEAN methods returned it in fifth position, whereas Elastic BM25 returned it in seventh position. That means that the user immediately finds the correct answer at the first or the second look if the system is based on Triplet-BERT or Word2Vec. In contrary, the user must spend more time to trace along the list of results to get a correct answer if the system uses BERT-CLS, BERT-MEAN or Elastic BM25. In this example, for Triplet-BERT: \( MRR = \frac{1}{1} = 1.0 \); for Word2Vec: \( MRR = \frac{1}{2} = 0.5 \); for BERT-CLS and BERT-MEAN: \( MRR = \frac{1}{5} = 0.2 \) and for Elastic BM25: \( MRR = \frac{1}{7} = 0.14 \). So, the higher value of \( MRR \) is, the less time the user spends to find the correct answer for a given query.

Doing further analysis on this example, Triplet-BERT returns top five results including: the correct concept in the first position, its sibling concept 1667003 in the second position, its parent concept 248382004 in the third position, an uncle concept 249079005 in the fourth position and a grandparent concept 248381006 in the fifth position. Based on the respective gain defined above, Triplet-BERT obtains an \( nDCG@5 = 0.976 \). This number shows that the order of the returned results is very close to the ideal order, which means that the user can find not only the correct concept but also its close neighbours.

Despite the fact that all five methods have found the correct results in their top 10 returned lists, which means the all have the same Hits@10 score, the order of returned results is different. This difference impacts the time that a user needs to find the correct answer. Our experiment shows that on average, the results obtained from Triplet-BERT were more useful than those from other baseline methods.

Evaluation on ontology matching task

In this experiment, we look for relevant concepts in an ontology for a given concept from another ontology. This is ontology matching task, where each concept from an ontology can be mapped to one or several concepts from the other ontology. The concept-to-concept search slightly differs from the previous text-to-concept search in the way a the query is formulated. In concept normalisation (text-to-concept), a single query for a short text or a label was executed, whereas in concept-to-concept search, multiple queries, i.e., labels of a query concept, will be run.

Table 4: Hits@K evaluation on concept to concept searching

<table>
<thead>
<tr>

</tr>
<tr>
<td>Triplet-BERT</td>
<td><strong>0.770</strong></td>
<td><strong>0.926</strong></td>
<td><strong>0.947</strong></td>
</tr>
</tbody>
</table>

Table 4 shows the Hits@1, Hits@5 and Hits@10 values for concept normalisation. Triplet-BERT outperforms other methods on all metrics. If Hits@10 is considered, there is a \( \approx 94\% \) chance that Triplet-BERT find a relevant SNOMED CT concept be found for a given HPO, FMA and NCI concept. A high recall at top 10 searching results can be used as an input to automate ontology matching\(^29\). It would also greatly reduce the time and cost on manual ontology alignment.
Conclusion

In this work, we proposed Triplet-BERT — a label embedding model that can be used to build a semantic search system for large scale clinical ontologies. We also proposed a method for generating a training data set for the model directly from an ontology. The method is generic in nature and can be used for both concept normalisation and ontology matching. Several experiments were conducted using SNOMED CT and showed that the proposed method outperforms baseline methods such as Elastic BM25, Word2Vec and BERT in all evaluation metrics on five benchmark data sets. In particular, the method was effective at mapping queries that had little or no common terms with relevant concepts. The strong empirical results suggest that Triplet-BERT can be used as the basis for both automatic ontology matching algorithms and searching tools to assist humans building ontology maps.

Abstract

Multimorbidity, the coexistence of two or more health conditions, has become more prevalent as mortality rates in many countries have declined and their populations have aged. Multimorbidity presents significant difficulties for Clinical Decision Support Systems (CDSS), particularly in cases where recommendations from relevant clinical guidelines offer conflicting advice. A number of research groups are developing computer-interpretable guideline (CIG) modeling formalisms that integrate recommendations from multiple Clinical Practice Guidelines (CPGs) for knowledge-based multimorbidity decision support. In this paper we describe work towards the development of a framework for comparing the different approaches to multimorbidity CIG-based clinical decision support (MGCDS). We present (1) a set of features for MGCDS, which were derived using a literature review and evaluated by physicians using a survey, and (2) a set of benchmarking case studies, which illustrate the clinical application of these features. This work represents the first necessary step in a broader research program aimed at the development of a benchmark framework that allows for standardized and comparable MGCDS evaluations, which will facilitate the assessment of functionalities of MGCDS, as well as highlight important gaps in the state-of-the-art. We also outline our future work on developing the framework, specifically, (3) a standard for reporting MGCDS solutions for the benchmark case studies, and (4) criteria for evaluating these MGCDS solutions. We plan to conduct a large-scale comparison study of existing MGCDS based on the comparative framework.

Introduction

Most recommendations from clinical practice guidelines (CPGs) focus on the management of single diseases. Such recommendations may be harmful or impractical for patients with multimorbidity. Multimorbidity has been defined as one of the “grand challenges in clinical decision support” by Sittig et al¹ because of a difficulty with creating mechanisms to identify and eliminate redundant, contraindicated, potentially discordant, or mutually exclusive guideline-based recommendations. Using a computer language such as PROforma or GLIF3, one can computerize CPG as Computer-interpretable guidelines (CIGs)²,3 that enable CIG-driven clinical decision support systems (CDSS). These have typically addressed a single morbidity as per the single-disease focus of the CPG they are ultimately based on. However, the rise in multimorbidity is driving the need for complex treatment plans with many potential interactions and adverse events among CIGs. Several researchers have begun developing multimorbidity CIG-based
clinical decision support (MGCDS) that can detect and mitigate interactions among recommendations belonging to different CIGs in order to develop non-conflicting management plans for patients with multimorbidity. Given the number of active research groups and different MGCDS approaches, we decided to create a standard framework for comparing these approaches. Our framework consists of (1) the relevant features of the multimorbidity problem that should be addressed, (2) a set of benchmarking case studies that are representative and cover the features, (3) a standard for reporting the MGCDS solutions for the benchmarks, and (4) criteria for evaluating these solutions. We intend for this framework to be used in standardized evaluations of prior or new/updated MGCDS, to help assess their functionalities, and identify gaps in the state-of-the-art. This paper reports results of research on the first two parts of the framework. We will use the complete benchmark framework in a comparative MGCDS study, which is currently underway and involves a number of groups who have previously developed MGCDS. A companion paper, to be published after the comparative study has completed, will report on the development of part 3 and part 4 of the framework as well as the comparative study results themselves.

**Background and related work**

MGCDS has gained attention in recent years and multiple approaches have been proposed and described in the literature. A comprehensive review and comparison of relevant approaches are provided elsewhere and here we summarize the relevant characteristics (e.g., an employed CIG representation formalism or reasoning method) of most recent proposals. We also point at clinical case studies that were used to test these approaches. We applied a semi-formal process to search for relevant publications. Specifically, we identified candidate papers based on the description of related works in two recent publications on MGCDS by Kogan et al. and Michalowski at al. Then we limited the list of candidates to journal papers published in the last 5 years. Finally, we screened the eligible papers to select those that present the latest versions of MGCDS methodologies and illustrate their applications in case studies.

Kogan et al. propose a goal-oriented MGCDS which frames patient management as a goal attainment problem. The methodology, implemented in the form of the GoCom system, relies on CIGs represented in PROforma and augmented with knowledge about goals and physiological effects of specific CIG tasks. This knowledge is encoded with standardized terms coming from controlled terminologies (e.g., SNOMED CT) and medical ontologies (e.g., NDF-RT). The planning algorithm used by GoCom operates on goal forests that capture goals associated with specific CIGs applied to the patient, identifies inconsistencies among goals and mitigates them by proposing alternative solutions. GoCom is able to reason at different abstraction levels (e.g., specific drugs and their classes) by exploring external ontologies and to generate explanations for specific solutions. Alternative solutions, together with supporting explanations, are then presented to the clinician who makes the final decision. GoCom relies on the HL7 FHIR standard to represent clinical data, thus facilitating integration with existing hospital information systems (HISs). GoCom was tested on 6 clinical scenarios involving concurrent application of multiple (2-3) CIGs -- one of the scenarios describing a patient being managed for stroke and duodenal ulcer (DU) and diagnosed with osteoporosis was used as the basis for development of Case 1 described in this paper. Moreover, GoCom was evaluated by medical students and interns in two empirical studies that confirmed its usefulness and validity of delivered recommendations.

Michalowski at al. describe MitPlan – a planning-oriented MGCDS that frames multimorbid patient management as a planning problem that allows to mitigate adverse interactions between multiple CIGs and to derive safe management plans. MitPlan constructs a plan for a given time horizon that optimizes some objective function (e.g., overall cost) – with time horizon and objective function being specified by the clinician. It also considers patient preferences – if several options are possible, it selects the most preferred one. Unlike GoCom, MitPlan generates a single optimal management plan that is presented to the clinician for approval. It accepts CIGs represented as Actionable Graphs (AGs) that are based on the task-network model and can be easily derived from other representations, such as GLIF or PROforma. AGs are automatically transformed to Planning Domain Definition Language (PDDL) for further processing. PDDL is also used to represent secondary domain knowledge on possible interactions and strategies to mitigate them. MitPlan was evaluated by collaborating physicians using a scenario describing a patient suffering from chronic kidney disease (CKD) and hypertension (HT), who experiences an acute episode of atrial fibrillation (AF). This scenario was used as a basis for development of Case 2 described in this paper.

Jafarpour et al. propose an ontology-based MGCDS for execution-time integration of multiple CIGs. The approach assumes integration points need to be first identified by the clinician, and then appropriate integration policies are instantiated and applied to mitigate adverse interactions at execution-time. Integration policies are defined using the CIG-IntO ontology that is represented in OWL and processed by a standard OWL reasoner (the authors employ Jena). The approach is able to discover drug-drug and drug-disease interactions using the Bio2RDF DrugBank ontology, handle temporal aspects of mitigation (e.g., delaying tasks to avoid conflicts), and rollback integration policies that...
are no longer safe or efficient at execution-time. CIG-IntO also allows for defining conditional integration policies where revisions introduced to CIGs may be further customized depending on additional conditions, e.g., related to the patient’s health profile. This increases the flexibility and generality of integration policies. Moreover, in addition to mitigation integration policies the authors also propose optimization integration policies that minimize resource use and costs by removing redundant tasks from management plans and re-using test results. The approach was tested using 6 case studies with pairs of CIGs and positively evaluated by a panel of health informaticians and physicians.

Another MGCDs is presented by Fdez-Olivares et al. who propose a Multi-Agent Planning (MAP) framework. The MAP framework relies on Hierarchical Task Networks (HTNs) to represent and control the planning process and involves multiple agents that develop different candidate management plans. Possible plans are evaluated using an objective function that considers plan cost and complexity assessed according to the patient’s quantitative preferences. Finally, the optimal plan is presented to the clinician for approval. MAP accepts CIGs represented in Hierarchical Planning Description Domain Language (HPDL) – such representation can be obtained from the CIGs modelled in Asbru formalism. Proposed approach uses HPDL to capture possible adverse interactions and patient’s qualitative preferences related for example to the mode of drug administration or frequency of administration – these preferences are considered when constructing candidate plans. As with the approach by Jafarpour et al., MAP takes into account temporal aspects of interactions and mitigation. MAP was evaluated using a case study involving a patient with diabetes mellitus (DM) and hypertension (HT) and managed at different time points of disease progression and treatment process.

Piovesan et al. describe the MGCDs implemented as the GLARE-SSCPM system. The proposed system relies on multiple methods to identify interactions and mitigate them, such as temporal reasoning, cost-benefit analysis and model-based verification. The system employs ontology with medical CIG-independent knowledge represented in OWL (so it can be processed with standard reasoners), developed in collaboration with domain experts and integrating parts of SNOMED CT and ACT terminologies. GLARE-SSCPM accepts CIGs represented in the GLARE formalism as conditional and hierarchical graphs. Similarly to GoCom, the authors adopt the mixed initiative planning paradigm where the final management plan is developed by the clinician who interacts with the system following the “focus, hypothesize and test” modality. Specifically, the system supports the clinician in focusing on relevant parts of CIGs (where adverse interactions may occur), identifying alternative management options and testing these options in “what-if” analysis. GLARE-SSCPM was tested on a case study of a patient suffering from venous thrombosis (VT) and peptic ulcer (PE).

Zamborlini et al. propose MGCDs that combines the Transition-based Medical Recommendation (TMR) knowledge representation model with first-order logic (FOL) rules. The TMR model describes CIG recommendations augmented with additional domain knowledge, such as causes and effects of actions and possible interactions between recommendations. Similarly to GoCom, recommendations are associated with goals and these recommendations may have negative, neutral or positive contributions towards the goals. FOL rules are used to identify interactions between multiple CIGs based on the knowledge encapsulated by corresponding TMR models. These models are generic and reusable, thus they do not need to be customized to specific CIGs and in this sense they are similar to integration policies introduced in CIG-IntO. The proposed approach was tested in complex case study of a patient with breast cancer and three additional multimorbidity conditions: osteoarthritis (OA), HT and congestive heart failure (CHF).

As shown in the above summary, there are multiple approaches to creating MGCDS. These approaches have diversified (but often complementary) capabilities, use different representations of the CIGs and related domain knowledge, and use different methods to develop management plans. Moreover, they were assessed using unique case studies, which makes their comparison from methodological and practical perspectives even more challenging. We believe a comprehensive comparative framework, similar to the one developed to compare CIG representations, should facilitate MGCDs comparison of functionalities, provide a common platform for presentation of various approaches, and support development of new ones.

Methods

Our methodology for identifying and confirming the features of the MGCDs consisted of three parts. First, we conducted a literature review to identify features of MGCDS used by research groups in the field. Second, we created a number of case studies that embody these features. Finally, we developed a survey whereby physicians were asked to confirm and comment on the list of identified MGCDS features.

Identification of MGCDS features
Most of the research on MGCDS is published in several health informatics journals, such as Journal of Biomedical Informatics, Journal of American Medical Informatics Association, International Journal of Medical Informatics, Methods of Information in Medicine, Journal of Medical Systems, and Artificial Intelligence in Medicine. In line with the PRISMA systematic review process\(^\text{13}\), we searched Google Scholar, PubMed and Web of Science with relevant keywords, screened the title and abstracts of the records found, assessed eligibility of the full-text, and finally reviewed the remaining publications. As a result of this review we identified 18 multimorbidity features, spread across the reviewed publications, which can be categorized as follows: (a) interactions among recommendations coming from disease-specific CIGs; (b) mitigation strategies when CIGs offer interacting recommendations; and (c) other possible features. Features from category (a) were identified based on clinical case studies presented in the literature, whereas features from categories (b) and (c) were identified based on the approaches to integrating comorbid CIGs. A complete list of features together with illustrative examples is presented in Table 1.

Case studies to demonstrate MGCDS features

All groups with prior work on MGCDS were invited to contribute relevant case studies, i.e., cases where recommendations from different clinical guidelines result in adverse interactions or introduce resource inefficiencies for a multimorbidity patient. These case studies were either based on previously published examples for demonstrating their multimorbidity decision-support methods, or represented new case studies that similarly illustrated the identification and/or mitigation of adverse interactions.

Initially, the groups were provided with a sample multimorbidity case study from Kogan et al.\(^\text{6}\) in a uniform, comprehensive format, supplemented by references to specific statements from the CPGs involved, the set of interactions to be detected and the solution – i.e., sets of treatment options that mitigate the multimorbidity interactions. We asked the groups to submit case studies in this uniform format. We selected a minimal set of submitted case studies (4) that together cover the full set of the previously identified multimorbidity features. The 4 case studies provide good coverage of the features - 9 of the 18 features are demonstrated in 2 -3 case studies. The case studies were reviewed by clinical partners for correctness. The 4 case studies are intended as a starting point to begin the comparison study of existing MGCDS; additional case studies will be added as the research progresses.

Next, we revised and expanded the selected case studies based on a rigorous process, which started with a review of the CPG repositories to identify updated versions of the guidelines and supplementary references for specific statements and actions. Collaborating medical experts were consulted for validating the clinical accuracy of the cases. As a result, we were able to establish a set of validated interactions together with the set of treatment options to be considered. Representative synthetic patient scenarios were developed with the help of medical experts and added to each of the case studies.

Validation of the MGCDS features

We started by consulting members of the groups with prior work on MGCDS to review and comment on the set of 18 MGCDS features. Secondly, we developed an online survey using the Qualtrics platform to survey physicians in order to determine the validity of the proposed MGCDS features for our framework. Physicians were recruited to complete the survey via convenience sampling. The survey preamble introduced physicians to the purpose of the study and defined notions of adverse interactions and mitigation strategies in the context of the MGCDS. The survey included 18 questions partitioned into three sections - the first section was devoted to the adverse interactions that may occur as a result of applying guidelines (7 identified features), the second section was devoted to types of mitigations to be applied when addressing such interactions (7 identified features), and the third section was devoted to other possible features of MGCDS (4 identified features). Short examples from the developed case studies were included to illustrate each feature. Physicians were asked to evaluate whether each identified feature was relevant or not for the multimorbidity problem. At the end of each section, they were provided an opportunity to add and describe any missed features. The survey was piloted with two physicians and adjustments to the phrasing of the questions was made based on their feedback. The final version of the survey can be viewed at our GitHub repository\(^\text{14}\).

Results

Case study descriptions

Twelve case studies were contributed by four of the participating groups. The minimal set of cases, which cover all identified features of MGCDS, included four cases provided by three groups and are summarized below. The full case descriptions can be accessed at our GitHub repository\(^\text{14}\).
Case 1, adapted from Kogan et al., involves three cascading morbidities. The first morbidity was managed with a drug, resulting in an adverse drug event (ADE). The ADE is regarded as another morbidity and is treated with a drug, resulting in a second ADE, which is regarded as a third morbidity. The possible mitigation strategies include either (a) adding a drug for the third morbidity; or (b) preventing one of the ADEs by replacing or stopping the drug that caused it. The various management plans may meet all clinical goals (address all current morbidities) or may compromise one of them. Specifically, Case 1 describes a patient that is on aspirin for prevention of stroke, which causes DU due to NSAID, which has been treated by stopping aspirin and adding omeprazole (a proton pump inhibitor, PPI). Aspirin was continued with the PPI to prevent DU recurrence. Now secondary osteoporosis is diagnosed, caused by the PPI.

Case 2, adapted from Michalowski et al. involves three morbidities that need to be simultaneously managed, while at the same time considering patient preferences. It describes a situation where a patient successfully treated for two concurrent conditions is diagnosed with a third one and this new diagnosis triggers the need for a revised treatment plan. The mitigation strategies include (a) making more aggressive treatment of one of the underlying conditions, and (b) managing drug contraindications and interactions. Additionally, when developing a management plan, the patient’s preferences need to be taken into account. Specifically, Case 2 describes a patient suffering from CKD and HT that are managed with ACE inhibitors, calcium channel blockers (CCB), diuretics, and low dosage aspirin (for prevention of cardiovascular disease). New diagnosis of atrial fibrillation requires the following, in line with the strategies described above: (a) replacing aspirin with an anticoagulant (warfarin) for more aggressive anticoagulant treatment, and (b) using sodium channel blockers (SCB) instead of potassium channel blockers (PCB) in anti-arrhythmic therapy (as PCB is contraindicated for the CKD patients), and abandoning beta blocker medication routinely used for rate control because of its possible interactions with ACE inhibitors or CCB. In light of patient preferences, warfarin is replaced with one of the direct anticoagulants.

Case 3, adapted from Jafarpour et al., involves two morbidities where clinical guidelines recommend adversely interacting drug treatments, both of which are nevertheless needed for treating the multimorbid conditions. The mitigation strategies include (a) increased frequency in monitoring relevant vital signs during concomitant drug treatment; and (b) adjusting drug dosage to compensate for negative evolutions of these vital signs. Further, increased frequency of monitoring must be maintained after completing one of the drug treatments until stable vital signs are observed. Specifically, Case 3 describes a patient with venous thromboembolism (VTE) and bacterial urinary tract infection (UTI) where VTE is managed by warfarin and UTI is managed by antibiotic such as trimethoprim–sulfamethoxazole (TMP/SMX). Warfarin was chosen due to availability of specific reversal agents (e.g., vitamin K); and TMP/SMX because of its low cost, effectiveness and familiarity among clinicians. During concomitant treatment, it is recommended to increase the monitoring frequency of the patient’s international normalized ratio (INR) value (e.g., daily) and adjust warfarin dosage accordingly. Upon completion of the antibiotics regimen, the increased measuring frequency should be kept in place until a stable INR is observed. At that point, regular INR monitoring should commence.

Case 4, developed especially for this study by coauthors AK, RE, MP and SWT, involves temporally managing a multimorbidity patient who needs to undergo an emergent surgical procedure. Because of the procedure, the patient has a new health risk that cannot be simultaneously addressed with other multimorbidity risks. The mitigation strategies include (a) focusing on surgery for the urgent condition; (b) suspending a long acting irreversible antagonist drug that adversely interacts with the treatment from (a); and (c) replacing it with a short acting reversible antagonist drug to minimize the time that the patient is unprotected by suspending (b). Specifically, Case 4 describes a cardiac patient with high cardiovascular risk that is on dual antiplatelet (aspirin and clopidogrel, a P2Y12 inhibitor) for 12 months following implantation of drug-eluting stent for prevention of stroke. Two months after stent implantation he is diagnosed with lung mass and needs to undergo an urgent surgical procedure that cannot be postponed past 12 months after the stent implantation—this places him at high risk for surgical bleeding due to concomitant dual antiplatelet treatment. To manage the risk, the long acting irreversible antagonist drug (clopidogrel) is suspended five days before surgery until 12-24 hours after surgery. Bridging therapy with the short acting reversible antagonist (tirofiban) is recommended. Tirofiban is started 48 hours after clopidogrel is suspended, continued until 4 hours before surgery to allow time for the drug to dissociate from platelet receptors and allow for normal aggregation and coagulation during surgery. After surgery either clopidogrel or tirofiban are resumed as soon as possible, depending on the expected degree of post operative bleeding.

Features of MGCDS
Table 1 lists and provides examples for the 18 MGCDS features. The table also points to the case studies that cover the features.

</tbody>
</table>
A16. Optimization of clinical resources
Grouping tests recommended by different CPG on the same day, or avoiding multiple imaging scans, recommended by different CPG, where results can be re-used for diagnosis of both comorbid illnesses.

A17. Explanation of the mitigation strategy(ies)
Including an explanation for a recommended mitigation (e.g., all patient conditions are treated, the largest number of conditions are treated, or the condition that is at the focus of the medical investigation is treated).

A18. Alternative mitigation strategies for a single interaction
For a patient taking aspirin for secondary prevention of TIA, who developed DU due to aspirin, one strategy may be to add a PPI to protect the duodenum, and a second strategy may be to replace aspirin with clopidogrel.

Validation of MGCDS features
Members of all groups with prior work on MGCDS were asked to review the identified MGCDS features and to suggest any missing ones. The 11 group members who responded were positive about the set of 18 proposed features and did not suggest any new ones. After this initial validation, we developed and validated an online survey and recruited 15 physicians of different specialties and different levels of experience for assessing and commenting on the features. The survey was completed by all invited physicians. The results are presented in Table 2.

Overall, the results of the survey confirmed the relevance of the identified MGCDS features. There were only a few instances where physicians did not endorse the features unanimously and these are outlined here. Regarding features associated with interactions among recommendations coming from disease-specific CPGs, identification of duplicate or redundant advice from different CPGs (A5) was found to be relevant by 9 out of 15 physicians while identifying temporal relationship between different CPGs (A6) and identifying conflicting actions from different CPGs (A4) were found to be relevant by 13 and 14 out of 15 physicians, respectively. Regarding features associated with the mitigation strategies when CPGs offer interacting recommendations, the mitigation strategies of monitoring the effect of a drug (A10) and replacing a drug with a safer/non-interacting drug/more effective drug for comorbidity (A11) were found to be relevant by 13 and 14 out of 15 physicians, respectively. The least agreement among the physicians was observed for the other possible features’ category. Here, only identification of alternative mitigation strategies for a single interaction received unanimous support. Fewer physicians were convinced that explanation of the mitigation strategy(ies) (A17) with 11 positive responses out of 15, optimization of clinical resources (A16) with 12 positive responses out of 15, and inclusion of patient preferences and/or patient burden (A15) with 14 positive responses out of 15 are relevant.

</table>
Physicians did not indicate that any features were missing from the set provided for evaluation. Physicians made few comments mostly related to prioritizing goals from CPGs: one suggestion was to ignore actions that are associated with less important goals and prioritizing goals based on clinical needs. Another physician suggested that goals should be prioritized based on what treatment a patient can or is willing to follow. Finally, one physician commented that the most difficult aspect of MGCDS is an assessment of risks and benefits when guidelines are in conflict.

**Discussion and Future Work**

Multimorbidity is complex clinically but also challenging for effective decision support. This challenge is manifested by a relatively large number of published MGCDS, with none of them covering all possible features associated with supporting the management of multimorbidity patients. Therefore, it is important that there is a unified framework that, on the one hand, allows for comparing functionalities of existing MGCDS, and, on the other hand, can help guide development of new ones by highlighting gaps in the state-of-the-art. The purpose of the research described in the paper was to create such a framework. We have identified a set of MGCDS features, developed 4 case studies to cover those features and conducted a survey with physicians to confirm the features.

The survey results largely confirmed the feature set. There were three features where relevance was somehow questionable for the physicians. Five respondents did not consider *duplicate or redundant advice of different CPGs* (A5) as a relevant feature. The most plausible explanation is that experienced clinicians find such advice to be rather straightforward. However, considering that an MGCDS might be used by physicians of different levels of experience, having such a feature may be useful. Similarly, three physicians considered *explanation of mitigation strategy(ies)* (A17) to be less relevant. Such thinking seems to be related to the ongoing discussion in the medical informatics community about the “black box algorithm effect”, with some arguing for system explainability while others focus on the quality of performance of a black box algorithm. It is our assertion that the assessment of this feature reflects this debate. Finally, two physicians asserted that *optimization of clinical resources* (A16) is not relevant. In our context, optimization of the resources implies avoiding unnecessary tests or grouping these tests together so they can be conducted during one visit. While this is probably one of the most relevant features from a patients’ perspective, physicians consider such optimization to be beyond scope of their practice and being under control of laboratory and imaging services.

The strengths of our method to develop this comparative framework includes the thorough review and analysis of the existing MGCDS literature, the participation of original developers of various guideline-based multimorbidity methods, the rigorous vetting of the cases by physicians, the confirmatory survey by physicians not involved in the development process, and the upcoming comparison study that will use, refine, and extend the framework. At the same time, we recognise certain limitations. Firstly, our sample size of physicians is small (15 physicians), however, we believe it achieves the goal of verifying the validity of features at this point in the work, and we intend to validate the MGCDS framework with a larger group of physicians in the upcoming phases of our work. Second, given that we
derived the set of interaction, mitigation, and other features from a review of the existing MGCDS literature, it is possible that additional features may be discovered as researchers work on new domains and new combinations of morbidities. Thus, this framework will necessarily be an evolving one and will merit future reviews. Finally, another limitation of our method is that we did not mine the clinical literature for potential sources of new features. While many of us were inspired by the landmark 2005 Boyd et al. paper, it is beyond our expertise and scope to review the clinical literature for interesting and novel multimorbid interactions and mitigations. Nevertheless, given the rigorous review of the case studies and the affirmation of the features by physicians—whereby no additional features were suggested, with one caveat (see below)—we are confident about the robustness of the case studies and the multimorbidity features that we have identified. It is our hope that this comparative framework and upcoming study will be of interest not only to informaticians, but to clinicians as well. With a consolidation of existing understanding of multimorbidity interactions and mitigations, we will be in the position to have further dialog between informaticians and clinicians.

Another aspect of our framework is that it is more methodologically-oriented than implementation-oriented—meaning that it is focused on high-level features and mitigation strategies rather than concrete implementation and deployment methods. What the groups contributing to this framework share is that they have developed MGCDSs that in totality cover the identified features. Originally some of us hoped that the framework and the survey could shed new light on the requirements of implementing MGCDS as well. However, the implementation of MGCDS as actual systems for deployment depends on myriad factors (e.g., the target audience and the workflow settings) beyond what the framework can accommodate. The downgrading of explainability and optimization of clinical resources by some physicians may also be a reflection of this issue.

The clinicians’ comments about the need to prioritize conflicting goals or weighing risks and benefits of different actions suggest that a new “other feature” may possibly be relevant, which focuses on explicit support for decision making among conflicting goals and actions. Some approaches in the literature already provide such decision support. For example, MitPlan tries to optimize an objective function (e.g., overall cost) that is selected by the clinician. GoCom makes the choices among different alternatives explicit, some of which may not satisfy a given guideline-suggested goal, but does not support weighing the priorities, costs and benefits, and trade-offs among the alternatives.

We plan to complete (3) a reporting standard for MGCDS solutions and (4) criteria for evaluating MGCDS solutions of our framework as part of the upcoming comparison study. In this study, we will use the complete comparative framework to evaluate the existing MGCDSs with direct involvement from groups that designed the systems. A quantitative evaluation will assess functionalities of MGCDS and in a qualitative evaluation we will interview physicians about the MGCDS solutions. We will also use a larger set of case studies, including real world case studies, investigate further conflicts and how to mitigate these conflicts, and explore the identification of further possible MGCDS features with physicians. A companion paper describing comparison study will present the development of part 3 and part 4 of the framework as well as the study results themselves. A reporting template will necessarily incorporate some evaluation criteria of the MGCDS systems themselves (e.g., the use of standard terminologies or knowledge sources). Several groups are already piloting a reporting template proposal, using not only their own cases but also external cases as exemplars. We expect to present the piloted reporting templates and a few reporting exemplars to the groups participating in the comparison study and iteratively refine them to the groups’ satisfaction. Once the comparison study starts, we expect each group to implement guideline fragments sufficient to execute the common cases to the extent possible and then to report on their results.

To summarize, the results described in this paper represent first steps towards creating a validated, comprehensive framework for comparing functionalities of MGCDS. Having such a framework should help with identifying gaps in MGCDS research and subsequently help with moving this research area forward. In order to facilitate this progress, we plan to prospectively evaluate our proposed framework by inviting different research groups working on MGCDS to use the framework and its accompanying clinical use cases. This should help with identifying gaps in MGCDS research as well as provide guidance for future research directions.

Abstract

“No-shows”, defined as missed appointments or late cancellations, is a central problem in healthcare systems. It has appeared to intensify during the COVID-19 pandemic and the nonpharmaceutical interventions, such as closures, taken to slow its spread. No-shows interfere with patients’ continuous care, lead to inefficient utilization of medical resources, and increase healthcare costs. We present a comprehensive analysis of no-shows for breast imaging appointments made during 2020 in a large medical network in Israel. We applied advanced machine learning methods to provide insights into novel and known predictors. Additionally, we employed causal inference methodology to infer the effect of closures on no-shows, after accounting for confounding biases, and demonstrate the superiority of adversarial balancing over inverse probability weighting in correcting these biases. Our results imply that a patient’s perceived risk of cancer and the COVID-19 time-based factors are major predictors. Further, we reveal that closures impact patients over 60, but not patients undergoing advanced diagnostic examinations.

Introduction

The outbreak of the coronavirus disease 2019 (COVID-19) pandemic in early 2020 led to a unique unprecedented societal shift. Governments implemented a wide variety of nonpharmaceutical interventions (NPIs) aimed at controlling the disease spread and enforcing social isolation. Confinement and school closure as well as entertainment and cultural sector closure were the predominant NPIs taken by governments in 2020. Accordingly, many radiology departments decreased the number of elective imaging examinations to minimize the spread of infection and free up much needed medical resources and staff. One specific example is the reduction of breast imaging to 28% of baseline imaging volumes reported by Stanford Health Care during the first months of the pandemic outbreak. Another is the 85% drop in mammography examinations over five days during March 2020 as reported by a large, metropolitan hospital system consisting of six outpatient practices across three New York City boroughs. Many radiology centers in the United States started to gradually reopen these examinations in the summer of 2020. In parallel to the variability in the outpatient radiology practices regarding examination availability, there was also a change in the behavior of patients coming to the exams, showing a distinct rise in no-show rate that seemed to be correlated with the height of the pandemic.

No-shows to medical appointments significantly impact revenue, cost, and the efficient use of resources. Understanding this issue can help us to better manage resources, target interventions to prevent the no-show, and reduce some of the associated revenue loss and cost. Predicting patient no-shows and identifying the major individual attributes associated with no-show have been the key approach to understanding this phenomenon. Patient cohorts with retrospective data derived from electronic health records (EHRs) have been leveraged to train prediction models, with logistic regression being the most widely-used model. Specifically, among the different modalities used in radiology examinations, mammography (MG) and CT were identified as having the highest no-show rates. Among the different predictors, age and scheduling lead time were often identified as highly associated with not showing up.

In recent years, scalable methods were developed to better understand different phenomena by applying causal inference to patient cohorts. Causal inference can help quantify the magnitude of the effect of specific interventions on no-shows. In the context of the pandemic and the NPIs imposed by governments, it is important to assess the effect of NPIs on the no-shows. Following the common design of causal inference studies, we analyze two groups in the data: appointments that took place when NPIs were not imposed and appointments that took place during the time of imposed NPIs. Inverse Probability Weighting (IPW) is a method frequently used to correct for unequal confounders distribution across the groups. It is aimed at eliminating biases in the data and enabling an inference of the average
effect at the population level\textsuperscript{9}. However, IPW is not guaranteed to successfully remove biases. A recently developed method called Adversarial Balancing (AdvBal)\textsuperscript{10}, based on generative adversarial networks (GANs), is better posed to address covariates biases in high-dimensional data and generate weights that are closer to uniform. We tested and compared IPW and AdvBal to estimate the average effect of the NPIs on the no-show rate.

In this study we analyze the data of patients coming from the largest private network of hospitals in Israel, which performs 30\% of the screening mammography exams in the country. Excluding several days, which were dismissed from our no-shows analysis, this network did not apply any policy to decrease the number of imaging exams during the COVID-19 pandemic, but rather adjusted service to changes in the demand. We present a comprehensive study of no-shows during COVID-19, taking into account time-based coronavirus factors such as \% confirmed cases, reproduction rate, NPIs, and changes in population mobility, which are derived from multiple data resources. See Figure 1 for the trend of selected time-based statistics over the year 2020. The correlations between changes in the growth of COVID-19 morbidity, population mobility, and the ratio of show-to-no-show are easily noticed. To the best of our knowledge, this is the first study to combine pre-pandemic known predictors of no-show with pandemic associated predictors. Our study is also unique in the causal inference analysis that we perform to assess the average effect of NPIs on no-show in the entire study population, and in subgroups of interest.

**Methods**

Our study analyzes no-show appointments over the course of 2020. We refer to the time period from January 3 till February 6, 2020 as the *Pre-COVID-19 period*, and to March 15 till December 31, 2020 as the *COVID-19 period*. The Pre-COVID-19 period was defined in a manner similar to the baseline period used in Google Community Mobility Reports\textsuperscript{11}. We focused on the COVID-19 period and used the Pre-COVID-19 period as a reference for its comparison. The inspection of NPI data revealed large correlations in these data, as expected. Therefore, we decided to include in our analysis a single NPI, school closure, which is more easily defined, and serves as an indication for other NPIs. Similar to previous studies\textsuperscript{12,13}, we consider late cancellations as no-shows since they do not allow the scheduling
system to set an appointment for a new patient. We randomly partitioned the patients in this study into train (56%), validation (14%), and test (30%). We trained our prediction models on the train dataset and evaluated them on the validation dataset during the development process. The train and validation sets were also used for the development of the causal analysis. The test dataset was held-out until the model, analysis, and all hypotheses were finalized. Unless specified otherwise, the results presented in this study are from the held-out data.

Data

This retrospective study was approved by the institutional review board of Assuta Medical Center (0033-20-ASMC), who waived the requirement for patient consent. The appointments dataset was extracted from the EHR datamart of Assuta Medical Centers and included all imaging appointments from January 1, 2020 to December 31, 2020. Our initial cohort included all patients with mammography (MG) and/or breast ultrasound (BUS) appointments during 2020. In addition to the scheduled date, the information on each appointment included the creation and cancellation dates, with the latter filled only for cancelled appointments. Rescheduling an appointment involves cancelling the old appointment and creating a new one, and therefore all dates in an appointment record are assumed non-modifiable. The information on the scheduled exam included: the imaging modality (MG, BUS), the procedure code, a pre-exam urgency indicator, and the site of the exam. The information on the patient included: a (de-identified) patient-ID, gender, age, and town of residence. We received additional data on each patient selected for our study, which included the results of the patient’s last MG, BUS, breast MRI, and breast biopsy exams, if present.

We obtained socio-economic measures and population sizes for localities in Israel from the Central Bureau of Statistics (CBS) reports. We downloaded Israel Transverse Mercator (ITM) coordinates for localities in Israel from the public Israeli Government Databases and used these data to compute pairwise distances between the patients’ towns and exam sites. Time-based statistics of coronavirus morbidity in Israel, and for specific towns, were downloaded from the COVID-19 Data Repository of the Israeli Ministry of Health. We obtained data on NPIs in Israel from the IBM Worldwide Non-pharmaceutical Interventions Tracker for COVID-19 (WNTRAC). The data included information on confinements, school closures, public services closures, work restrictions, and more. Finally, we acquired community mobility data in Israel from Google Community Mobility Reports. These reports include the per-day change in movement across six different categories of places, with respect to the median value of the same day of the week during the five-week period January 3 to February 6, 2020.

No-Show Outcome

We defined a no-show outcome for a pair of (patient, date), if the patient had an appointment for an imaging exam on that date. There were many patients with multiple appointments on the same date, e.g., MG and BUS for breast cancer screening were often scheduled for the same date. We classified a pair of (patient, date) as show if the patient attended at least one appointment at that date, and no-show if the patient attended none. Our assumption was that partial attendance to appointments is likely not the patient’s choice. We inferred that a site had no service for a certain modality on a specific date, if no corresponding exams were performed on that date. We then refined the no-show definition to exclude (patient, date) pairs for which there was no service for all patient appointments on that date.

Cohort Selection and Index Date

Our initial cohort included all (patient, date) pairs during the year 2020, where the patient had an ambulatory appointment for an MG or BUS exam on that date. We included only patients aged 18 years or older. We set the index date of each (patient, date) sample to be one-week (7 days) prior to that date, and discarded (patient, date) samples for which all appointments were created at or after the index date. We referred to these discarded samples as “same week schedules” and analyzed them in a separate study, as these were shown to have distinct characteristics. We also excluded (patient, date) samples for which all appointments were cancelled prior to the index date. We refer to such samples as “early cancellations” and assumed the health system can accommodate for these. To summarize, we selected (patient, date) samples with at least one planned appointment by the index date, by excluding samples that had all their appointments cancelled at that date, or not yet created. The process of cohort extraction is depicted in Figure 2.

Features

We used the data from the time period prior to the index date to extract features for our no-show prediction model. The same set of features was used in the analysis of closure effects. We extracted a total of 140 features, using a previously described feature extraction tool. Below we present these features:

Patient demographics: age, gender, town socio-economic index-value, town distance from site.
Figure 2. Cohorts’ inclusion/exclusion criteria

Index exams: waiting time (time between the date of the appointment creation and the scheduled date, aka “lead time”), imaging modality, total number of modalities, MG/BUS procedure indicator, total number of MG/BUS procedures, pre-exam urgency indicator, site indicator.

Imaging history (3 months): total number of show dates (all imaging modalities), total number of show dates for the same modality, total number of no-show dates (all modalities), total number of no-show dates for the same modality.

Cancer diagnostic phase: we mapped each MG/BUS procedure to a cancer diagnostic phase. Basic and extended breast cancer screening procedures were mapped to phases 1 and 2 respectively; diagnostic exams of patients recalled after screening exams were mapped to phase 3; phases 4 and 5 pertain to biopsy-related procedures, indicating the existence of findings suspected as potentially malignant. The feature “is screening” indicates basic screening (phase 1).

Previous MG and BUS exams: has a previous exam indicator, time to last exam, last procedure indicator, last cancer diagnostic phase, last procedure is screening, last BI-RADS score (i.e. the result of the exam), last breast density measure (1-4).

Previous breast MRI and biopsy exams: has a previous MRI indicator, time to last MRI, MRI procedure indicator.

COVID-19 related measures: # new confirmed cases, % confirmed cases, change in population mobility for each of the six place categories, school closure indicator, reproduction rate. All these features refer to measures at the country-level. We also extracted town-specific time-based features corresponding to the patient’s town: total number of new confirmed cases in town (per 10K), % confirmed cases in town. All time-based features were computed after the underlying time-series data were smoothed with a moving average of seven days. The COVID-19 reproduction rate was inferred with the EpiEstim\textsuperscript{19} application.

Predictive Analysis of No-Shows

We trained our no-show prediction model with the gradient boosted trees algorithm, using the XGBoost\textsuperscript{20} package. Hyperparameters were tuned with 5-fold cross validation on the train dataset, via a randomized grid search. We were unable to map the town of residence to the list of towns published by the Israel CBS for 7% of the samples, with a higher rate for no-show samples. Inspecting the unmatched town values revealed that most of these corresponded to either “unknown” or “other” values. We preprocessed the train data and imputed missing values in town-based features, to prevent XGBoost from learning predictive patterns of missing values in these features. The imputation was done with the stochastic “multivariate imputation by chained equations” (MICE) method, with ten iterations, using the “Statsmodels”\textsuperscript{21} package. We relied on the inherent XGBoost imputation mechanism to handle missing values in the remaining features during train, and in all the features during inference. We used TreeExplainer from the Shapley Additive exPlanations (SHAP)\textsuperscript{22} package to estimate the contribution of each feature to our XGBoost
model, based on the classic game-theoretic Shapley values. We obtained an agglomerative hierarchical clustering of time-series data using average linkage, and the Euclidean distance between the pairwise Pearson correlations as the distance metric.

**Causal Analysis of Closures**

We divided our (patient, date) samples into closure and no-closure groups based on whether there was a school closure on the date. We leveraged the average treatment effect (ATE) to examine the effect of school closure on no-show rate:

\[
ATE = \mathbb{E}(Y_{\text{closure}}) - \mathbb{E}(Y_{\text{no closure}})
\]

(1)

where \(\mathbb{E}(Y^1)\) and \(\mathbb{E}(Y^0)\) are the potential no-show rates for the entire cohort if all samples were during closure and no-closure, respectively. In other words, the ATE is the average effect, at the population level, of moving the entire study population from no-closure to closure. Estimating the ATE from the observed data requires accounting for confounding biases between closure and no-closure groups. For each feature, we measured the bias between the two, possibly weighted, closure and no-closure groups by computing the absolute standardized difference:

\[
d = \frac{|\bar{x}_{\text{closure}} - \bar{x}_{\text{no closure}}|}{\sqrt{(s^2_{\text{closure}} + s^2_{\text{no closure}})/2}}
\]

(2)

where \(\bar{x}_{\text{closure}}\) and \(\bar{x}_{\text{no closure}}\) are the feature means in the closure and no-closure groups, respectively, and \(s^2_{\text{closure}}, s^2_{\text{no closure}}\) are the corresponding sample variances. A standardized difference that is less than 0.1 is commonly regarded as negligible bias between compared groups. We visually compared the distributions of top-biased features within the closure and no-closure groups. We plotted the smoothed densities of the compared distributions using Gaussian kernel density estimation with a bandwidth of 1.

**Inverse probability weighting (IPW)**. IPW is a longstanding popular method that weights samples based on the inverse of their propensity to be in their assigned group. The propensity is estimated by fitting a model that predicts the assigned group. We used a logistic regression model, which is commonly used for IPW.

**Adversarial balancing (AdvBal)**. The AdvBal method borrows principles from GANs, to generate sample weights for a source data, such that the resulting weighted data becomes similar to a given target data. In our case, it was aimed at generating weights for the closure (resp., no closure) group, to make it indistinguishable from the entire cohort data. Similar to GANs, it operates by alternately training a classifier to distinguish between the source and target data, and a weights generator that uses exponentiated gradient descent to maximize classification error. We applied AdvBal with a logistic regression classifier. We set the number of iterations in AdvBal to ten.

Prior to applying logistic regression modeling to the data, in both IPW and AdvBal, we imputed missing values in all the features using the MICE method. We used the implementation of IPW and AdvBal from the CausalLib package.

**Evaluation Measures and Statistical Tests**

We measured the accuracy of our prediction models using the area under the receiver-operator curve (AUC). We assessed the statistical association between two binary variables with a chi-squared test, and between a binary variable and a non-binary variable with an unpaired one-sided t-test. These univariate statistical tests were performed after omitting missing values in the tested features. We compared two AUCs that were computed on the same data using the DeLong test. We estimated the standard error of computed effects with 100 bootstrapping iterations, and computed P-values by the normal distribution. We used the validation set for testing various hypotheses, from which we selected 25 that seemed most attainable. We applied the Benjamini-Hochberg procedure to account for multiple testing, and all the 25 P-values reported in this study were significant at false discovery rate lower than 0.002.

**Results**

Table 1 presents selected statistics for the train, validation, and held-out datasets for each of the COVID-19 and Pre-COVID-19 periods. As shown, the train, validation and held-out datasets exhibit similar statistics for both periods. A comparison of the COVID-19 and Pre-COVID-19 periods revealed that the no-show rate significantly increased during COVID-19 (35% vs. 31%, \(P\)-value = 0.0002, chi-squared test), due to the increase in late cancellations (11% vs. 7%). Note that late cancellations also include late reschedules, that is, reschedules during the week before the appointment. Another prominent difference between the two time periods is the shorter average waiting time during COVID-19 (41 vs 44 days, \(P\)-value = \(2 \times 10^{-16}\)), which can be explained by the 7% reduction in the average
number of appointments per week. Both “%confirmed cases” and “school closure” showed a significant association with no-shows during COVID-19.

Table 1. Cohort statistics. For binary variables, we present the proportion (%) and mean ± standard deviation for non-binary features. The association with the no-show outcome (show and no-show statistics, P-value) is presented within squared brackets.

No-Show Predictors During COVID-19

We examined the top-20 contributing features for our XGBoost model that was trained on COVID-19 data with the entire set of 124 extracted features (Figure 3a). The strongest predictor was “cancer diagnostics phase”, an ordinal feature with 5 categories, ranging from basic screening to biopsy related procedures. Additional related features that appear in this list of top-20 were: “last MG cancer diagnostic phase”, and “screening mammography”. The features “last MG BI-RADS score” and “last BUS BI-RADS score” are also related to “cancer diagnostics phase” since BI-RADS scores determine whether patients are recalled for the next diagnostic phase. An inquiry on “procedure BUS 760904”, which was classified as cancer diagnostic phase 2, revealed that it was commonly used when the patient co-scheduled a basic MG screening exam. Thus 6 of the top-20 important features pertain to the patient’s knowledge, or perception, of the a-priori chance of cancer diagnosis. The inspection of “time to last MG”, which was ranked second among the top-20 features, revealed that patients who had mammography exams approximately a year before had the highest tendency to show up on-time to their appointments. However, this tendency decreased as the time from the previous mammography increased.

Six out of the top-20 important features were COVID-19 related factors. The exclusion of these features from our model significantly reduced the AUC from 0.744 to 0.710 (P-value = 2 × 10⁻⁰⁹⁰, DeLong test). Our results imply that when there is a growth in COVID-19 morbidity, patients may be more reluctant to attend MG and BUS exams, as reflected by the positive trend of “% confirmed cases” and “reproduction rate” in Figure 3a. The time-series of COVID-19 measurements largely correlated with each other, and a clustering analysis of these data revealed two clusters that are negatively correlated with each other (see Figure 3b). The correlation of school closure with mobility changes, which were included in list of top-20 important features, may explain the exclusion of the former from that
Estimated School Closure Effect on No-Shows

We analyzed the average effect of school closures on no-show rate, after correcting for observed confounding biases between the two time periods. As mentioned above, school closure was selected as a representative of a larger set of highly correlated NPIs and its estimated effect corresponds to the entire set of co-occurring NPIs. We estimated the average effect of school closure in our entire study population, as well as for subgroups defined by (i) age and (ii) cancer diagnostic phase. Our set of potential confounders included all extracted features, excluding school closure itself, and the reproduction rate and mobility features, which were highly correlated with the school closure indicator (See Figure 3b). We tested and compared two causal inference methods for correcting observed biases: IPW and AdvBal. We used a logistic regression model in both methods.

Comparison of IPW and AdvBal. In all our analyses, AdvBal substantially diminished the standardized difference of all the confounders (d ≤0.02). Reducing the number of the iterations in AdvBal to 5 instead of 10 also successfully reduced biases below the required threshold of 0.1 (d ≤0.08). On the other hand, IPW failed to reduce major
imbalances, as shown in Figure 4; it even introduced much larger biases into confounders that had negligible biases in the original (unweighted) data.

Estimated effects. Table 2 presents the uncorrected and corrected effects of school closure on no-show rates, in the entire study population (“All”) and for subgroups by age and cancer diagnostic phase. As shown, the estimated effect practically vanished in the subgroup of patients with advanced cancer diagnostic exams (phases 3-5), and the remaining estimated effects also largely dropped, with a decrease of 60% to 80% of the original (uncorrected) effects. As an example, the estimated average effect in the entire study population dropped from 12% to 3% after accounting for the observed confounding biases. Among tested subgroups, patients at age 60+ were most affected by closures, with the estimated potential no-show rate lifting from 31% to 37%.

Discussion

This paper presents a comprehensive analysis of no-shows, defined as missed appointments or late cancellations, during the COVID-19 pandemic, systematically verifying previously made hypotheses. Measures of COVID-19 growth, such as “%confirmed cases”, “new confirmed cases”, and the reproduction rate, are often published in the Israeli media. Our results suggest these representations of the perceived severity of the pandemic play a major role in a patient’s decision of whether to attend a medical appointment. During 2020, there were two periods of school closures in Israel, in which additional non-pharmaceutical interventions were applied, such as confinements and bans of mass gatherings. These closures covered 25% of the appointments in our data during the COVID-19 period (see Table 1). We demonstrated that the observed large effect of school closures on no-show rate dramatically decreased by 60% to 80% when accounting for biases in COVID-19 growth measures. Moreover, we show that closure effect was magnified for patients over 60 years, presumably due to their elevated risk for coronavirus complications. Conversely, no effect was observed for patients in advanced cancer diagnostic phases. The adjustment for the observed biases was enabled by the adversarial balancing method, after the application of the popular IPW method failed to balance these biases. Adversarial balancing harnessed the power of GANs to generate balancing weights that made the multivariate distributions of the confounders in the closure and non-closure groups less diverged. In this study, we

![Figure 4. Distribution of top-biased confounders during closure and no-closure periods.](image) Plots depict smoothed estimated densities for the 5 biased features in the original data (left column, d>0.1), and after reweighting the data with IPW (middle column, d>0.1) and AdvBal (right column, d<0.007). The standardized difference d (see Methods section), which measures the bias between the closure and no-closure groups, appears at the upper right corner of each subplot. Green and red colors indicate negligible (≤0.1) and non-negligible (>0.1) values for d, respectively.
applied adversarial balancing with a simple logistic regression classifier, but stronger deep learning classifiers can be used to increase its power.

Our results are in agreement with existing literature on no-shows5,7: patient’s historical behavior, wait time (aka “lead time”), distance from the exam site, and age were found to be predictive for no-shows. Age was also found to be predictive for no-shows but with mixed effects due to several reasons. First, breast screening in Israel is recommended at ages 50 to 74, and hence women under 40 are more likely to attend MG/BUS exams due to some indication, or suspicion, for elevated risk of breast cancer. In addition, in the screening population (diagnostic phase 1), the cancer risk is known to increase with age; however, patients at age 60+ in our data were at risk for coronavirus complications, which may have caused these patients to refrain from attending medical exams. We also demonstrated that including per-site indicators in the model can significantly improve the model accuracy, as it allows the model to identify predictive patterns that are site-specific. Finally, an important finding of our study is the inclusion of the cancer diagnostic phase as a predictor in our model. This predictor, which may reflect cancer risk as perceived by the patient, was ranked as most influential in our model. This discovery demonstrates that the patient’s comprehension of the health risks is important for reducing no-shows.

**Conclusion**

We employed state-of-the-art machine learning and causal inference methods to study no-shows in the data of more than 160,000 screening and diagnostic breast imaging appointments made during 2020. Our results suggest that a patient’s perceived risk for breast cancer, as implied by the diagnostic phase, is the most influential factor in their decision to attend an imaging appointment. Additional novel predictors correspond to time-based factors indicating the growth of COVID-19 morbidity. After adjusting for confounding biases with the AdvBal method, the effect of closures on the no-show rate largely diminished. This was especially noted in patients in advanced diagnostic phases, who seemed to maintain their lower rate of no-shows. On the other hand, the impact of closures was most pronounced in patients at age 60+, presumably due to their higher risk for coronavirus complications. Our study further demonstrates the need for personalized medicine to target additional women at higher risk for breast cancer within subpopulations associated with increased no-show rates. In a future study, we intend to leverage richer clinical data to estimate the coronavirus and cancer risks more accurately and analyze them in the context of no-shows.

Discovering Associations between Social Determinants and Health Outcomes: Merging Knowledge Graphs from Literature and Electronic Health Data

Yoonyoung Park¹, Natasha Mulligan², Martin Gleize², Morten Kristiansen³, Joao H Bettencourt-Silva²
¹IBM Research, Cambridge, MA, USA; ²IBM Research Europe, Dublin, Ireland; ³IBM Watson Health, Dublin, Ireland

Abstract

Social Determinants of Health (SDoH) are an increasingly important part of the broader research and public health efforts in understanding individuals’ physical and mental well-being. Despite this, non-clinical factors affecting health are poorly recorded in electronic health databases and techniques to study how SDoH might relate to population outcomes are lacking. This paper proposes an approach to systematically identify and quantify associations between SDoH and health-related outcomes in a specific cohort of people by (1) leveraging published evidence from literature to build a knowledge graph of health and social factor associations and (2) analysing a large dataset of claims and medical records where those associations may be found. This work demonstrates how the proposed approach could be used to generate hypotheses and inform further research on SDoH in a data-driven manner.

Introduction

With the increasing emphasis on delivering high value and accessible care, there is a growing awareness of the importance of non-clinical factors contributing to people’s physical and mental well-being collectively called social determinants of health (SDoH). A large body of prior work has shown significant effects of SDoH on health related outcomes. For example, measures of SDoH were shown to be associated with increased risk of preterm birth, readmission risk, hospitalization rate, or healthcare utilization. The global SARS-COV-2 pandemic has further revealed the stark inequity and inequality in healthcare resource across the US, often associated with different dimensions of SDoH such as race, income, education level, or job security. Timely and effective intervention regarding SDoH seems more important than ever.

From a healthcare provider or policy maker point of view, having insights on social factors that affect his/her population of interest can help design monitoring and public health interventions, prioritize resource allocation, and achieve health equity. Limited insights on the prevalent social issues of the population may exist, but it’s less likely that a thorough understanding of how much a particular issue affects which subset of the population exists. For example, a hospital knows that a large proportion of the population in its catchment area suffers from poor transportation, but is unclear about how the transportation problem adversely impacts different aspects of population health.

The interest in SDoH has led to a need for analytic and data-driven solutions, with a newly coined term social informatics. Probably the biggest challenge pointed out by both researchers and practitioners is the lack of data on SDoH. Existing health databases such as electronic health records or administrative claims data often do not collect information on SDoH in a reliable manner. A new set of codes was introduced during the conversion from ICD-9 to ICD-10 to better capture SDoH in claims data, but the utility of these Z-codes known to be under utilized are not fully understood. Area-based composite indices of SDoH based on US Census data have become more popular as a public resource. However, limited applications exist to date among healthcare organizations possibly due to both technical and privacy related concerns. Research on the impact of social factors is active in domains other than healthcare as well and vast amount of literature exist, but incrementally digesting that information and producing actionable insights would not be a feasible or efficient task. Therefore, developing tools to utilize previously untapped sources of data to guide clinical and policy decision making would be highly beneficial from both research and practice point of views.

In this work, we introduce a systematic approach to identify and quantify associations between SDoH and health related outcomes in a specific cohort of people. Our approach has two parallel pipelines, one that mines associations from published evidence in PubMed, and the second which identifies related cohorts in electronic health data. The combined results then inform the subsequent analysis with stronger hypotheses on the association between SDoH
of interest and specific health-related outcomes for further investigation. The main contributions of this work are the construction of a PubMed knowledge graph for identifying SDoH associations based on our prior work and the demonstration of methods to augment it with a real-world health data set.

Background and Related Work

Social factors are reported to account for more than half of the deaths in the US in any given year. As the focus on population health grows, interest is also rising in data and analytic solutions to better understand SDoH and how we might integrate them with clinical outcome information. One way to achieve this is to analyze electronic health data based on a priori hypotheses, such as administrative claims data generated from insurance processes or electronic medical records (EMRs) generated by providers. However, these data are built for purposes other than research and do not suitably capture information on patients’ social factors. Despite the efforts to address this limitation by, for example, introducing Z-codes in ICD-10, the utilization level of Z-codes has been very low in Medicare beneficiaries. Unstructured data, such as case notes, may be an additional source of SDoH information when coding is unavailable or sparingly documented. Recent efforts are also underway to create or improve existing standards and represent SDoH information, such as the SIREN and Gravity Projects, LOINC’s models for the representation of screening assessments and measures of SDoH, or HL7 FHIR profiles and extensions, among others.

Knowledge extraction and text mining techniques may be used to discover associations and patterns in large datasets. The application of data and text mining in health informatics is increasing especially with the availability of large electronic health data and improved computing power. Recently, researchers are realizing the potential of text mining through Natural Language Processing (NLP) in medicine to gain additional insights from traditionally underused unstructured data. For example, text mining has been used to extract medical concepts or SDoH related information from patients’ medical records. Previous work has also focused on extracting homelessness and adverse childhood experiences large corpora of clinical notes while other work has used ontology-driven tools embedded in health records to identify individuals at an increased psychosocial risk.

Our prior work in this domain is probably one of the first attempts to utilize a novel source of textual data, PubMed, for SDoH research. Published peer-reviewed articles available in PubMed provide a great opportunity to gather new insights from a very large corpus of data. In this paper, we build on the prior work and extend the approach to identify and quantify the relations between SDoH and health outcomes in a real-world cohort through electronic health data analysis.

Methods

Figure 1: Illustration of the approach used in this paper
Figure 1 illustrates our approach to assessing the associations with SDoH using two sources of data. We begin by imagining the hospital decision maker mentioned earlier, who has some knowledge about SDoH challenges in her population and wishes to know more about their impact on an undetermined set of health related outcomes. Starting from the specific social factor of interest, we identify possible associations by creating a knowledge graph (KG) based on published abstracts in PubMed. By doing this, we are collecting all available insights on the chosen SDoH topics from all research publications. However, information extraction based on co-occurrence gives at best measures of correlation which may or may not be applicable for the specific target population. While they are useful for hypothesis generating purposes, this is a critical limitation for the decision maker because information extraction from such sizable corpus will return numerous pairs of correlated terms with weak evidence. We augment the findings from PubMed by adding electronic health data, which represents data collected from the population of interest. Cohort-specific data analysis may seem self-sufficient to understand the SDoH effect, but in reality, electronic health data poorly captures SDoH and even when these are recorded, some or all of the results may be spurious correlations due to nonrandom data collection and other unobserved confounders. In addition, electronic health data are highly fragmented, often unable to produce long-term effect estimations. We therefore focused on the intersection of the two KGs that generate stronger hypotheses informing the subsequent cohort analysis, which involves quantification of the strength of association for specific SDoH-outcome pairs to generate actionable insights.

SDoH for Information Extraction and Data Analysis

We focused on two specific SDoH factors, housing problems and unemployment. The motivation for choosing housing problems is largely based on the prior evidence from Centers for Medicare Medicaid Services (CMS) showing that the most utilized Z-code among Medicare beneficiaries was Homelessness, in addition to other studies reporting adverse effects of unstable housing issue on health outcomes. Ensuring we have a reasonable prevalence of the ICD social codes in the Claims-EMR Data was important to reliably quantify the association level for these codes. The motivation for choosing unemployment came from our prior work monitoring Google Trends across several SDoH dimensions in the year 2020. The term ‘Unemployment’ had the most significant increase in terms of the average interest compared with previous years, implying that employment was a severely affected SDoH dimension at the outset of the global pandemic. Although it is not as frequently recorded in data as housing problems, we believe examining unemployment would be a timely and informative analysis in light of the SARS-COV-2 pandemic, as shown in recent studies.

Information Extraction from PubMed

![Concept network representing housing problems. Each hexagon is a category and circles are UMLS entities that represent each category. Circles that are grayed out were not found by PubMed MetaMap.](image-url)
A natural way to mine relationships between socio-medical concepts is to look for their co-occurrence in published literature\(^1\). Although a high frequency of co-occurrence does not directly indicate association between concepts in the real world, knowing that they are often talked about together is a good indication that the link has been explored by the scientific community at the very least.

We indexed the full 2019 MEDLINE/PubMed Baseline\(^2\) which notably includes the abstracts of research articles. We used MetaMap\(^3\) to tokenize and identify UMLS concepts in the sentences of the abstracts, and indexed each single sentence with Lucene\(^4\) so that it could be retrieved using multiple annotation layers, like words and phrases, UMLS semantic types, or UMLS concepts. It is possible to apply statistical methods on medical text alone but it is generally preferred to overlay a text corpus with concept annotations from an ontology like UMLS to address language variation: there is more than one way to designate the same entity. UMLS is a very extensive ontology\(^5\) and the concepts identified by MetaMap vary widely in nature, so we restricted the medical concepts to only semantic type\(^6\) representing health issues that individual people might have, like: Disease or Syndrome, Sign or Symptom. UMLS semantic types are an upper-level ontology on top of UMLS, providing broader categories that each UMLS concept can fit into\(^7\). In addition to this subset of UMLS concepts, we also highlighted Social Determinants of Health (SDoH) annotations in our indexed version of PubMed. As a starting point, we used a SDoH lexicon of concepts defined in-house and strongly inspired by the World Health Organization’s definition\(^8\). Different coding terminologies represent SDoH in different ways with varying degrees of detail and specificity. Our team then semi-automatically mapped the SDoH concepts to UMLS concepts: looking manually for the closest denomination and checking that queries using this UMLS concept yielded a non-negligible amount of results in PubMed. The mapping process itself is a challenging task, with some identified SDoH not mapping to any single UMLS concept: for example “Teenage Pregnancy” could require a combination of concepts to properly describe both the teenage and pregnancy aspects of the concept. The SDoH looked at in this contribution, identified in the previous section – Housing and Unemployment – could be straightforwardly mapped to the corresponding UMLS concept. Figure 2\(^9\) shows the SDoH Housing and related subterms, mapped to UMLS concepts.

In our experiments, we queried the index for any pair of a SDoH Housing or Unemployment, and another SDoH or another UMLS concept – as annotated by MetaMap and restricted as described above. Since our index is a sentence-level index, this defined the set of sentences where the SDoH appears together with another socio-medical concept of interest. It is important at this point to note that MetaMap’s coverage is not perfect and some concepts in UMLS are never detected by it – even on such a large collection of documents as PubMed. In Figure 2\(^9\) MetaMap detected no instance of the grayed out concepts in PubMed despite them being defined as children of Homelessness in UMLS. Grayed out concepts could be eligible for further revisions of MetaMap’s annotation of PubMed as it is important to continuously improve coverage through time.

To build a knowledge graph, we created edges between concepts found together in at least one sentence, and weighted these edges using relative frequency. Formally, the edge \((x, y)\) defined between concept \(x\) and concept \(y\) is weighted with \(W(x, y) = P(y | x)\), a conditional probability estimated on our corpus by dividing the size of the set of sentences containing both \(x\) and \(y\) (called cofrequency) by the overall frequency of \(x\) in the corpus. An optional step in the graph building process is to prune edges with too low of a weight, to get rid of noisy relations. In this contribution however, this is not necessary as our conclusions will focus on the top ranked relations.

**Analysis of Claims-EMR Data**

We used IBM\(^{®}\) MarketScan\(^{®}\) Explorys\(^{®}\) Claims-EMR Data (CED), created by linking administrative claims (IBM\(^{®}\) MarketScan\(^{®}\) Research Databases) and electronic medical records (IBM\(^{®}\) Explorys\(^{®}\) EMRs)\(^{10}\) The claims data comes from both privately insured individuals through a variety of fee-for-service, fully and partially capitated plans and individuals with employer-based Medicare supplemental insurance. The EMR data provide additional details. The linked CED is a statistically de-identified, standardized, and normalized data set that contains 5 million patient-level records on demographics, diagnostic and procedure codes, lab tests and vital signs, admission records, payments, and

prescription drug information. Social aspects of patients’ lives are captured by the V-codes in ICD9 and Z-codes in ICD10 in electronic health data, and both were used to identify recorded SDoH issues in patients’ claims. Based on co-occurrence of codes, we extracted correlated diagnoses in the cohort of patients with that SDoH. For housing problems, we combined all housing related codes including Homelessness, Inadequate housing, Other specified housing or economic circumstances, etc. The ICD codes were grouped to represent more general diagnosis groups (Table 3) when summarizing and interpreting the results. By using the cohort created from all available CED data, we then create a very general cohort of people residing and receiving healthcare in the US (Table 1) - however, this can be replaced by any specific cohort data based on study settings.

Results

Several relations were found from PubMed under Disease or Syndrome and Sign or Symptom types (Table 2). For housing problems, the majority of the disease terms were associated with infectious diseases (Infection, Tuberculosis, Malaria, Mastitis, Parasite Infection, or Worms) or chronic conditions (Asthma, Obesity, AIDS, Diabetes, Stroke, and Respiratory disease). A number of mental health related symptoms were identified such as Emotional Depression,
Mental symptoms, or Acute stress. There were also a number of irrelevant or erroneous terms found as expected. Notably, common English words like fed, ten or march are annotated incorrectly as acronyms by MetaMap (e.g. FED for Fish Eye Disease) and their frequencies are skewed as a result. Similarly for unemployment, a diverse range of diagnosis and symptoms was extracted. Some degree of overlap with housing problems is observed but with less emphasis on infection-related diagnoses. These associated terms from a large pool of published research can generate a number of hypotheses regarding the relationship between SDoH and clinical conditions. For example, one can hypothesize that housing problems, such as homelessness, may expose a person to environments with higher probabilities of microbial infection; or that unemployment can put a person under severe mental stress that results in insomnia. One can also think about less obvious but inferred hypotheses - living conditions with housing insecurity may lead women to suffer from mastitis with little postpartum support; being unemployed can delay dental visits and lead to more people having caries. But these hypotheses are not yet specific to the population of interest and may not be applicable.

### Table 2: Top 20 Diseases or Syndromes (dsyn) and Signs or Symptoms (sosy) associated with Housing Problems (C0014003) and Unemployment (C0014003) in PubMed.

We then obtained the top 10 most prevalent diagnoses associated with either housing problems or unemployment from an analysis of CED data (Table 3). Unsurprisingly, many were chronic conditions known to be highly prevalent among general population such as hypertension, diabetes, hyperlipidemia, or reflux disease. However, an interesting observation was that the two SDoH generated the same list of top 10 diagnosis with different order of prevalence. Compared to housing problems cohort in which chronic physical conditions were the top 3 most prevalent, psychiatric diagnosis such as mood disorders or anxiety took place in the top 3 diagnoses in the unemployment cohort. The nature
of health related challenges associated with a social factor may differ across different SDoH.

Table 3: Top 10 most prevalent diseases associated with Housing problems and Unemployment in the Claims-EMR dataset.

Combining the two KGs, represented with the extracted relations, led to the identification of several concepts that are directly or indirectly linked to the concepts in the other KG. Disease concepts such as diabetes, obesity, and hypertension appear in both PubMed and CED results. Concepts from PubMed like emotional depression or acute stress can be linked to mood disorder diagnosis in CED. We calculated the prevalence of the top 10 diseases in the general CED population and in the cohort specified by each of the two SDoH examined. The largest relative difference in prevalence was observed for diabetes and episodic mood disorder (Table 4) so we focused on these two in the subsequent analysis.

The last part of our experiment was quantifying the level of association in the CED cohort. Specifically, we examined whether the healthcare cost and utilization level among those with a disease diagnosis differ across the general cohort and the subgroups of people with housing problems or unemployment codes. As Table 5 shows, for patients with diabetes diagnosis, having a code for housing problems was associated with greater outpatient cost (per year per patient) and outpatient service use measured by number of claims (per year per patient). Similarly, for patients with mood disorders diagnosis, having a code for housing problems was associated with greater outpatient cost and outpatient service use. Notably, emergency department cost was significantly higher for patients with housing problems or unemployment code compared to the general population, for both diabetic and mood disorder patients. On the other hand, we observed that inpatient service utilization and related cost was higher for the general CED population compared to the SDoH-specific subgroups.

Discussion and Conclusion

We describe a systematic approach to identify and quantify meaningful associations between SDoH and health related outcomes using published knowledge as well as electronic health data. The novelty of this work is the augmentation of knowledge extraction from PubMed by adding a cohort-specific, independent source of clinical data. The final set of pruned associations with the chosen SDoH can be informative and actionable from a decision maker point of view – whether it be a population health specialist in a hospital or a policy maker at a public health department – because it provides augmented insights specific to the population group of interest that may not be observable in data alone. As
our approach does not attempt to identify causal relationship, evaluating the impact of SDoH should be followed by additional data collection or more rigorous analysis. Ongoing efforts to address the need for a more comprehensive SDoH terminology, such as methodologies to detect new SDoH concepts or the Gravity project should, in the future, provide additional structure to the work presented in this paper.

The ability of our proposed approach to identify meaningful SDoH associations from KGs were supported by literature findings. The increased emergency service utilization among people with housing problems we observed in the data has also been reported in prior literature. The observation that unemployment is associated with higher prevalence of mental health diagnosis can also be supported through prior evidence. The validation of selected hypotheses through literature means that other associations we observe in data are potentially worth further investigating. For example, one relation we observe from PubMed knowledge extraction is between housing problems and respiratory diseases or symptoms, which is not captured by the 10 most prevalent ICD codes in the CED data. While it is possible that this is just a spurious association, it can also be a meaningful association not captured due to incomplete data collection or low prevalence. Considering the disease burden and clinical significance of managing chronic respiratory diseases, it may be worth investigating this association further to see whether this association is true, and if so what may be the factors that contribute to both housing problems and diseases like asthma or COPD, such as geographic characteristics.

There are extended application use cases for this approach. For example, housing problems may be selected as an input for outcome risk modelling to adjust for confounding. Also, it can be used as an input for predictions to improve the model performance.

The known limitations of observational health data are applicable for this study, including non-randomly missing diagnosis, incomplete capture of data such as lack of information on the duration of illness or SDoH, and coding errors or variability in coding practice. A claims data point is generated at the time of a patient’s interaction with health system, so those who lack access to care, who will likely have more severe SDoH problems, may be absent from the data. By combining claims with the EMR data, information from CED can provide more complete picture of individual patients and increases the likelihood of capturing all data compared to using only claims.

Implementation matters: How patient experiences differ when genetic counseling accompanies the return of genetic variants of uncertain significance

Abstract

Precision medicine presents challenges for effective return of results (ROR) to patients, particularly for variants of uncertain significance (VUS) where the need for genetic counseling and the impact of results are underexplored. We investigated patients’ experiences with VUS ROR. Through interviews we compared experiences of patients who were referred to genetic counseling with those not referred. Although participants from both groups (n=16) reported curious enthusiasm and relief after ROR, the 5 referred participants reported less confusion, less disappointment, and better confidence in understanding their results than the 11 non-referred participants. Although VUS did not impact healthcare or daily lives, some participants who shared VUS fostered communication about future healthcare. Suggested ROR improvements included patient-friendly terminology, on-demand education, and ongoing consultation. Although patient experience of VUS improved when ROR involved expert consultation, scarcity of genetic counselors presents challenges. Improving the ROR process with patient-centered solutions could enhance the patient experience of receiving VUS.

Introduction

As precision medicine becomes integrated into healthcare, questions emerge about how best to return genetic results to patients, particularly for variants of uncertain significance (VUS). VUS are genetic changes for which the association with disease is unknown. Although the American College of Medical Genetics and Genomics recommends reporting incidental or secondary findings from actionable genes that are not the target of testing in clinical practice,1,2 they recommend against returning VUS as a secondary finding. However, when VUS are primary findings, detected for a gene that is the target of the ordered test, VUS are generally clinically returned even though most are not clinically actionable nor found to be pathogenic.3

Strategies for returning genomic results range from in-person/phone consultation4,5 to passive notification through patient portals or mailed letters.6 Prior work has examined patient experience with return of genomic results in general. For example, patient-friendly genomic test reports have been designed to improve patient engagement and understanding of complex genetic data.7 More advanced tools for returning results, such as “My46”, offer self-guided management of results.8 Other researchers have infused direct-to-consumer personal genomic reports interactive features to enhance understanding.9 Prior work has examined patient experience with such patient-facing strategies for return of genomic test results. For example, patient-facing genomic reports have been shown to improve patient communication with providers, educators, and therapists, which led to increased engagement and satisfaction.10 Yet, how such strategies impact the patient experience of receiving VUS remains poorly understood.

Clift et al.11 call attention to the potential for patient misinterpretation of VUS and the need for counseling and education for both patients and providers. Although the behavioral and experiential consequences of receiving a VUS results are not well studied, early evidence suggests taking caution in how VUS are returned. In a study on return of Lynch Syndrome related VUS results, Soloman et al.12 found that patients may be surprised by VUS and interpret its clinical significance in a wide range of ways. Similarly, patients who received VUS demonstrated mixed understanding and expressed both uncertainty about the impact of VUS on clinical management and concern for family members’ wellbeing.13 However, these studies did not examine the impact of how results were returned on patients’ experiences. Given the uncertainty associated with VUS, better understanding this experience can inform effective return of result (ROR) strategies that patients find acceptable.
Methods

The objective of this qualitative study was to investigate the ROR experience of patients for VUS. We conducted semi-structured interviews to compare participants’ experiences of receiving VUS with and without referral to clinical genetics.

Study setting and recruitment

This study takes place within the context of The Electronic Medical Records and Genomics network (eMERGE).\textsuperscript{14} eMERGE began in 2007 to develop best practices for genomic research in bio-repositories linked with electronic health records (EHR). As a collaborating site in eMERGE, Kaiser Permanente Washington and the University of Washington conducted a comprehensive program of genomic discovery and clinical implementation research\textsuperscript{15} in which genetic results for bio-repository participants were integrated into the EHR.

Our study population was eMERGE participants with a colorectal cancer (CRC) diagnosis or colon polyps and a VUS, including those referred and not referred to clinical genetics to receive counseling for their VUS. Only participants with a VUS in one of the genes associated with Lynch syndrome were referred for genetic counseling and in-person ROR. Other VUS were not offered genetic counseling (Figure 1). Inclusion criteria were being a Kaiser Permanente member and remembering receiving the VUS.

Participants with a VUS who were referred to genetic counseling received a mailed letter describing the study and results written at 8th grade level and a referral for clinical genetics consultation. Results were returned during consultation, and then placed in the EHR and accessible to the participant via the patient portal. The participant’s primary care provider was sent a copy of the results and consultation. Participants with a VUS who were not referred also received the mailed letter, and their results were sent to their primary care providers and placed in the EHR, where they were accessible to the patient via the patient portal. Participants who were not referred were considered an appropriate comparison as they did not have a VUS in one of the Lynch syndrome genes and as a result did not receive in-person genetic consultation.

We sent study invitation letters to 108 participants of whom 32 were referred (30%) and 76 were not referred (70%). Forty-six (43%) responded (17 referred, 29 not referred) and completed a phone screening. Of those screened, 29 declined (11 referred, 18 not referred) and one who was referred failed to meet inclusion criteria.

Data collection and analysis

From March to April of 2019, one member of the research team (AH) conducted interviews using a semi-structured guide covering participants’ experience with the VUS ROR process (Table 1). Interview questions covered the following domains: 1) emotional and cognitive reactions to receiving VUS, 2) whether and how they shared results with healthcare providers, family, or friends, 3) perceived impact of results on their healthcare and daily life, and 4) recommended improvements to the ROR process given perceived benefits and barriers. We collected age, gender, race, ethnicity, education, and self-reported familiarity with genetics on a 5-point Likert scale from 1 “not at all familiar” to 5 “extremely familiar”.

Interviews were audio-recorded and transcribed for qualitative analysis. Two coders (HP, AH) used template analysis\textsuperscript{16} to deductively code transcripts in Dedoose\textsuperscript{17} following the four domains of the interview guide. Once the coders achieved intercoder reliability of K=0.90 on a 25% sample of transcript excerpts, the remaining transcripts were split between coders and independently coded. After coding was complete, we compared experiences by domain between participants who were referred and not referred.

Results

Participants

Of the 16 participants (P1-P16), 5 were referred for genetic counseling (P5, P6, P8, P10, P12) and 11 were not referred. Participants were largely white, non-Hispanic/Latino, and female, ranged in age from 43 to 82 years old (mean=66), and had varied education and familiarity with genetics (Table 2).
Figure 1: Colorectal cancer VUS ROR workflow detailing how participants were assigned referred/non-referred status after review by Kaiser Permanente Washington (KPWA) geneticist and how results were sent to patients.

1. Reaction to VUS

Participants’ emotional reactions varied when asked “Overall, how would you describe your experience with receiving your results?”. Those who were referred primarily reported enthusiasm, curiosity, and relief:

“I like that kind of stuff so I was excited to get it. Didn't really understand what it was.” (P6, referred)

“I felt curious and intrigued … It was something that I was kind of interested in, seeing how it happened and what the results were.” (P12, referred)

“I was a little bit relieved, I guess, because from the day I had the colonoscopy and they took the sample, I -- the surgeon said, you know, I saved your life. And then -- but everybody else since then has been very noncommittal as to whether I had cancer or not. And so finally, this study, I will say that, that it came right out in front and said it was cancerous.” (P5, referred)

Although most who were not referred shared similar sentiments of curious enthusiasm and relief, a few expressed confusion and disappointment:

“Well, it was confusing. They said I had a marker … but the implication was that I had cancer.” (P1, not referred)

“I felt a little concerned because they still -- I mean, I just remember they weren't being specific … I haven't really been told exactly what they have found … So I'm still a little confused.” (P4, not referred)

When asked “How well did you understand your results?”, most participants expressed challenges. Six of the 11 participants who were not referred indicated they did not understand the results on their own:

“I was excited about taking the test, but I don't remember understanding the results … I know it was disappointing because I didn’t understand … so it didn't make, you know, much sense to me.” (P2, not referred)

“I thought it was a little bit too much in medical terms … and it was kind of hard to understand.” (P13, not referred)

“It was a lot of inconclusive stuff, and I don't remember learning a lot.” (P15, not referred)

In contrast, referred participants reported feeling more confident in understanding the results after speaking with the genetic counselor:

“[I] didn't really understand what it was. I went in for an interview [genetic counseling] which helped more … I sat down one on one … and went through, you know, I think there was a list of genes and things that impacted me … It was very informative.” (P6, referred)

“You really definitely need to have the one-on-one with a geneticist or someone in the genetics department to explain the technical sides… There has to be that discussion.” (P8, referred)

“We were able to sit down with the person … she walked us through it … It was clear. Both my wife and I understood it clearly.” (P10, referred)

2. Sharing VUS

Most participants (13/16) shared their results through email or conversation with family members, primarily children, spouses, or siblings. Most participants with colon polyps (11/12) shared with family whereas two of the four with CRC did so.

Most participants who shared with family, both those who were referred and those who were not referred, expressed a duty to share VUS with family in case of future health implications:

“But the fact that I did, in fact, have a marker was something that I wanted to let my family members know. ... They need to be aware of that. They needed to take action and that needed to be part of their health strategies. ... I remember being very clear with my nieces and with my brother.” (P10, referred)

“I sat him [son] down and said, do you realize that this could be a possibility, you know, this really could, and it's important that find out as much as you can about this, whether genetically you would be at risk.” (P3, not referred)

“I just emailed them [my kids] that I was in this study and it looked -- and I had the marker for colon cancer
and they should put that information somewhere so they have it at the ready if they need it.” (P1, not referred)

However, other participants were selective in sharing with select family members due to inherent uncertainty in VUS:

“I talked to one of them, my sister, and said no, I'm not going to go any further than that. You know, we're all in our 70s and 80s. And there's no sense in me stirring people up. Well, yeah. Because -- because -- because the results are so iffy. So uncertain. It even says of 'uncertain significance.' That doesn't mean anything to me. So I'm not going to get people to worry about stuff they don't -- can't do anything about.” (P5, referred)

In contrast to the majority of participant who shared with family, only five participants explicitly shared with a healthcare provider. Of those five, four had colon polyps and one had a diagnosis of CRC. For example, one of the two referred participants who shared with a healthcare provider made a copy of the VUS letter and gave it to them:

“[I] couldn't remember if this was passed on to my doctor or not, but I did make a copy and gave it to him ... so I figured they must know about it.” (P6, referred)

The three participants who were not referred and shared results with providers talked about the value that providers can add to help interpret and bring meaning to VUS results and their impact on future healthcare:

“Well, I asked my gastroenterologist if it [VUS] was meaningful in the plan that we had developed. 'Should I?', you know -- so we had a conversation.” (P1, not referred)

The majority of participants chose not to share their results with their healthcare providers. Some participants reached the conclusion that sharing with their provider was not warranted:

“And the first thing it [result] says is that there is a variant of unknown significance. So it may or may not mean something. We don't know if it means anything. And so -- and then reading through the report, it was clearly all scientific language. And the conclusion was you don't need to talk to your doctor about it. Nobody's really going to contact you because we don't know what this means”. (P7, not referred)

“Nobody seems to be alarmed by the information in this report, so I'm not going to let it alarm me if I have some -- one gene that looks a little weird... They're not telling me that there's any particular risk. Some unknown possible risk but we don't know, and there are a whole bunch of big words too in scientific medical language about what it is. But clearly, they don't care if I understand it, because they would have put it in different language.” (P7, not referred)

3. Perceived impact of VUS

No participants reported changes to their healthcare based on receiving VUS results. However, four participants described how receiving results reinforced healthy lifestyle choices in daily life, such as diet and cancer screening.

4. Recommended improvements

Despite barriers to understanding VUS, most participants found benefit from receiving VUS. Participants who were not referred reported increased awareness of their genetic makeup and feelings of altruism from participating in research. Participants who were referred found benefit in genetic counseling, ability to ask questions, and additional information they received beyond the mailed report.

Participants from both groups recommended patient-centered improvements to the VUS ROR process. Most participants (11/16) recommended expert consultation, links to videos, and primers on genetics and VUS:

“I do think it would be really helpful for people to get the results face-to-face with a professional who could explain what was done and what the results meant and describe the process more thoroughly if someone wanted the process described more thoroughly. I think I had a pretty good understanding of genetic testing and how that operates and what kinds of things they're discovering and all of that. But I think that rather than just getting, you know, a typical result of a test in the mail.” (P10, referred)

“I'd rather speak to somebody so I could say, well, ... what am I doing wrong? You know, if it's not genetic, then what am I doing wrong? You know? Am I overweight? Am I drinking too much? Am I not getting enough exercise? Should I eat carrots? You know, things like that. Those questions I would have liked to have asked of the people that did this type of testing” (P3, not referred)

To address drawbacks, such as feeling hindered by confusing medical jargon and inability to find clarifying
resources, several participants who were not referred suggested framing explanations in lay terminology and providing education resources:

“Well, just more in lay terms. Like on additional notes, you know, they have KC and Q1 92 percent, you know, PM as to 93, you know, that kind of thing. You have no idea what all that means...They detailed, you know, the interpretations and what they did, but I don’t -- maybe it’s just me, but I didn’t understand a lot of it. ” (P13, not referred)

“You know how, like, when you read a medical paper or a legal paper there are footnotes that you can read further about this if you go to this source. So that could be kind of helpful for people. Even if it was as simple as, you know, an article on the basics of genetic studies. ” (P16, not referred)

Participants who were referred also suggested improving after-visit documentation, more timely communication, and the potential for future consultation:

“Maybe if a CD was made of the interview at the time, that you could take with you would just accompany the written information. That way down the road you could plug it in as you're looking through the written information and have that explanation freshen you. “(P6, referred)

“I think there was a delay in the time between getting the results and having the conversation, so I think people who maybe are not as comfortable with the healthcare system and terminology might prefer a closer time opportunity to discuss the information sent to them in the mail. ” (P12, referred)

Discussion

In several ways, ROR experiences differed between participants who were referred and not referred to genetic counseling for VUS. Those who were referred reported less confusion, less disappointment, and more confidence in understanding their VUS than non-referred participants. Although some participants who were not referred also expressed positive experiences, confusion and frustration with the ROR process was evident. Several participants did not understand their results and desired expert consultation and clarifying resources. Although VUS did not appear to impact healthcare, participants who shared VUS may have fostered communication about future healthcare. All participants offered suggestions that can inform healthcare systems in patient-centered improvements to the ROR process that prioritize patient experience (e.g., patient-friendly terminology, on-demand education, ongoing consultation).

Many patients want to be included in deciding what genetic results are returned and find value in the results beyond clinical utility, yet we know comparatively little about patients’ perceptions of VUS. Although the consequences of receiving VUS are not well studied, early evidence suggests taking caution in how VUS are returned. Patients may misinterpret VUS and interpret their clinical significance diversely. For example, some women with BRCA1/2 VUS pursue mastectomy and/or salpingo-oophorectomy. Other work demonstrates similar mixed patient interpretation of uncertainty and implications of VUS. However, these studies did not examine the impact of how results were returned on patients’ experiences. Our sample may limit transferability of findings. Because participants who were referred had a VUS in one of the Lynch syndrome genes and those who were not referred did not, group differences beyond referral could have impacted results. Given limitations of our small homogeneous sample, future work whose scope is broader and examines potential racial and other disparities is needed to fully understand best-practice communication methods and gauge patient understanding. Although our small sample was from a single health system, our findings add in-depth insight for patients’ experiences into this poorly understood topic.

The process through which patients receive VUS matters - a text report alone may be insufficient and leave patients without needed assistance to interpret the results. Patients may experience less confusion, less disappointment, and greater confidence in understanding VUS when ROR involves expert consultation. Given the scarcity of genetic counselors, our findings present challenges for meeting the needs of patients in the era of precision medicine. Patient-centered solutions, such as virtual agents, educational portals, and patient-friendly formats could scale support to reach diverse audiences. However, future work should demonstrate the value and acceptability of such solutions to patients. More fundamentally, our findings give pause to whether the benefits of returning VUS outweigh the potential risks when genetics consultation is not indicated.
Conclusion

Healthcare systems should gauge the needs of patients and report genetic results in patient-friendly ways. Although genetic counselors are critical to effective ROR, information technology and processes that carefully consider patient experience could ease emerging challenges of precision medicine.

Creation of a Mapped, Machine-Readable Taxonomy to Facilitate Extraction of Social Determinants of Health Data from Electronic Health Records

\textsuperscript{1}Veradigm, Chicago, IL, \textsuperscript{2}Veradigm, San Francisco, CA

Abstract

A comprehensive, mapped social determinants of health (SDH) taxonomy in machine readable format was developed. The framework is intended to facilitate the extraction of social risk factors (SRFs) out of electronic health record (EHR) data and categorize them by domain and determinant to facilitate interpretation. Where other SDH frameworks have been focused on data input, this framework is designed from a data extraction point of view using EHR data in conjunction with published literature, public health policy documents, and official crosswalk maps. Frameworks developed by leading public health organizations were reviewed and synthesized to create an SDH framework comprising of 97 distinct SRFs organized under 16 domains. 2,329 medical codes across three standardized medical vocabularies, 10,896 free-text diagnosis descriptors, and 25 health insurance keywords were mapped to individual SRFs in the SDH framework. The framework is available as an open-source resource in Python dictionary or JSON format.

Introduction

Evidence on the impact of social and economic drivers on patient health outcomes has been mounting over the past two decades.\textsuperscript{1} This research posits that factors such as geography, housing, food, employment, education, and income can substantially shape health and well-being. With the push for value-based, patient-centered medicine in recent years, health care provider institutions have become increasingly focused on addressing these SDHs with the goals to improve patient outcomes and control health care costs.\textsuperscript{2,3} While much of the work and funding involved with managing social needs occurs outside the health care setting, these institutions recognize that health care providers, especially primary care, can play a pivotal role in identifying at-risk patient populations, screening for social needs, developing care plans that account for social factors, and directing patients to community and government resources.\textsuperscript{4} Implementation of a carefully considered infrastructure is required to effectively carry out these tasks. An institution’s population health informatics capabilities and its EHR are key elements of this infrastructure, particularly in identifying at-risk populations.\textsuperscript{5}

However, even identifying SDH patients presents a challenge; population health informatics professionals face a three-fold problem. First, there is no standardized definition of what factors are considered social determinants.\textsuperscript{6} Multiple public health organizations have published frameworks identifying individual SDHs and associated domains including the World Health Organization (WHO)\textsuperscript{7}, National Academy of Medicine (NAM)\textsuperscript{8}, Kaiser Family Foundation (KFF)\textsuperscript{9}, and the United States Department of Health and Human Services’ (DHHS) Healthy People 2020\textsuperscript{10}. Further, the International Classification of Diseases, Tenth Revision (ICD-10) includes a section of diagnosis codes (Z55-Z65) which provides a framework of SDH domains and social risk factors (SRFs).\textsuperscript{11} These frameworks overlap in many respects, but each also uniquely highlights important determinants and domains not addressed by the others. Without a universally agreed upon framework of SDHs and SRFs, an informatics professional must either choose one or attempt to reconcile them.

The second challenge is identifying the multitude of EHR data elements that could potentially record SRFs either directly or indirectly. Failure to carefully consider all the possible ways that SRFs could be documented in the EHR would yield only a partial picture of its prevalence in a population. EHRs in their current form contain a wealth of data elements that can be used to flag patients with social risks. Such SRFs can take the form of standardize medical vocabularies\textsuperscript{2}, unstructured text\textsuperscript{12}, demographic classifications, or administrative information.

The third challenge is the lack of a comprehensive, machine-readable map that connects data elements to a defined determinant or SRF. Creating these linkages is critical so that captured data can be aggregated, no matter how or where in the EHR the data is encoded, at a level that is meaningful from a population health perspective. The Social Interventions Research & Evaluation Network (SIREN) started the development of such a map by conducting a systematic review of standardized medical vocabularies to develop a compendium of medical codes for 20 domains and subdomains. These domains aligned with six widely recognized screening tools used to collect social and economic risk factors.\textsuperscript{13} SIREN’s compendium aligned key survey questions and patient responses to standardized codes available within the Systematized Nomenclature of Medicine Clinical Terms (SNOMED-CT), ICD-10, the
Logical Observation Identifiers Names and Codes (LOINC®), and the Current Procedural Terminology (CPT®). This pivotal work, and resulting map, facilitates documentation of SDH in clinical settings within the EHR as structured data. While the SIREN provider-focused compendium enables EHR data input, there is no complementary machine-readable tool that enables data extraction. SIREN’s aim was to be thorough in its mapping to ensure providers were able to input all potential patient responses to SDH survey instruments; it does not, however, define target SRFs for data extraction. The SIREN tool also does not address character-limited, free-text data elements or indirect data elements that could be used to identify at-risk patients.

To that end, we conducted literature reviews and utilized EHR data to derive a comprehensive, machine-readable taxonomy of SDH domains and determinants mapped to both standardized and character-limited free-text data elements. The goal was to build upon SIREN’s seminal work to create a mapped SDH taxonomy that can facilitate data extraction and serves as a tool to identify at-risk patients within an EHR. This tool, as well as other materials discussed in this paper, have been made available as an open-source resource for others in the community to use, add to, and refine.

Methods

This study involved two steps. The first step was a review and synthesis of the many SDH frameworks issued by public health organizations with the goal to consolidate them into a broader framework of domains, determinants, and SRFs. The second step focused on identification of data elements and mapping them to this SDH framework in a machine-readable format that can readily be passed into data queries. We prioritized formats that could be applied across a broad range of use cases and analytics approaches.

To aid this twofold endeavor, we introduced a unique aspect to our project: we derived and tested our SDH taxonomy using de-identified data set from three large national ambulatory EHR systems collected and maintained by Veradigm®, Veradigm, a business unit of Allscripts®, is a health information technology, analytics and intervention solutions company that manages the largest source of de-identified ambulatory patient records in the U.S. Its ambulatory EHR dataset contains medical information on patient demographics, prescriptions, problems, laboratory test results, vaccinations and allergies from providers using any of three ambulatory EHRs: Allscripts Professional EHR™ (PRO), Allscripts TouchWorks® EHR (TW), and Practice Fusion EHR (PF). Collectively, these three EHRs represent a nationally diverse range of ambulatory provider organizations, from single-provider or small group practices (PF) to mid-size physician practices (PRO) to large, single or multi-specialty physician practices (TW). By leveraging this vast and growing ambulatory EHR footprint, we were able to develop an SDH taxonomy that is generalizable and relevant to the real-world clinical setting.

Framework Development: Defining Domains and Determinants

We focused our review on commonly cited frameworks promulgated by WHO, NAM, KFF, and DHHS Healthy People 2020 as well as the one outlined in the ICD-10 section Z55 to Z65 code set (“ICD-10’s Z-codes”). The review of ICD-10 was limited to just the ICD-10’s Z-codes as this is the section of the code set that is generally recognized as containing SDH codes.15

We chose ICD-10 Z-code’s domains and determinants to be the initial outline of our SDH taxonomy. Of the five reviewed, ICD-10’s Z-codes represents the only framework with determinants that are fully articulated as SRFs. For example, while several frameworks mention literacy as a determinant under their education domain, the education domain within ICD-10’s Z-code includes the SRF illiteracy and low-level literacy. Literacy is the SDH that refers to a person’s ability to read or write. Anyone can be evaluated for literacy. Illiteracy, however, refers to a specific subgroup of people whose literacy skills are low or nonexistent. Given the value a society places on literacy skills, illiterate individuals are considered at risk. In this scenario, education is the domain, literacy is the SDH, and illiteracy is the target SRF.

The remaining four frameworks by WHO, NAM, KFF, and DHHS Healthy People 2020 were then assessed against this outline. Areas of overlap were noted. We recorded overlaps in both domains and individual SRFs. In some cases, frameworks would reference a domain such as Housing but not include individual SRFs such as Homelessness or Housing Inadequacy. Further, we also evaluated the need for reorganization of SRFs within the outline to improve conceptual groupings under each domain.

1 Codes for many other social and economic drivers can be found throughout ICD-10, but they are typically contained within sections that, unlike the ICD-10 Z-codes, do not necessarily call attention their status as SRFs and are not organized as such.
Gaps between the four frameworks and ICD-10’s Z-codes were recorded as well. We set a goal to develop an inclusive SDH taxonomy that drew upon unique aspects of the frameworks reviewed rather than a least common denominator approach. We reasoned that such a framework would help future-proof our taxonomy as the definition of SDH evolves over time. Thus, domains and SRFs that were not covered by ICD-10’s Z-codes but were mentioned in the other reviewed frameworks were evaluated for inclusion. This evaluation was conducted by both authors and decisions for adding new domains and SRFs were made on the basis of three factors: (1) the number of frameworks with coverage, (2) the utility of extracted data in health informatics and modeling, and (3) the ability for health institutions to deploy targeted inventions for the SRF.

A full copy of our comparative analysis of SDH frameworks is available online.

Data Elements: Selection and Mapping

Standardized Medical Vocabularies

The SDH taxonomy was populated with mapped ICD-10 codes, ICD-9 codes, and SNOMED codes using a number of methods. First, for areas where our two SDH frameworks overlapped, we used SIREN’s publicly available compendium\(^1\) of mapped ICD-10 and SNOMED codes to identify codes to add to the SDH taxonomy. SIREN’s compendium did require modification to accommodate our data extraction-oriented taxonomy. We manually distilled SIREN’s mapped standardized medical vocabularies down to just the codes representing SRFs. For example, SIREN’s Income/Poverty determinant was mapped to SNOMED codes that described a range of income levels, from wealthy to middle-class to destitution. For our taxonomy, however, we only included the codes associated with the SRFs low income, destitution, and poverty. We also eliminated duplicative mappings to ensure that each code was assigned to only one determinant. The ICD-10 code Z60.8 (other problems related to social environment), as an example, was mapped to five different social determinants. Such multiple mappings would make data aggregation difficult and distort comparative results. In these situations, we mapped the code to the most appropriate determinant based on official descriptors and public coding guidelines.

Literature reviews\(^1\), value sets\(^18\)\(^20\)\(^23\), and keyword searches of official code descriptors further supplemented our code search and mapping activities. We also obtained medical codes that were collected as part of our free-text diagnoses descriptors search strategy which is described in greater detail in the next section.

Lastly, we conducted a comprehensive code search using publicly available crosswalk maps: an ICD-10 to ICD-9 map\(^23\) and an ICD-10 to SNOMED map\(^25\). Our first round of searches identified crosswalk matches for ICD-10’s Z-codes and for all the codes identified using the methods mentioned above. Subsequent rounds used newly identified codes captured from prior searches to find additional crosswalk matches. This was done several times to ensure thoroughness. Code lists obtained from each round of searches were reviewed manually to assess relevancy before inclusion. We also considered alternative mapping if the case could be made that a code had a better fit elsewhere within the taxonomy.

Free-Text Diagnosis Descriptors

While harder to extract, unstructured and character-limited text offers a rich source of SDH data.\(^1\)\(^2\)\(^3\)\(^4\) Documentation of free-text data isn’t necessarily reserved to only the clinical notes section of the EHR. Many EHRs, including PRO and TW, allow free-text capture of diagnoses when a provider is unable to find a code or code descriptor that properly characterizes a patient’s circumstance. In some cases, these free-text diagnosis descriptors may eventually be mapped to discreet medical codes, but most are not.

Table 1 provides an example of how these free-text diagnostic records might appear in a data table within a clinical database for PRO or TW. The descriptor field represents either a code descriptor (when a code is selected by the provider) or a character-limited, free-text diagnosis descriptor (when the provider adds a custom diagnosis).

To capture this free-text data, we text mined the descriptor field within our diagnostic tables using string searches of both keywords and word pairings. Ideas for words and word pairings were obtained from multiple sources: (1) definitions found in published literature\(^12\)\(^14\), (2) common synonyms associated with individual ICD-10 codes\(^5\), and (3) official descriptors for mapped ICD\(^9\) and SNOMED codes\(^2\). Retrieved descriptors were manually reviewed for accuracy. ICD-9, ICD-10, and SNOMED codes that were frequently included in captured records were also collected and evaluated for potential inclusion in the taxonomy. Examples of keywords and word pairing used for text mining have been made available online.

Surrogate Data Elements: Health Insurance Status

Clinical data is not the only source of information on a patient’s SRFs; administrative information can also provide a means to indirectly discern this information as well. It is well documented that Medicaid, for example, can serve as a reliable indicator of a patient’s low-income status. \(^{28,29}\) Thus, we explored the use of health insurance data recorded in the EHR to determine if we could use a patient’s coverage status and/or their health insurance carriers to identify patient SRFs.

Results

SDH Framework

We created a framework that is comprised of 97 distinct SRFs organized under 16 domains (see Table 2). Our comparative evaluation showed that the ICD-10 Z-codes were comprehensive, covering a wide scope of SRFs beyond those addressed by the other frameworks. In line with our broad approach, we included all these ICD-10 topics areas even if they were not addressed in other frameworks.

Mapped Data Elements

We identified and mapped 2,329 medical codes across three standardized medical vocabularies, 10,896 free-text diagnosis descriptors, and 25 health insurance keywords. Each of these data elements were mapped to a single social determinant. Table 3 provides an aggregate count of mapped data elements by domain. The crosswalk maps were the largest source for standardized medical codes. Approximately 44% (n=852) of SNOMED codes came from the ICD-10 to SNOMED crosswalk map. The ICD-10 to ICD-9 map yielded 37 ICD-9 codes.

Through our mining of health insurance names, we found searching with simple keywords did an excellent job in extracting target patient records. Using words like “Medicaid” and “Veteran” was a more efficient extraction approach as compared to collecting thousands of individual health plan names. These words alone were not entirely perfect. We needed to add the local names used by states for their Medicaid programs (e.g. TennCare, CalOptima, Peach State Health...). We also discovered that health institutions often document uninsured status, homelessness, and immigrant status within health insurance data tables.

Machine Readable Formatting

After experimenting with multiple ways of storing our mapped SDH taxonomy, we ultimately organized the information using a nested Python dictionary. The primary keys of the dictionary are the 97 individual SRFs found in the taxonomy. Under each SRF are secondary keys consisting of the five data element categories we examined to which individual data elements (code or text) are linked as mapped dictionary values. Figure 1 provides a visual example of the dictionary’s structure and organization.
Discussion

The SDH framework shown in Table 2 is a result of our comparative evaluation of ICD-10’s Z-codes and SDH frameworks promulgated by DHHS Healthy People 2020, WHO, NAM, and KFF. Our analysis showed that ICD-10’s Z-codes covered most of the determinants and domains found in the four other SDH frameworks. We did find a few notable domain gaps, specifically access to health care, socio-political status, and exposure to violence. We chose to add the first two domains (and associated SRFs) to our framework because they were extensively covered and recommended by 4 of the 5 reviewed frameworks. We included the last domain (and SRFs) because it was prominently featured within the SIREN compendium under the Safety domain. We did not include all proposed SRFs or SDHs under these three new domains because some lacked clarity on how such risk factors could be captured in the EHR. For example, we chose not to include the SDHs quality of care and provider availability under the new Access to Care domain given the uncertainty on how this information could be measured and documented within a patient’s medical record. Finally, we chose not to include other domains gaps like behavioral/biological factors and gender given that these topics are either typically addressed as medical risk factors (rather than SRFs) or the proposed scope of the domain is so broad that a data extract would have limited usefulness in SDH informatics. The full comparative analysis, made available online, outlines all the domains, SDHs, and SRFs found in the five reviewed frameworks and highlights those that were and were not included in the final taxonomy.

We reorganized and consolidated domains and SRFs to create a more efficient and intuitive framework. Changes we incorporated include: (1) separating out Financing and Housing into two separate domains, (2) consolidating all SRFs: (a) related to violence under a new domain called Psychological Trauma, (b) related to military or veteran issues under a new domain called Military/Veterans, and (c) related to raising children under a new domain called Child Rearing, (3) consolidating ICD-10 “catch-all” codes (e.g. those codes with descriptors starting with Other problems related to or ending in Unspecified) within each domain, and (4) moving 10 SRFs to different or new domains where they thematically aligned with domain definitions. For example, we moved the Acculturation Difficulty and Target of (Perceived) Adverse Discrimination and Persecution SRFs to the newly created Societal/Cultural domain which includes determinants regarding minority status, immigration, and language barriers.

In terms of our data elements mapping activities, not all standardized medical codes were mapped as indicated within the crosswalk map. In some cases, we assigned certain codes to SRFs that were a better fit. We also chose not to use 142 SNOMED codes and 11 ICD-9 codes that came from the crosswalk maps for two general reasons: (1) the code descriptors were so vague that there would be uncertainty about whether it represented an actual SRF; and/or (2) the
codes represented concepts that most health care institutions would not consider an at-risk situation. For example, we chose to forego mapping SNOMED codes for *inadequate play space* and *inadequate exercise space* to the Inadequate Housing SRF as recommended by the crosswalk maps. The supplemental code search strategies discussed in the Methods section yielded mostly duplicative results; however, each did, to a lesser extent, identify relevant SNOMED codes that would have otherwise been missed. Collecting associated codes as part of the search strategy for free-text diagnosis descriptors, for example, led to the discovery of SNOMED’s “Country of Birth” and “Main Spoken Language” code series which were, respectively, mapped to *Immigration/Migration* and *Primary Language Other Than English*.

Our search strategy for free-text diagnoses revealed quite a bit of redundancy amongst retrieved descriptors. Many of the descriptors would be considered parallel structures (e.g. *loss of job, job loss, lost his job, losing job…*), and, thus, the actual count of meaningfully distinct diagnosis descriptors is likely much less than 11,000.

Our choice of machine-readable format for the taxonomy has many advantages. One benefit of a dictionary format is it allows secondary keys to remain empty if there are no data elements to map as values. Further, arranging the taxonomy and its mapped data elements in a modular fashion around a determinant, instead of in multiple lists or tables, improved our ability to curate an unwieldy amount of interconnected information. The dictionary can be saved as a Python file or JSON, making it portable and shareable. Conversion to JSON format also makes the taxonomy code agnostic. The dictionary is also customizable; readers can unzip and extract the entire mapped taxonomy or just the SRFs of interest. To help readers understand what data elements can be found within the taxonomy, we used the Python library *python-docx* to produce a content catalog that lists all codes (with official descriptors) and all text by domain and SRF. Readers can find a copy of this content catalog at the same site where they can download the taxonomy itself.

There are a number of ways readers can set up the taxonomy for use in their data platforms. Figure 2 provides a Python example on how we typically access the information, specifically the ICD-10 codes. We first open the *.p* file with Python’s *pickle* library. Then we extract all the ICD-10 codes and their associated SDH/SRF label into a data table. We also create a list of these codes that we feed as inputs for filtering queries run against the database containing our EHR data. For a query involving ICD-10 codes, we’d typically extract unique patient ids, unique provider ids, dates of documentation, and ICD-10 codes for all records that match a code contained within our ICD-10 list. The extract is processed at a data table and then we use a *LEFT JOIN* to merge our taxonomy ICD-10 table (right table) with our database extract (left table), matching on the ICD-10 field. With this join, the records in our extract of patient ids, provider ids, and dates are each tagged with one of the 97 SDHs/ SRFs found within our taxonomy. At this point, one can conduct various aggregations to yield patient counts, provider counts, rankings list, or frequencies.

There are a number of weaknesses with our study that should be noted. First, our keyword search strategy was derived from our understanding of how social concepts may be characterized in English within the EHR. Thus, it is limited by “what we know we know”. It is likely diagnosis descriptors were missed because we are not aware of all the possible ways social concepts may be articulated in words and abbreviations. Because the EHR data set is multi-state, there could also be regional differences in use of words and abbreviations. We envision a future role for natural language processing (NLP) to help us gain an understanding of what might have been missed. Second, the taxonomy in its current form solely focuses on identification of documented SRFs. It does not, however, validate the accuracy of this documentation nor does it account for the transient state of many SRFs. Additional work will be required by health informatics professionals to determine if the patients identified by using the taxonomy have a valid and current SRF. Lastly, the taxonomy is only focused on clinical assessment and is binary in nature (i.e. presence or absence of an SRF). It does not currently include a means to capture a richer level of detail of a patient’s social circumstance (e.g.
severity, current/past interventions, etc…). These are details that will be needed by those health care providers who are tasked with intervening to improve the patient’s social situation. Currently, such a taxonomy does not exist, but plans should be made to incorporate these data elements once efforts to build one, like the work being done by the Gravity Project, come to fruition.

Available Materials

A copy of the machine-readable SDH taxonomy in a Python dictionary and JSON formats has been made available online as an open-source resource for others in the community to use, add to, and refine. It can be found at https://github.com/Veradigm-Life-Sciences-Research/SDoHTaxonomy. At this site, readers will also find an SDH taxonomy content catalog, a full copy of our comparative analysis of SDH frameworks, Python code examples, and a list of keywords and word pairing that were used for text mining.

Next Steps

Future work will focus on using our EHR data set and the taxonomy to gain an understanding of SDH documentation patterns amongst health care institutions using Allscripts EHRs. We also plan to investigate a way to leverage the free-text diagnosis descriptors we collected to build a corpus to use with our NLP work, especially in regard to conducting analytics and information retrieval on alternative characterizations of social concepts and on the EHR’s unstructured clinical notes. We plan to determine the importance of adding free-text diagnosis descriptors to an SDH data extraction strategy. This is a unique contribution to SDH informatics and we hope to quantify the value it adds. We plan to continue expanding the taxonomy with LOINC codes and zip codes/census tracts. For the latter, geographic data elements could serve as additional surrogates to identify at-risk patients, particularly areas such as food deserts, housing instability, violence, and financial inequities. We plan to evolve the taxonomy to incorporate the work of the Gravity Project as it becomes available. Our taxonomy is risk factor and data extraction focused which intentionally complements a subset of the critical work of the Gravity Project. We view it important to adapt it as national standards for documenting SRFs are set by the this consensus group.

Conclusion

Using a large, multi-institutional EHR data set in conjunction with published literature, public health policy documents, and existing crosswalk SDH maps, we assembled a comprehensive, mapped SDH taxonomy designed from a data extraction point of view. This work is unique in that it mapped standardized medical codes, free-text diagnosis descriptors, and surrogate data elements, allowing informatics professionals to search for SRF documentation in multiple areas within the EHR. This multifaceted approach is crucial to characterizing the full scope of the impact of SDHs on an institution’s patient population. The layout of the taxonomy within a machine-readable format enables end-users to efficiently unzip, modify, maintain, and share its mapped content. Our work has the potential to help health care organizations characterize their at-risk populations, a critical first step in addressing social needs that impact their patient’s health and well-being.

Characterization of Electronic Health Record Documentation Shortcuts: Does the use of dotphrases increase efficiency in the Emergency Department?

Rimma Perotte, PhD¹,², Christina Hajicharalambous, DO, MSEd, MS¹, Gregory Sugalski, MD¹, Joseph P. Underwood, MD, MHCDS¹

Abstract

The problem of clinical documentation burden is ever-growing. Electronic documentation tools such as “dotphrases” were invented to help with the documentation burden. Despite the ubiquity of these tools, they are understudied. We present work on the usage of dotphrases within the emergency department. We find that dotphrases are most often used by medical scribes, they significantly increase note length, and are completely unstandardized as to their naming conventions, content, and usage. We find that there is inconsistent usage across and within providers and that there is much duplication in the dotphrase content. We also show that dotphrases have no effect on the time to complete and cosign a note. Finally, we demonstrate that even when accounting for patient complexity upon presentation, note authorship, and note length – notes with higher dotphrase usage are billed at higher billing levels.

Introduction

Documentation is a key part of healthcare. Clinical notes account for a crucial part of all clinical documentation and have important implications for clinical, medico-legal, and reimbursement. In an ideal world, clinical notes are able to provide an up-to-date, accurate, thorough, useful, organized, comprehensive, and succinct narrative describing the patient care trajectory. Accurate and useful clinical notes are especially important in the Emergency Department (ED) setting as the ED is the gateway to the hospital for the large majority of patients. However, the burden to create high quality clinical documentation is sizeable. Proper documentation can be onerous and time-consuming.

There have been some innovations and strategies employed in an effort to combat this pervasive issue. Many clinical departments have employed medical scribes, utilized dictation software, or experimented with personalized EHR documentation shortcuts. Most EHR vendors have the ability to allow for these shortcuts. The two main vendors that account for over 50% of the US healthcare market (Cerner and Epic) both have this type of tool. The Epic version of this functionality is called SmartPhrase and the Cerner version is called AutoText. Both have been referred to as “dotphrases” as the method for calling upon these shortcuts is by typing in a “.” Here, we focus on the Epic SmartPhrase tool.

SmartPhrases are defined by Epic as “shortcuts for entering text quickly.” They are small pieces of text that start with a period and upon typing them in the note, they expand into a larger body of text. They are a powerful tool – they aim to enable high quality, structured documentation while reducing documentation burden and maintaining natural language in clinical text. Dotphrases, if used appropriately, can reduce the number of abbreviations in the clinical record, making the text more readable. They can also enable more consistency, fewer misspelling, and fewer grammar mistakes in the clinical notes. They can also alleviate the need for word sense disambiguation because of their ability to perform abbreviation expansion. For example, if a provider would normally chart “aa” in the record, it could mean

969
“African American” or “antacid”; however, if the provider has predefined an “aa” dotphrase then when she types “.aa” it automatically populates the term “antacid”. In addition, dotphrases can aid in secondary data reuse by enabling the extraction of structured data within an unstructured clinical note.

Dotphrases have been in use for over a decade and have resulted in many shared resources like crowd-sourced tools for creating dotphrases (www.dotphrase.org) and books about best dotphrases to use. As users are able to define their own dotphrases or use shared ones, the functionality is very flexible. Dotphrases can be very broad or specific for a certain clinical condition; they can contain other elements pulled from the chart (Figure 1) or simply be a single word of text.

Figure 1: An example of a dotphrase for documentation of transitions of care at change of shift. “@” indicates automatic pulling in elements from the record. “****” indicates a field that must be filled in by the author before the note can be completed. May also contain “{}” which indicates that a clinician must fill this space in with a value from a predefined dropdown menu.

Another area in which EHR charting innovations can provide value is in increasing provider efficiency. While there has been some work demonstrating that physicians perceive that dotphrases allow them to be more efficient and consistent, our work aims to use EHR data to study whether there truly is a link between dotphrase usage and provider efficiency. We briefly explain the reimbursement methodology for the ED to illustrate our provider efficiency measures.

In order to be financially healthy as a department, providers need to provide quality patient care in an efficient manner. Compensation for care is measured using the following equation:

\[
\text{Compensation} = \frac{\text{Relative Value Unit}}{\text{Patient}} \times \frac{\text{Patients}}{\text{Hour}} = \frac{\text{Relative Value Unit}}{\text{Hour}}
\]

where a relative value unit (RVU) has a set dollar value amount based on the Current Procedural Terminology (CPT)® that is coded. Because of this equation, you can increase efficiency by either increasing your RVU (by increasing the CPT level that is coded) or by seeing your patients more efficiently. Emergency department visit-level CPT codes are based on the level of complexity of the patient’s care. Visits are assigned CPT codes based on the documentation of their complexity in the EHR. For ED visits there exist 6 different visit-level (99281-99285,
99291) codes ranging from non-urgent to critical care. Codes that reflect higher complexity provide higher RVU and therefore higher reimbursement to the provider.

In most EDs, the codes are assigned by outside coders who use the clinical documentation provided to assign one of the 6 codes for each visit. There are Centers for Medicare and Medicaid Services billing requirements as to the necessary elements that need to be present in the clinical documentation for each visit level. As expected, the required elements increase substantially as the visit complexity level increases. For low level visits (99281), the required documentation of history, physical exam, and medical decision making is quite sparse. For a high complexity encounter (99285), the requirements of documentation are much greater, requiring at least 10 body systems to be reviewed for the history section alone.

Our work aims to explore the relationship between dotphrase usage and a set of factors that can measure efficiency such as: note length, time to note completion, time to note co-signature, and CPT coding level. We also generally examine and describe the dotphrase usage landscape within an organization and dotphrase content similarity.

Methods

Data Acquisition and Processing

This study was conducted using EHR data from the Hackensack University Medical Center adult ED. The adult ED had over 65,000 patient visits in 2020 and treats all patients aged 22 and older.

We conducted a retrospective analysis of all ED clinical notes written from January 1, 2020 - March 4, 2021. The analysis focused on the “ED Provider Note” note-type which is the standard and most comprehensive note written for every patient visit in the adult ED. The clinical note metadata and visit-level information was extracted from the Epic enterprise data warehouse. The note corpus was filtered to only look at completed notes. As any providers in the entire organization can use an ED Provider Note, and may do so by accident on occasion, we filtered the corpus further to only look at notes that were signed by an advanced practice provider (APP) or attending, and that the note signer had at least 100 notes signed over the time period.

In a modern day emergency department, many different parties contribute to clinical documentation. In a large academic department, the routine workflow is for residents to initiate and complete the majority of clinical documentation. In this scenario, attending physicians always review the residents’ documentation and then cosign those notes making any edits they deem necessary. In instances where the resident presence is not as robust, medical scribes may be employed to shadow physicians and document the care that is being provided. Their notes are also reviewed, edited and cosigned by the attending physician or APP. A third scenario in documentation workflow would be for the attending physician or APP to construct the entirety of a note from scratch. Regardless of the pathway, an attending or APP is ultimately responsible for the care of the patient and the makeup of the final ED Provide Note text.

To capture all of these variations in documentation contributors, we separately extracted author and co-signer information. The set of extracted variables included: note author, note co-signer, time of note creation, time of note signing by the note author, time of note signing by the note co-signer, note length, and dotphrases used for the note.

In addition, for each of the encounters accompanying the clinical notes, the triage acuity level and the visit-level CPT code was extracted. The triage acuity level is measured using an emergency severity index (ESI) level which ranges from 1 to 5. An ESI level is a measure of the resources required for an ED patient based on their initial presenting signs and symptoms. An ESI level 1 would require maximal resources to treat in the department and would be the most medically complex patient. Although an imperfect predictor of a patients’ complexity, on the whole it is expected to correlate with the final CPT visit-level code assignment.

Analyses

In our analysis we describe the dotphrases prevalence and usage patterns across the department. To understand whether dotphrases are used uniformly across all users we examine the joint distribution of dotphrase usage.
frequency and frequency of usage for individual providers. We also report on dotphrase usage patterns across different author types (scribes, attendings, APPs, and residents).

To examine the impact of dotphrase usage on documentation we looked at four different measures: note length, time to note completion, level of billing code, and dotphrase template similarity.

Correlations were completed in two different ways, 1) using raw counts of dotphrases per note, and 2) using a threshold to categorize high vs. low dotphrase usage per note. A threshold of 2 was chosen after examining the distribution of dotphrase usage across notes. The correlation between dotphrase usage and note length, time to note completion by the author, and time to note signature by the signer were all measured with a Pearson correlation coefficient.

To assess whether the usage of dotphrases could lead to a higher CPT code level, a multiple linear regression model was constructed. The independent variable was the number of dotphrases used and the dependent variable was the level of CPT code. The model adjusted for length of the clinical note, ESI level, and whether a scribe, resident, attending, or advanced practice provider wrote the note.

Finally, to more thoroughly understand the issue of dotphrase expansion and proliferation, a deep-dive was performed into a set of dotphrases meant to deal with the same presentation. To examine the actual content of dotphrases, we extracted dotphrase template text for any phrase with the title containing the word “syncope”. Similarity between these templates was calculated by transforming the dotphrases into vectors using tokenization, stemming, and term frequency-inverse document frequency (tf-idf) and assessing their cosine similarity.

All analyses were completed using Python v3.7.

Results

Descriptive Statistics

Our corpus contained 82,429 ED Provider notes written during the 14-month period. 239 unique individuals across four different types of providers wrote these notes: scribes, residents, advanced practice providers, and attendings. We had 110 unique clinicians across two different types (advanced practice providers and attendings) who cosigned these notes.

Out of the total 82K notes, 11% of them did not contain a single dotphrase. Within the other 73K notes there were a total of 190,777 dotphrases used (an average of 2.3 dotphrases per note). There were 1,763 unique dotphrases. Most of the dotphrases contained elements meant for pulling information from the medical record (such as MRN, age, sex, etc.) but 3.4% of the unique dotphrases were exclusively text phrases such as “Labs, imaging and EKG reviewed and interpreted by me”.

The most popular dotphrase used was “SANOW”. This phrase auto-fills the current time when the author is writing the note. It was found in 23% of all notes and used by 45% of all writers.

We identified that there does not exist a standard naming convention. Some dotphrase names were simply numbers “5”, “88”, “99”, etc. This naming is presumably for ease of searching and typing. We also found that many dotphrases were named for the user, either with a full name, such as “ANDREW1” or with initials. In addition, we found many users creating dotphrases with their name and the name of a condition, such as “CHSYNCOPE”.

Aside from unconventional naming, we also identified a large amount of duplication. Within this span of 14 months, we found that 20 different dotphrases whose titles contained the term “syncope” were used, and 85 different dotphrases whose title contained “COVID”. The prevalence of user-specific dotphrases is evidenced by the finding that over half of the 1,763 dotphrases were only ever used by one author and only 38 dotphrases were in at least 1% of the notes in the corpus (Figure 2).
We also found that intra-author variability in dotphrase usage was quite high. The average intra-author variability was 1.0 ranging from 0 to 6.5. Medical scribes were the most variable in terms of the number of dotphrases used per note. In addition to increased variability, medical scribes were found to have written the most number of notes (40%) and consistently used double the number of dotphrases than residents, APPs, or physicians (Figure 3).
Figure 3. A violin plot demonstrating the distribution of dotphrase usage per note, by different author types. The plot is scaled by the number of observations in each bin. The data points represent the distribution of the raw number of dotphrases used in each note.

Impact of Dotphrases on Documentation

The usage of dotphrases was found to be positively correlated with note length (Figure 4).

Figure 4. A box-and-whiskers plot demonstrating the positive correlation between the number of dotphrases used and the length of an ED provider note (pearson $\rho =0.52$).

When examining the department as a whole, there was a statistically significant difference in the time to note completion by the author. Less dotphrase usage actually correlated with faster note completion time. However, when conducting a paired t-test and examining each individual author’s time to note signature with high or low dotphrase usage, the effect disappeared.
In addition, when grouping the notes into high vs. low dotphrase usage, there was significant difference in time to clinician signature and triage level (Table 1).

**Table 1.** Comparison of note statistics for notes where there was low dotphrase usage vs. high dotphrase usage. Variables with an asterisk indicate statistically significant differences using a t-test.

A linear regression model was created to test whether higher dotphrase usage was correlated with higher billing codes. The model adjusted for triage ESI level, note length, and author (resident, advanced practice provider, attending, scribe) type. The model found that high dotphrase usage was significantly correlated (p<0.0001) with higher-level CPT codes. Another model was also trained using raw dotphrase counts rather than a binary classification of high or low dotphrase usage and the results did not differ.

**Deep Dive into Disease-Specific dotphrases**

To examine the level of duplication and similarity across dotphrases, a sample of dotphrases was extracted and analyzed. The text of the templates for the 20 dotphrases with the term “syncope” contained in the title were studied.

A practicing ED physician assessed each of the phrases and categorized them as such: 70% represented text for medical decision making or medico-legal language, 15% represented guidelines for syncope management, 15% represented other types of text such as EKG interpretations and review of symptoms. There was remarkable similarity within the dotphrase types. In fact, two of the three “pathway” dotphrases were identical.
Discussion

Dotphrases are a flexible and powerful tool. However, similarly to clinical decision support and note templates, without appropriate governance structures the number and content of dotphrases can balloon and become unmanageable.\(^9,10\) Individual dotphrases created by users who have left the organization can linger, dotphrases with outdated clinical practices can remain in the system, or dotphrases minimally used can be forgotten. Our analysis showed that over a 14 month period, half of all dotphrases were only ever used by one provider and 19% of all the dotphrases were used in a single note. In addition, providers can create their own dotphrases because they are unsure of what exists in the system thereby leading to a lot of unnecessary duplication. Our disease-specific analysis found multiple identical or nearly identical dotphrases for a single presenting condition.

We also found that high dotphrase utilizers were most commonly medical scribes. This is anticipated as many scribe training programs encourage and educate scribes to use dotphrases. In fact, proper scribe training has demonstrable benefits - it has been shown that scribes may be writing higher quality notes than physicians themselves.\(^8\)

Our analysis focused on identifying whether dotphrases were able to demonstrate efficiency gains. We found that there was no evidence for efficiency with respect to time: there was no difference in time of note completion by the author or time to co-signature by the signer. However, we did find that there was a significant effect on efficiency reflected as relative value units per patient: CPT coding level was significantly higher when more dotphrases were used. This is likely because use of dotphrases allows the provider to more easily meet the requirements for the highest level of billing by bringing in required elements into the note with relatively few keystrokes. It is clear that many parts of the EHR are designed to assist with billing and dotphrases are likely no exception.

In general, dotphrases can be useful in a number of ways. Most notably, they can decrease cognitive load by incorporating clinical decision rules, pathways, risk calculators, and common differential diagnoses for frequently encountered complaints. These added benefits can also serve as prompts for early EHR users or trainees. Similarly, dotphrases that establish frameworks for infrequently performed, specialized physical exams can help providers with recall. They can also be used as an avenue to store patient resources such as proper discharge instructions, expectant...
management of common conditions, and contacts for addiction or mental health resources centers. While dotphrases have potential as clinical, teaching, and research tools, they can have their downfalls if used improperly.

As our work demonstrated, dotphrases significantly increase note length. This increase in text within a note can increase the signal-to-noise ratio with extraneous information that does not impact medical decision making or patient care. Providers weary about litigation may lean towards higher utilization of unnecessary dotphrases to justify evaluation and treatment plans that oftentimes prove useless in the further management of the patient. The need to comb through extraneous information may result in confusion and unsafe patients’ transfer of care between providers. Even worse, and similarly to the problem of copy-and-paste, using dotphrases without careful thought can proliferate incorrect information, materials, or text.

Our work shows that although there is a lot of work to be done surrounding dotphrase standardization and duplication removal, there seems to be a positive and measurable effect of EHR shortcuts on the billing aspects of clinical documentation.

Limitations

A limitation of this work is that the study time frame was during a pandemic, where practices may not be equivalent to a pre-pandemic time period. However, we don’t anticipate that this changes the study findings. In addition, as the study is conducted within a single academic medical center on the Epic EHR, there is risk of limited generalizability. However, since dotphrases are so ubiquitous in all EHRs, we believe that this work presents an important finding for the informatics community as a whole.

We recognize that there is no control for this work but it would be improbable for us to turn off dotphrases for some subset of the note-writers. There may be a future state in which this era of documentation will serve as the historical control. For example, if the requirements for visit-level coding are modified to be time-based instead of documentation-based, it is certain that many aspects of documentation and dotphrase usage would be altered.

We also note that we may not be capturing all dotphrase usage. Many clinicians may use dotphrases as quick reference guides to aid in appropriate care, but then may delete the dotphrase as it wasn’t meant to be used as part of the documentation for the patient. We do not think that this practice is very common and since we are studying documentation, it is reasonable to focus on dotphrases that are actually used and saved in the text of clinical notes.

In general, although we aim to measure the effect of these EHR shortcuts on efficiency, and thereby documentation burden, we concede that documentation burden is exceedingly difficult to measure. We note that especially in the ED, it may be difficult to assess actual time spent on documentation only using note creation and note signature time.

Conclusion

We found that dotphrases are often used in emergency department clinical documentation. We also found that dotphrases are often very individualized and are not uniformly used across the department. Dotphrases are highly correlated with note length: the more dotphrases that are used, the longer the clinical note. However, although others have demonstrated a perception of increased documentation efficiency we found that there was no effect of dotphrases on note completion time. We also discovered that even when accounting for triage acuity level, note length, and author type there is a significant effect of more dotphrase usage leading to higher visit billing levels.

Abstract

Objectives. Remote monitoring (RM) of health-related outcomes may optimize cancer care and prevention outside of clinic settings. CYCORE is a software-based system for collection and analyses of sensor and mobile data. We evaluated CYCORE’s feasibility in studies assessing: (1) physical functioning in colorectal cancer (CRC) patients; (2) swallowing exercise adherence in head and neck cancer (HNC) patients during radiation therapy; and (3) tobacco use in cancer survivors post-tobacco treatment (TTP).

Methods. Participants completed RM: for CRC, blood pressure, activity, GPS; for HNC, video of swallowing exercises; for TTP, expired carbon monoxide. Patient-reported outcomes were assessed daily.

Results. For CRC, HNC and TTP, respectively, 50, 37, and 50 participants achieved 96%, 84%, 96% completion rates. Also, 91-100% rated ease and self-efficacy as highly favorable, 72-100% gave equivalent ratings for overall satisfaction, 72-93% had low/no data privacy concerns.

Conclusion. RM was highly feasible and acceptable for patients across diverse use cases.

Introduction

Accelerating the fight against cancer calls for enhanced information technology that will give clinicians access to patients’ therapeutic response data in real-time, provide those patients with information critical to and tailored for self-care, and allow researchers to more easily identify emerging trends surrounding those processes.[1] This goal may be achieved with the implementation of systems that enable remote, and when warranted, real-time monitoring of patients’ symptoms and other health-related outcomes in the context of cancer prevention, treatment and survivorship. Home- and sensor-based technology has provided a continuous assessment method for patients with heart conditions, diabetes, and asthma. [2-6] More recently, studies have shown that remote monitoring of symptoms during cancer treatment using a web-based questionnaire platform, coupled with intervention and support by care providers, was associated with better quality of life, fewer treatment interruptions, and improved survival in metastatic cancer patients. [7, 8]

The growing accessibility of mobile and sensor technology may offer scalable and cost-effective strategies to develop and test remote monitoring systems with the goal of optimizing cancer care outside of the clinic setting.[9, 10] The need for additional research has been cited, particularly to help define for which groups of patients and under which circumstances remote monitoring with mobile and sensor technology is most appropriate and acceptable and effective; this need may be particularly pronounced in oncology, where sequelae can be long-lasting.[11-16]

Envisioning the ability to use home-based mobile and sensor technology to address a wide array of challenging problems related to cancer prevention and treatment, and aiming to identify real-world problems faced by cancer clinicians and patients, we designed a software-based cyber-infrastructure to enable collection, storage, processing, visualization, analysis, and sharing of cancer patient and survivor data from multiple domains.[17, 18] The CYCORE (CYber-infrastructure for COMparative effectiveness REsearch) system was designed to combine data from user-friendly, patient-accessible platforms—including mobile sensors and smartphones—with web-based
data display interfaces from multiple sources, to help clinicians and researchers decipher important trends in research participants that are needed to facilitate assessment and clinical decision-making.

CYCORE was built as a service-oriented architecture (SOA) to provide loose coupling between its various system services, promoting independent development and reuse of software components. SOAs provide the means to offer, discover, and interact with CYCORE’s capabilities, such as acquiring sensor data, storing and linking data from various sensors, processing data, or exporting data to other software packages used for outcomes assessment. The CYCORE cyber-infrastructure (CI) is the underlying computational and data infrastructure, which achieves coherent system integration out of a variety of distributed components and manages the lifecycle of all resources. Furthermore, CYCORE uses a Rich Services (RS) architectural blueprint, a type of SOA suitable to integrating crosscutting concerns. The RS architecture allows for infrastructure services, such as encryption, authentication, authorization, and auditing to be plugged into the architecture without modifying core system functionality. This feature ensures scalability, so CYCORE can grow without changes to the underlying CI as new needs are identified and new users engage with the system. We also continuously assess maintenance, usability, and reliability, and we integrate new device models as they become available to improve system quality.

The CYCORE user interface mandates role-based access and provides tailored views for each role. For example, the clinician interface provides a list of patients monitored by a given clinician and displays all sensor data and patient-reported outcomes in a format that simplifies decision-making. The researcher, on the other hand, may access the tools for study monitoring, patient enrollment, sensors assignment, and data analyses. CYCORE provides an integrated view of data from various sources and the ability to run analyses that correlate data and trigger alerts if required by clinicians.

**Objective**

Our research objective was to evaluate the feasibility and acceptability of using CYCORE for remote data collection, outside of the clinic setting, with cancer survivors in three studies that represented unique oncology settings and that assessed: (1) physical functioning in colorectal cancer (CRC) patients; (2) adherence to swallowing exercises in head and neck cancer (HNC) patients during radiation therapy; and (3) tobacco use in cancer survivors who completed an evidence-based tobacco treatment program (TTP).

**Materials and Methods**

This research was approved by the Institutional Review Board at the University of Texas MD Anderson Cancer Center (MDACC).

**CYCORE system overview.** The CYCORE system combined physical entities, such as sensors and mobile devices, with an underlying computational and data fabric. CYCORE had several data acquisition strategies to assimilate multiple sensor types. The CYCORE system consisted of a small plug-in computer-server with the role of sensor hub in the participant’s home, and a backend CI that presented raw and analyzed data to researchers or clinicians. In the prototype used for this study, we developed and implemented our own sensor hub called the Home Health Hub, which was a physical device that aggregated sensor data collected by the patient and relayed these to the CI over an Internet connection. We also developed a smartphone application to enable patient self-recording of videos that automatically uploaded into CYCORE; these were used to monitor adherence. We integrated a customized electronic patient-reported outcome (PRO) system developed at MDACC to provide an app for patient questionnaires via an Android smartphone or tablet.

The system supported an interface with a wide range of consumer-grade sensors that wirelessly transmit data to the home-based server. The sensors integrated into CYCORE for this study were blood pressure monitor and weight scale (A&D Medical), accelerometer (AwareTech Action Tracker), heart rate (Zephyr Technology Bio-Harness), GPS location, and CO monitor (PICO). The accelerometer, heart rate monitor, and GPS provided continuous data. For consumer-grade sensors, the manufacturer's procedures for determining the device calibration tolerance and for recalibration were implemented prior to each deployment. For validation, we employed sensors that exposed a digital interface to the measured values. Sensor data were aggregated, encrypted, and transmitted to a central CYCORE server, which notifies a server database of new data events. Using a web interface, research staff registered and assigned devices to patients, monitored data transmission, and handled technology issues that arose. CYCORE also supported the creation and use of clinician web interfaces for patient monitoring of data during the duration of the study.[18]

**Study descriptions.** We evaluated the feasibility and acceptability of the CYCORE system in three distinct studies with unique study populations, described below. Table 1 describes the types of sensor and mobile technology used in each study.

Physical activity to promote optimal quality of life in patients with advanced colorectal cancer (CRC). Home monitoring and receipt of reminders to remain physically active may help patients with advanced CRC maintain physical functioning and reduce symptoms and side effects during periods of acute treatment. Staying physically active and managing treatment side effects may, and in turn, help patients tolerate treatment with fewer interruptions, and potentially increase both the length and the quality of their survival. Since higher levels of physical activity are associated with reduced cancer incidence and recurrence, [19-21] we evaluated whether CYCORE would be feasible and acceptable for assessing activity and treatment side effects in CRC patients.

Adherence to swallowing exercises in head and neck cancer (HNC) patients receiving radiation treatment. HNC patients undergoing radiation treatment are recommended to follow a rigorous self-care regimen at home during their 6 to 7-week course of therapy. This regimen includes adherence to a standard-of-care [22-24] prescription of range-of-motion swallowing exercises intended to reduce long-term radiation treatment-induced swallowing complications, [25-27] including trismus, aspiration, mucositis, xerostomia, loss of taste, and fibrosis of the skin and soft tissue. [27-33] Because adherence to both the performance of swallowing exercises as well as appropriate technique is a critical goal for HNC patients during treatment, we assessed the feasibility and acceptability of capturing patients’ self-recorded videos of their daily swallowing exercises. Such videos could be valuable tools for speech pathologists to review and counsel patients on proper technique and adherence to their prescribed swallowing exercises.

Remote collection of exhaled carbon monoxide measurements to assess smoking cessation. MDACC offers evidence-based smoking cessation treatment to cancer survivors and their family members through its Tobacco Treatment Program (TTP), as tobacco use is a contraindication for some cancer treatments and increases risks for complications from the disease as well as mortality. Treatment includes non-nicotine-based medications, nicotine replacement therapy, and behavioral counseling. A standard method of determining cessation status is
through in-clinic exhaled carbon monoxide (CO) monitor measurements, which are only clinically relevant if collected within a day or so of the last smoking bout, limiting the test’s usefulness in validating less frequent smoking behavior. We assessed the feasibility and acceptability of remotely collecting exhaled CO measurements 3 times daily from cancer survivors who had completed the TTP, and to video-record those measurements as an indicator of adherence.

**Participant eligibility and recruitment.** Eligible participants for all studies were 18 years of age or older, English proficient, and had a prior cancer diagnosis. The CRC study included CRC cancer survivors who had completed surgery at least 8 weeks prior to study entry, and who may or may not have been receiving chemotherapy. Those recruited for the HNC study were currently undergoing radiation treatment but were excluded if they had a current swallowing disorder unrelated to their cancer diagnosis. TTP recruits had a history of any cancer other than non-melanoma skin cancer and were current or former smokers but were excluded if they had a known active substance use disorder or had undergone major surgery during the previous eight weeks. For the CRC and HNC studies, eligible patients were identified from medical records and were recruited in clinic. For the TTP study, candidates were identified from program completion records and were recruited via a mailed letter from the TTP director.

**Study procedures.** Participants were provided with study-specific devices and were instructed to use them at home for two non-consecutive 5-day periods, separated by 2 weeks of non-usage. Following informed consent, participants were trained on the use of their devices.

CRC study participants were asked to record two blood pressure (BP) readings, one sitting and one standing, upon arising in the morning and prior to bedtime in the evening. Using a smartphone provided by the study, they completed morning or evening assessments using a mobile app that included standard measures regarding exercise frequency, type, self-efficacy, social support and physical functioning, plus daily random assessments regarding severity of symptoms (fatigue, pain, trouble concentrating, and mood). CRC participants wore a heart rate (HR) monitor and accelerometer during waking hours and used a global positioning system (GPS) device. HNC study participants used a study-provided smartphone to video-record all swallowing exercise sessions prescribed by their speech pathologist and, once-a-day, to self-initiate an assessment of symptoms and adherence to swallowing exercises. TTP study participants exhaled into a hand-held carbon monoxide (CO) monitor three times a day and used a smartphone to video-record those breath tests. Prior to each use of the CO monitor, participants also used the phone to self-initiate questionnaires about the number of cigarettes smoked and exposure to second-hand smoke. Additionally, at three randomly-assigned time points, TTP participants responded to phone-prompted questions about fatigue, pain, trouble concentrating, and mood.

Participants’ perceptions of usability, acceptability, and satisfaction were assessed at seven time points across each study via in-person or phone interviews with research staff. After the baseline training, staff administered a four-item measure regarding ease of use and self-efficacy for using each device. On days 2 and 4 of each 5-day device-use period, participants answered a 6-item measure regarding device problems, medical concerns related to the devices, ease of use, ability to use each device (including reasons for not using a device or why using it was difficult), and what was disliked about each device or that reduced the desire to use that device. [32, 33] This measure was re-administered on day 6 following each 5-day device-use period and included additional questions that assessed belief about the usefulness of automatic data provision to their doctor, concern about data privacy, helpfulness of the initial training session and printed instructions, importance of viewing the data collected, confidence in ability to use at home, and overall satisfaction with device use. Open-ended queries, in all but the post-training survey, solicited additional comments about device use.

**Analysis.** We defined indicators of adherence to daily use of devices for each study as the percent of participants who completed the following during 7 of the 10 device-use days: any BP reading (CRC study), any video showing performance of swallowing exercises (HNC study), and any video showing a CO measurement (TTP study). Videos smaller than 1000 KB were not included in those counts as they were deemed to be unusable. The primary outcome was study completion, defined by completion of the final study (week 4, day 6) survey. Other outcomes of interest were usability and acceptability ratings, and adherence to the requirements for daily use of devices. Open-ended responses to survey items completed by patients were analyzed using a constant comparative approach based on grounded theory. [34]

**Results**

Sample size, demographic characteristics and completion rates, which established feasibility, for each study are shown in Table 2. In reviewing study-specific adherence, we found that 47/48 (98%) of CRC participants who completed the CRC study, transmitted BP data on at least 7 of 10 device use days. Of HNC study participants, 30/31 (97%) self-recorded any videos that captured performance of swallowing exercises (mean, 32.7; range, 1-118 of
1000 KB or greater in size) over the 10-day device-use period; while 16/31 (52%) captured videos on at least 7 of those 10 days. Of TTP participants, 48/48 (100%) self-recorded any video of CO monitor usage (mean, 27.7; range, 2-72 of 1000 KB or greater in size); while 43/48 (90%) captured videos on at least 7 of 10 days.

We found a high completion rate for the device usability and acceptability surveys for all three studies (includes missed surveys due to withdrawal): CRC, 316 of 350 possible surveys (92%); HNC, 213 of 259 (82%); and TTP, 328 of 350 (94%). Participants’ mean responses to the final (week 4, day 6) survey about device usability and acceptability are shown in Figure 1. Scores were generally high on ease of use of devices, self-efficacy, and overall satisfaction, and generally low regarding data privacy concerns.

We found commonalities in participant responses—when provided—to the open-ended questions about what they liked most about using the devices at home. CRC study participants most liked being able to see or monitor the BP results (13/45, 29%); being able to use the devices at home (or not having to travel [in general, or to see the doctor]) (9/45, 20%); and that device use was easy or simple (12/45, 27%) and convenient (5/45, 11%). Some example responses from open-ended questions follow: “Using the blood pressure cuff keeps you kind of in tune with what’s happening, blood pressure-wise.” “Someone received the data at the moment versus me having to explain how I felt at the moment. It picked up certain things that I may have forgotten about.” “I think that whenever you’re monitoring that information and you need it, it’s much easier to do it at the house than go to the doctor’s office.”

HNC study responders most liked that device use provided motivation or a reminder to do the swallowing exercises (8/29, 28%); and that using the devices was easy (7/29, 24%) and convenient (7/29, 24%). Answers to the open-ended questions included the following: “It motivated me to do exercises I might have skipped otherwise.” “This is something in the future that the patients can use to keep in touch with their doctors, and their doctors can monitor them at home while they’re going through treatment.” “I did it at my leisure, first thing when I woke up. I was at a hotel.”

TTP responders most liked being able to use the devices at home (or not having to travel [in general, or to see the doctor]) (15/39, 38%); being able to see or monitor the CO results (9/39, 23%); and that it was easy (8/39, 21%) and convenient (6/39, 15%). Some sample statements follow: “If I had to go into an office, it would be tough to get this in three times a day.” “I like the idea that I could see the readings, and I could tell how much how much carbon monoxide was in my body.” “If I could have kept the devices longer, it probably would have worked to wean me off of smoking.”

1Post-study evaluation questions included: 1) helpfulness of baseline training session (training); 2) clarity of printed instructions used at home (instructions); 3) ease of device use at home (ease of use); 4) Confidence in ability to use device at home (self-efficacy); 5) usefulness of automatic data provision to doctor (data to provider; N/A for GPS, Hub); 6) importance of seeing device reading at home (viewing data, N/A for Hub); 7) concern about data privacy (data privacy); 8) overall satisfaction with device (overall satisfaction).

**Discussion**

Based on the high study completion rates and participants’ responses to evaluative questionnaires, our findings showed that remote, home-based monitoring for important cancer-related health outcomes was feasible and acceptable in all three groups of patients in our study sample. We found that patients, some of whom were quite ill and were burdened by frequent clinic and hospital visits, willingly used a variety of mobile sensors at home to measure biometric and self-reported outcomes related to physical activity (CRC patients and survivors); swallowing exercise adherence during RT (HNC patients); and smoking cessation adherence (cancer survivors who were former or current smokers). Participants from all three studies were receptive to using the devices and found that doing so was simple, easy, and convenient.

Compared to participants in the CRC and TTP studies, those in the HNC group had the lowest rates of study- and survey completion, and device use. Based on responses to their user questionnaires, a subset of HNC participants indicated that recording the videos took too much time (4/29, 14% of responders), that the recordings were harder to do as treatment progressed and, subsequently, as patients’ treatment burden typically increases, causing them to feel worse (6/29, 21%), and that feedback about content of the videos was nonexistent during the course of the study (3/29, 10%). As these studies were conducted to determine feasibility and acceptability, we did not provide feedback to HNC participants regarding their adherence or quality of performance of swallowing exercises. Future efforts to incorporate rapid, specific feedback to patients that is aimed at helping them improve an important self-care regimen, such as the one recommended for HNC patients, may increase the perceived value, satisfaction and adherence to remote monitoring protocols.[35][36][37]

TTP participants’ responses also supported the value of incorporating clinician review of data and feedback to patients: after the final week of device use, TTP participants indicated that it would be useful for their physicians to be able to monitor the CO and the self-reported data: “It made me more accountable. I smoked less than I usually would because it reported my smoking habits.”

As noted above, the HNC group’s overall satisfaction with using the phone to record videos lessened end of the study; however, their week 4 mean score still indicated that the group experienced high satisfaction with using the phone for that purpose. This is quite impressive, considering that by week 4 of our study, this group was entering week 4 or 5 of RT, a time during which symptom burden is particularly onerous.

While studies like ours can demonstrate the potential feasibility, as well as efficacy, of integrating sensors, mobile devices, and wireless networks with the goal of improving cancer care and patients’ quality of life, concerns about security and privacy related to the use of this technology have been raised. Patients in our study reported relatively low levels of concern about data privacy, which may be an important factor in securing broader acceptability for remote monitoring models such as CYCORE. Patients’ privacy concerns may be minimized if they perceive a value in the use of technology, particularly in partnership with a trusted source, their health care providers. Nonetheless, systems such as CYCORE will likely achieve their potential benefits if the security and integrity of data can be assured.

Our study sample was limited in regard to diversity in race/ethnicity and educational attainment. While our sample reflects the overall patient population at our institution, our findings may not be generalizable to populations experiencing technology disparities. The COVID-19 epidemic illuminated longstanding systemic disparities in technology access and digital literacy.[40] These disparities hindered the ability to access health care during the pandemic through telemedicine, and also impeded early access to COVID-19 vaccines which depended on the ability to navigate mobile apps and internet portals. Persons at risk for experiencing these technological disparities are commonly in rural areas, lower-income neighborhoods and minority communities and often medically underserved and at increased risk for cancer as well as higher morbidity and mortality from the disease; potentially, those who may benefit from remote monitoring to help manage their illness. Future research on remote patient monitoring must focus on understanding how technology access and literacy affects usability and feasibility when implementing such interventions.[41]
Evaluation of CYCORE continues through expansion of its technical capabilities, increasing the number of participants studied, and through additional studies within the cancer care community. Ongoing and completed studies are focused on efficacy of remote monitoring during acute periods of cancer treatment, as well as research to further establish feasibility and define methodology for use in challenging patient populations. [39] These studies are expanding the types of sensor and mobile data collection methods within CYCORE, including widely used commercially available devices such as Fitbits, further demonstrating that the system is agnostic to the type of device used and the health-related application. The goal is to continue to develop a community of users who would benefit from CYCORE’s capabilities for remote monitoring of patient behavior, all in support of optimizing cancer care [38] by objectively assessing treatment adherence, symptoms, side effects, and toxicities. This should lead to greater patient understanding of and, thus, engagement in their own care, and improvements in data collection for clinical trials including capturing data not typically collected that is highly relevant to cancer recovery and survivorship.

**Conclusion**

Our study contributes to a growing body of research on remote patient monitoring in oncology, particularly studies that combine electronic patient-reported outcomes with collection of biometric outcomes using non-invasive digital devices. [42] A system like CYCORE that gathers and integrates patient-generated health information in cancer prevention and treatment research is highly feasible and acceptable to patients, clinician and researchers. It supports the collection of new forms of data on behaviors and symptoms that are needed to fully determine the course of cancer treatment and health outcomes. These successful examples of remote monitoring through sensors in the homes of different group of cancer patients show promise for broadening the scope and quality of data in cancer prevention, treatment and control. They also demonstrate how patients can be enabled to participate actively in their prevention and treatment regimens, an essential component of successful health outcomes.

Abstract

Deficiencies in data sharing capabilities limit Social Determinants of Health (SDoH) analysis as part of COVID-19 research. The National COVID Cohort Collaborative (N3C) is an example of an Electronic Health Record (EHR) database of patients tested for COVID-19 that could benefit from a SDoH elements framework that captures various screening instruments in EHR data warehouse systems. This paper uses the University of Washington Enterprise Data Warehouse (a data contributor to N3C) to demonstrate how SDoH can be represented and managed to be made available within an OMOP common data model. We found that these data varied by type of social determinants data and where it was collected, in the time period that it was collected, and in how it was represented.
Introduction

The COVID-19 pandemic has highlighted the urgency of existing informatics needs around clinical data sharing and the collection and integration of high-quality Social Determinants of Health (SDoH) data. While different organizations (Johns Hopkins, NYTimes) aggregated case data to generate publicly-available reports, data on patients and health care system response was limited. This challenge occurred even though most institutions had these data stored electronically and the potential value of such data sharing occurred at scales higher than it had ever been before. For some, we are still trying to understand their significance and determine the best approach to sharing such knowledge.

To address data sharing needs, the National COVID Cohort Collaborative (N3C) was created as an extension of the National Center for Data to Health (CD2H) project. With funding from the National Institutes of Health (NIH) and support from the National Center for Advancing Translational Sciences (NCATS), as of March 2021, N3C has collected data from electronic health records (EHRs) from 45 health systems across the country on 3.75 million patients, over 903,000 of whom have been diagnosed with COVID-19. Participating organizations provide data on biweekly to monthly schedules, based on extraction rules from the EHRs for COVID cases and matched controls. Each organization transforms data (e.g., patient demographics, visit history, diagnoses, medications, laboratory test results, procedures, vital signs) into 4 common data models -- the Accrual to Clinical Trials (ACT) Network, National Patient-Centered Clinical Research Network (PCORnet), Observational Medical Outcomes Partnership (OMOP), and TriNetX. These data are then submitted to N3C for storage in a secure enclave managed by NIH, harmonized into the OMOP common data model, which can be made accessible for researcher requesting data for analyses related to the COVID-19 pandemic. N3C significantly advances EHR data sharing capability being the first public national data sharing initiative with centralized data extracted directly from EHRs in this way.

Despite the fact that SDoH have been associated with COVID-19 incidence and outcomes, data elements required to study the role of SDoH are thought to be under-collected due to historic inattention to patient SDoH. SDoH are the non-clinical covariates of how people live, grow, learn and age as it relates with how they can manage stressors or prevent worsening health outcomes. As data representations for SDoH are not native to clinical informatics, mapping of detailed information bears a risk of information loss. Patient SDoH may be predominantly captured as diagnosis codes, narrative reports, and structured survey tools. Diagnosis coding, such as Z-codes in ICD-10-CM representing certain assessments, may be more easily modeled and shared across institutions, but will be limited to those conditions where this coding procedure is available and reliably implemented. Narrative text representations may be the easiest to document for clinicians and therefore could have the highest level of completeness and contextual information, but extracting narrative notes may be imperfect and inconsistent for sharing in common data models. Structured forms can be more readily disseminated and queried electronically; however, variations in research instrument used, instrument version, and coverage of SDoH questions and answer options presenting challenges for comparisons across institutions. Each of these approaches are further limited by whether or not SDoH are assessed as part of the standard clinical workflow. Efforts are needed to define how the data are included and how they can be used for N3C research.

Clinical screening tools for SDoH were introduced as research instruments to help care providers identify and address individual-level SDoH and social needs. These structured screening tools can provide a snapshot of non-medical conditions in the patients’ lives, and are broadly associated with patients’ ability to manage stressors and/or avoid worse health outcomes. Reliable collection of SDoH at the point of care can help clinicians to provide personalized recommendations, promoting health and well-being towards the overall population serviced by the health system.

To make SDoH from EHRs usable in research and other analyses, they must be made computable, which requires knowledge of how these data are being collected and represented. Social and environmental determinants of health continue to have a central importance in studying disparities in COVID-19 outcomes and predisposed vulnerabilities. These factors have been used to guide the US vaccine deployment strategy to protect the most vulnerable and at-risk individuals. Information collected from SDoH structured screening tools may be stored within EHRs as FlowSheets measurements, comparable to how depression is screened. FlowSheets offer a tractable tabular data-structure to examine related data-points for analytics purposes. However, FlowSheet measurements are encoded independently. Between health systems, the same measurements (questions/variables) and values (answers provided) will likely contain locally unique encoding and nuances. To facilitate cross-site analyses, sites must first harmonize their FlowSheet information into standard categories while maintaining...
attributions for source data provenance. With few exceptions, encoding of concepts in these forms is not captured in standard terminologies such as LOINC that enable interoperable analyses.

In this study, we characterize how SDoH data are represented in an EHR to assess their use, limitations, and what recommendations are needed to address challenges in using them for research. This was done using data from UW Medicine and University of Washington School of Medicine, which was an early contributor of data to N3C. The intention of this work is to contribute towards advancing data maturity for patient SDoH representation, data utility for research on social needs and health services research, and ongoing N3C SDoH research on COVID-19 efforts.

**Methods**

**Study design**

This case-study specifically focused on secondary use of information from an Epic Clarity Flowsheet structure into an OMOP database schema. We developed a process for triaging FlowSheet measurements for patient-level SDoH then map observational data elements for Extract-Transform-Load (ETL) operations. We focused primarily on SDoH information represented in clinical observations captured in FlowSheet tables, which includes survey responses and patient-provided occupation information. Post hoc analysis aims to measure data density and completeness to identify next steps in data engineering efforts.

**Data source**

Data were extracted from the UW Medicine Health Network Enterprise Data Warehouse (EDW), which are collected from four Hospital/Medical centers (Harborview, Northwest, UWMC-Montlake, Valley) and various outpatient clinics in the Greater Seattle King-County metropolitan area, but patients may be received from various geographic areas in Washington, Wyoming, Alaska, Montana, and Idaho (WWAMI) and neighboring regions. The cohort criteria include patients tested for SARS-CoV-2 RT-PCR viral presence test, tested for SARS-CoV-2 IgG antigen titer assay, and/or received condition diagnosis of COVID-19 between Feb 1, 2020 through Feb 20, 2021. Although UW employees and staff had increased COVID testing protocols, UW employees and staff at the time of testing were excluded from this dataset due to institutional policies protecting employee privacy. These data elements include patient demographics, visit history, diagnoses, medications, laboratory test results, procedures, vital signs and other observations that have been extracted from the medical records into the OMOP common data model.

Motivation to use OMOP schema was informed by N3C and the OHDSI CHARYBDIS design and rationale to create COVID-19 shareable data cohorts for research.

**Assessment for FlowSheet measurement records**

The general workflow can be represented within Figure 1. The lead author (JP) first explored the schema of the Epic Clarity FlowSheet tables to identify necessary entities. Next, the lead author (JP) performed manual review to triage the FlowSheet measurements to identify data elements relevant to SDoH and generate initial concept mappings. We used the UCSF SIREN project social needs categories as reference taxonomic labels for qualitative coding of Epic FlowSheet measurement names and display names. We initiated the Epic FlowSheet measurements coding as inquiries of ‘Housing Insecurity / Instability / Homelessness’, ‘Food insecurity’, ‘Employment’, ‘Education’, ‘Health Care / Medicine Access & Affordability’, and ‘Immigration / Migrant Status / Refugee Status’. Of note, we separated questions/inquiries of ‘Household size’ into its own category and we lumped inquiries related to ‘Annual Household Income’ as a measure under the ‘Employment’ category.
During exploration, the FlowSheets schema should allow for recognizing (A) templates (surveys tools), (B) individual measurements (survey questions), (C) measurement values (provided responses), (D) the visit encounter (instance of data collection), and (E) linkable to the OMOP person instances (subjects reference).

2) Triage the FlowSheet measurements into a mapping table with information about the data type and OMOP observation concept semantic equivalent. Retain the relationship between each measurement, unique measure value, and their equivalent value_as_concept_id in a separate table.

3) Join the tables, apply conversion logic, apply a filter for values occurring more than 10 instances (optional), then insert into the OMOP Observation table.

Harmonization to OMOP

Once it has been established that SDoH information was captured within the FlowSheet structure, we examined the unique measurement values related to each FlowSheet measurement for value data types (e.g., string, numeric) and concept representation. Concept representations were triangulated with the FlowSheet measurement comments, which are clinician memos. FlowSheet measurements with overwhelming singleton values were considered free-text and flagged for separate extraction approaches. Flowsheet measurements and their standardized unique values were searched for within the ATHENA vocabularies repository. Using ATHENA, we identified and viewed OMOP version 5.3.1 vocabulary, which contains standardized concept relationships from biomedical vocabularies such as the Logical Observation Identifiers Names and Codes (LOINC) database and the Systematized Nomenclature of Medicine -- Clinical Terms (SNOMED-CT) vocabulary. We prioritized OMOP standard concepts from the LOINC vocabulary, which have incorporated survey tools with defined ‘has answer’ relationships, which we used to verify the question-answer relationships. OMOP concepts were reviewed and assigned on the basis of the question and answer having adequate semantic representation. For example, ‘3-years’ can be represented with ‘36 months’; ‘how long have you been homeless’ cannot be represented with ‘Current housing status,’ or vice versa. Where LOINC concepts were not available for the question or answer, we broadened the concept representation to the SNOMED-CT and AllOfUs_Columbia vocabulary. The lead author (JP) conducted qualitative member checking with subject matter experts in OMOP data engineering (AW) and concept mapping using LOINC and SNOMED (DM) to ensure accuracy and validity of the mapping interpretations. Mapping discrepancies were reconciled to an agreed upon set of corrections.
The triage results in a mapping table that associates each ‘Flowsheet Measurement ID’ with their OMOP representation of concept ID and source concept ID (Table 1). FlowSheet measurements marked for exclusion would have RUN_SET set to NULL.

Table 1: Features from the FlowSheet Observations table

Once the mapping table was established, we refined ETL scripts to generate new Observation records. Regular expressions apply logic between 1) FlowSheet measurement IDs that were triaged and 2) the measurement’s unique value sets to decide on the 3) corresponding OMOP value_as_concept_id. For numeric values, like ‘Annual household income’, we retain the raw value in value_as_number then discretize into value ranges, which are encoded as value_as_concept_ids. After the ETL has been implemented, we conducted patient-level random walks to review for accurate concept representations.

Assessment of employment information

During patient encounters, patients may provide or update their occupation titles (e.g., ‘nurse’) employment status (e.g., ‘full time’), which may be separately collected as free-text and time-stamped within patient demographics tables. Occupation and employment circumstances may be expressed in a variety of ways. We referred to the 2018 US Census Bureau Occupation Code list (as of Sept 26, 2019)\(^3\) Level 2 categories to form regular-expression rules for mapping occupations. These Level 2 categories are also represented with OMOP standard concepts, originating from the LOINC National Trauma Data Standard vocabulary. We link these mappings to extract occupation titles to OMOP concepts. For example, with an occupation label of ‘icu nurse’, an observation record would be mapped to OMOP observation_concept_id 36203487 for “Occupation [Type]”, and value_as_concept_id 36308137 (corresponding to “Healthcare practitioners and technical occupations” (3000-3550)”), and the source string would be retained for data provenance in the value_as_string and the observation_source_value. We repeatedly reviewed the occupations and occupation category assignments until saturation was achieved and all interpretable values were accounted for. To prevent uniquely identifying information, we imposed that occupation labels must have a minimum occurrence of at least 10 patients, else the record would be excluded for unacceptable risk.

Results

Out of 4200 FlowSheet measurements reviewed, initial triage detected 35 FlowSheet measurements of relevance to understand patient-level SDoH. Assessment of FlowSheet measurement records resulted in 21 FlowSheet measurements that had interpretable concept representations available in OMOP v5.3.1; however, the 21 FlowSheet measurements were orphan questions without obvious linkage to survey templates, so the source screening tool and version could not be established. 14 FlowSheet measurements had measurement values that were non-interpretable or not amenable for secondary use and, therefore, were removed from further extraction and analysis. These 14 FlowSheet measurements that were removed accounted for less than 1000 observation records. The 21 FlowSheet measurements that were mappable accounted for the gross majority of SDoH Observation records (n=445222).

As of Feb 20, 2021, the UW COVID-19 OMOP Limited dataset includes 133833 patients that have been assessed for COVID-19. Of the patients assessed for COVID, 83535 patients had pre-COVID medical conditions,
observations, vitals, and medical procedure information, the timeframe between Jan 1, 2010 through Dec 31, 2019 (Table 2). In contrast, 124021 patients who were assessed for COVID had at least 1 medical record generated since COVID-19 reached epidemic scales, between Jan 1, 2020 through Feb 19, 2021. The number of patients with SDoH observations ranged from 11.7% of patients (n=9795) generated during the pre-COVID period to 82% of patients (n=101717) generated since COVID-19 reached epidemic scales.

Of the 133833 patients, approximately 34.8 million patient observations were extracted into the UW COVID OMOP limited dataset as of Feb 19, 2021, where 1.2% of records were SDoH observations (n=445222 total; n=231651 pre-COVID; n=213571 since COVID reached epidemic scales). Since Jan 1, 2020, 81.88% of patients (n=101522) assessed for COVID have provided updates to their ‘Employment’ information. Pre-COVID documentation of patient SDoH was sparse though most frequently collecting information on ‘Housing insecurity / Instability / Homelessness’, followed by ‘Employment’, ‘Education’ and ‘Household size’. The earliest indications of FlowSheet adoption for SDoH observations started in Aug 2010 for ‘Housing insecurity / Instability / Homelessness’. FlowSheet documentation for patient ‘Employment’, ‘Education’, ‘Immigration’, and ‘Household size’ began in Aug 2014 and later included ‘Food insecurity’ in Apr 2018. In contrast, since COVID, the Patients-to-SDoH-observations ratio indicates that knowledge about patient SDoH have increased drastically, especially for Employment information; other SDoH observations have been collected at a slower pace and indicate repeated data collection for a small pool of patients.

**Table 2**: Data availability for each SDoH

Since COVID, of the 101552 patients who provided Employment information, approximately 101497 patients described their ‘Employment: current occupation status’. Based on the most recent ‘current occupation status’ information, 34% indicated ‘Full-time’ employment, 27% ‘unemployed’, 18% ‘retired’ and 17% ‘undetermined’, ‘Part-time’, ‘self-employed’ or a ‘student’ status. Only 9.1% of these patients who provided Employment information (n=9344) provided their occupation title. We were able to map 90% of the occupation titles: 46% were ‘retired’, ‘disabled’, ‘unemployed’, ‘self-employed’, or a ‘student’ status. Only 44% of the occupation titles (n=3737) were successfully mapped to the 23 National Trauma Data Standard occupation concepts [https://athena.ohdsi.org/search-terms/terms/44786930], leaving 10% of occupations as unmappable. The discrepancy between 9344 patients and 101552 patients suggests that 91% of patients did not provide their employment occupation titles. Figure 2 depicts the collection of SDoH information for patients within this dataset and the shift in recent months. The recent spike in ‘Employment’ information coincides closely with the phased COVID-19 vaccine deployment (Figure 2b). Collection of SDoH information in all categories since the start of the Pandemic has exceeded or reached within one order of magnitude as the amount collected over the past 10 years.
Discussion

In this study, we characterized SDoH data collected in EHRs at a healthcare delivery institution and stored in the electronic data warehouse. This characterization allowed for queries to extract these data into a common data model that was used for sharing data with a national cohort study. Data were primarily extracted from Epic flowsheet data, which represented assessments in ambulatory care of SDoH. We found that these data varied by type of SDoH data and where it was collected, in the time period that it was collected, and in how it was represented.

The data we collected from flowsheet data involved a process of manually reviewing the data elements that were being used, by ranking them according to frequency and then assessing whether they were SDoH-related. Many of the concepts were available as social history concepts, and standard documentation structures exist in many EHRs in similar ways. However, we found many concepts that were not part of this single approach for collecting data and that often represented multiple assessment tools that may have overlap in content. This is important to recognize with research data sets that may not have specifically identified and queried SDoH data. Unlike more common data elements that are consistently recorded and extracted (e.g., diagnosis and laboratory results), SDoH assessments will be incomplete without focused queries.

Even when attempting to be comprehensive in gathering structured SDoH data, many of the data elements were stored on a minority of patient records. Business and operational concerns, such as subjective screening for program eligibility and clinical and standardized, department-specific intake workflows drive data collection. SDoH observations may be stored on less than 10% of patients seen in health-settings for any specific measure in earlier years, which may be explained by either new programs and policies or by migration from paper to electronic processes. Espinoza et al. provide some understanding to how this occurs with their development of a maturity model on SDoH data. Briefly, the proposed model describes five domains of institutional capacity (data collection policies, data collection methods, technology platforms, analytics capabilities, and operational and strategic impact) across seven detailed levels of maturity adapted for each domain. When SDoH measures are only stored for specific populations conditional on services provided or location treated, it can reflect a combinatorial data completeness problem of assessment, data collection and data accessibility on the different measures.

The change in data availability over time demonstrates these data collection issues and how they reflect the potential use of those data. Employment information as SDoH data is generally pulled from intake forms and demographic information. Until the COVID-19 pandemic, it had been collected for approximately one in 40 patients. During the pandemic, it increased significantly, possibly due to interest in how employment as “essential workers” may affect individuals’ infection risk, employment-linked vaccine eligibility screening, or perhaps a wider concern about employment loss during the accompanying economic effects. There was then a large spike where the majority of patients had employment information documented, coinciding with vaccine deployment. This demonstrated how a targeted need and workflow for collecting data could dramatically change completeness. This was not surprising, but
the magnitude of the change was impressive. This variation also highlights the ways in which standardization into a common data model may lose contextual information related to operational drivers of data collection that may need to be recovered with metadata related to organization, policy, physician practice patterns, and care setting.

Collecting, harmonizing, and tracking SDoH will likely prove incredibly beneficial as addressing SDOH is now promoted to improve population health outcomes and cost savings. An increased understanding of SDOH helps providers connect patients with relevant social services and target vulnerable populations with health-improving social policies and programs. Lofters et al. found that using self-reported SDoH allows primary care centers to identify cancer disparities. Another study screened children for SDoH during well-care checkups and identified that 25% had unmet needs and provided relevant services. Garg et al. conducted a compelling randomized controlled trial that systematically screened all patients using a validated SDoH instrument and saw an increase in the use of community services within their patient population. The work presented in this article provides the basis for ongoing procedure development to address patient SDoH data collection and use for continued benefit.

There remain important limitations to this work. First, this study was done at a single institution in a single region of the country studying SDoH during a period of time where there was increased focus on SDoH. UW Medicine employees and staff were excluded as their COVID testing and prior medical information were considered protected from research use. Data likely looks different in different organizations, though how they differ may reflect more the maturity of SDoH initiatives at the organizations than regional variables. Methods for automated text analysis and taxonomy development may streamline future efforts by analyzing not only text content but incorporating priors from structured and contextual information from FlowSheets. We did not quantify the inter-annotation agreement as a measure for validity; instead, we checked the concept mappings with subject matter experts in EHR data engineering and SDoH data collection. In addition, we studied only data that were collected in structured forms and did not evaluate data completeness compared to information in narrative text reports. The FlowSheet measurements that were mapped did not have survey or version documentation available. Concept mappings and concept coverage are limited to the vocabularies available within OMOP v5.3.1. Other researchers have demonstrated how SDoH variables can be extracted from narrative text and that it significantly increases data completeness. Knowing the extent of the increase could be helpful in determining strategies for increasing SDoH data. Finally, it is unknown whether changes in SDoH data collection represent only changes related to the COVID pandemic and their sustainability. Some monitoring of these metrics will be useful to identify how the data are changing long-term.

Conclusion

Reliable SDoH data are vital for understanding COVID-19 risks and outcomes, as well as for prioritizing medical resources. While there are large amounts of SDoH data available within most EHRs, these data do not conform to common data models, making them difficult to analyze at large scales. There are a multitude of methods for documenting SDoH data. Structured forms in EHR systems can replicate standard assessment instruments, but these forms can vary within and across institutions and may change over time. In order to enable semantic interoperability, we developed a workflow for triaging EHRs for patient-level SDoH then map observational data elements into the OMOP common data model. We found significant data completeness issues, though we identified increases in the collection of specific SDoH elements. Our work demonstrates the feasibility in making SDoH data elements readily available in OMOP data warehouses.

Abstract
Cognitive impairment is a defining feature of neurological disorders such as Alzheimer’s disease (AD), one of the leading causes of disability and mortality in the elderly population. Assessing cognitive impairment is important for diagnostic, clinical management, and research purposes. The Folstein Mini-Mental State Examination (MMSE) is the most common screening measure of cognitive function, yet this score is not consistently available in the electronic health records. We conducted a pilot study to extract frequently used concepts characterizing cognitive function from the clinical notes of AD patients in an Aging and Dementia clinical practice. Then we developed a model to infer the severity of cognitive impairment and created a subspecialized taxonomy for concepts associated with MMSE scores. We evaluated the taxonomy and the severity prediction model and presented example use cases of this model.

Introduction
There are an estimated 5.8 million individuals in the United States (US) age 65 and older living with Alzheimer’s disease (AD), with a projected increase to 13.8 million by 20501. As the sixth-leading cause of death in the US, AD is one of the most significant unmet medical needs of our time2. The Food and Drug Administration (FDA) recently approved a disease-modifying treatment, aducanumab, based on the expected drug’s effect on the surrogate endpoint – 18 years since the last FDA-approved treatment3. Clinical trials are the gold standard for providing evidence on the potential harms and benefits of an investigational treatment, but they are time-consuming and expensive. On average, the development of a disease-modifying treatment for AD requires 13 years and costs $5.7 billion4. This highlights how successful AD clinical trials are crucial.

Eligibility prescreening of potential participants is a major bottleneck to successful AD clinical trial recruitment, even though prescreening has resulted in decreased costs incurred by screen failures due to ineligibility and has helped in strategizing recruitment efforts5. One of the challenges is the determination of the level of cognitive impairment, which is a critical component for determining a potential participant’s eligibility to participate in an AD clinical trial5. The 30-item Folstein Mini-Mental State Examination (MMSE) is the most common measure of cognitive function used in AD clinical trials to define the severity of dementia6. Any score of 24 or more (out of 30) indicates normal cognition. Below this, scores can indicate mild dementia (19–23 points), moderate dementia (10–18 points), or severe dementia (≤9 points)7. However, recent MMSE score (i.e., within one year) is not always readily available in the electronic health record (EHR) and when documented is only found in unstructured clinical notes, rendering it difficult to determine without manual inspection8,9. Given the complexity and the long range of trajectory of changes of AD pathological process over time, determining the patient’s potential eligibility to a clinical trial is challenging without a recent MMSE score. This warrants the research team to consider other documented cognitive symptoms (e.g., increased forgetfulness, worsening word finding difficulty) in lieu of a recent MMSE score, which can result in an inaccurate representation of the patient’s level of cognitive impairment due to research staff’s subjective interpretation of the clinical notes10. Hence, a more efficient way to characterize cognitive status for AD clinical trials is needed.

Unsupervised learning approaches and automated search algorithms have been developed to identify clinical subtypes of AD using EHR narrative11-14. Subspecialized terminology based on keywords and phrases from narrative text were also constructed to classify cognitive impairment11. There are also ontologies available to formally represent AD such as the Alzheimer’s Disease Ontology15, the AD Map Ontology16, and the AlzFuzzyOnto17. The Common Alzheimer’s Disease Research Ontology was developed for AD research working to enable integration and comparative analysis of AD research18. The Semantic Web Application in Neuromedicine was developed to build applications for bench scientists initially for, but not limited to, AD research19. However, to the best of our knowledge, there has been no mapping from cognitive function concepts to MMSE score. Our goal is to develop a subspecialized taxonomy for cognitive status characterization and a model for MMSE prediction using related concepts. In this paper, we identified the concepts pertinent to cognitive function measurement in relation to MMSE from clinical notes and mapped them to the Unified Medical Language System (UMLS). We then developed a model to infer the severity of cognitive impairment and used this to construct a novel taxonomy. This paper reports on a computational method for

# Contributed equally, co-first authors

999
phenotyping cognitive impairment using EHR narratives that has the potential to support assorted downstream tasks, such as identifying patients for recruitment of prospective clinical trials, constructing and describing cohorts for retrospective observational studies, and implementation of supportive tools for providers embedded in EHRs and clinical workflows. These advancements could facilitate a personalized approach to care (therapies and supportive services according to the progression of disease) and provide insight into underlying mechanisms of disease to advance precision medicine. This method could be applied in other contexts with clinically relevant score-based proxies.

**Methods**

Data source and sample selection

This study was approved by the Columbia University Irving Medical Center (CUIMC) Institutional Review Board (#AAAD1873). We purposely selected 150 clinical visit notes, each containing an MMSE score, from 118 distinct patients diagnosed with prodromal (amnestic mild cognitive impairment (aMCI)) or probable AD and seen by CUIMC Aging and Dementia clinicians between February 1, 2020 and November 15, 2020. We extracted the following information from their EHR data: diagnosis (aMCI or AD); the date of visit; type of visit (initial or follow up; in-person or telehealth); MMSE during the visit; language used to administer the MMSE; chief complaint; history of present illness (for initial visits); interval history (for follow up visits); neuropsychiatric symptoms; functional abilities assessment; impression; and plans. Initial visit note is included only if a follow up visit note is available that indicates a diagnosis of AD or aMCI. MMSE score (0-30) was used as the label for this analysis. The eligibility of each patient for each visit was determined solely based on the MMSE score for three AD clinical trial protocols, representing phase 1 (NCT03822208), phase 2 (NCT03282916), and phase 3 (NCT03887455) studies respectively and covering a broad range of MMSE inclusion criterion thresholds (i.e., 16-28, 18-30, and 22-30). The workflow is outlined in Figure 1.

![Figure 1. Workflow overview.](image)

Data preparation and concept extraction

Python 3.6 was used for data processing and analysis. R 4.0.2 was used for descriptive statistical computations on demographic characteristics and the heatmap (using ggplot2). The corpus of extracted clinical text was imported and light text preprocessing was performed. A local version of MetaMap along with pymetamap was used to parse the clinical text and extract concepts. The objects that are extracted with pymetamap contain information about the terms tagged, including the UMLS Concept Unique Identifier (cui), semantic types (semtypes), the phrase that triggered the mapping (trigger), negation (1/0 last digit of trigger), scoring information on the quality of the concept match (score), and location codes (location, pos_info, tree_codes). An example MetaMap Concept Object is shown below:

```python
ConceptMMI(index='5', mm='MMI', score=5.18, preferred_name='Ability to Drive', cui='C4050139', semtypes=['[inpr]', triggers=['Driving'-tx-3-"driving"-verb-0'], location='TX', pos_info='137/7', tree_codes='')
```

Feature selection

After concepts were extracted, we experimented with different methods of selecting concepts for inclusion in subsequent modeling. Filtering based on semantic types was a particularly fruitful approach, specifically for excluding irrelevant or off-topic categories and ultimately selecting the ones used in the final model. Clinical expertise was also applied to review the remaining corpus and manually remove any CUIs that were not relevant (e.g., “wellplate”). We decided not to filter based on MetaMap score because even low scores (within relevant semantic types) matched well when manually compared in the patient chart. Finally, concepts occurring in >98% of notes or <2% of notes were omitted for their low salience or low prevalence.

Feature vector

MMSE score (0-30) was used as the outcome variable (label) for the regression model, and each concept feature (extracted from the EHR via MetaMap) was represented as 1 if it was present in the clinical note, 0 if absent, and -1...
if present but negated. Several sociodemographic features were also included in the feature vector, specifically: age (standardized), language (Spanish), and sex (male).

**Model training and evaluation**

**Split dataset.** The full dataset was split 80/20 into a training and test dataset. The training dataset (n = 120) was used to train the model, and the testing dataset (n = 30) was held out and after training was complete, the model was evaluated on this unseen testing set.

**Parameter tuning.** Regression with Lasso is useful for feature selection and modeling at the same time, producing a sparse matrix of features that are relevant in predicting an outcome of interest. The Lasso penalizes each additional model parameter, driving the coefficients towards either 0 or inclusion in the model. In training the model, we experimented with different alpha parameters between 0.05 and 0.4. These parameters resulted in inclusion of more or fewer concept features in the final model, with varying performance on metrics across the data. In the end, an alpha parameter of 0.25 resulted in a reasonable model that was sparse and not overfit or underfit.

**Model parameters and evaluation.** The magnitude and direction of association for final model parameters are returned from the model training and can be used to calculate predicted MMSE scores for a set of feature vectors. The concepts selected by the model were inspected to determine broad categories for important terms, and to examine positive or negative associations between concepts and cognitive status and the magnitude of this association. The R-squared value and Root Mean Square Error (RMSE) were used to evaluate the model, comparing performance on both the training and held-out test data. Sanity checks were performed across a subset of the clinical notes, to verify if concepts extracted and included as important were indeed present in the clinical text and used in the way assumed from the mapping.

**Taxonomy development and evaluation.** The final concepts selected by the model were then used to generate the novel taxonomy by card sorting iteratively among authors (BI and AP) until consensus was achieved, led by BI who has domain experience in this clinical setting. The face validation of the final taxonomy was evaluated by two independent clinicians, a nurse practitioner who sees individuals with AD in clinical and research settings and a lead clinical research coordinator of an AD research center.

**Results**

**Study sample and MMSE-based eligibility**

The study sample (Table 1) included 118 distinct patients corresponding to 150 clinical visits notes (63% female, 50% White, and 53% Non-Hispanic) with mean (SD) age of 74.3 (8.3) years. Of these clinical notes, 49 (33%) visits were conducted in person and 101 (67%) visits were completed via telehealth. A majority of the clinical notes were from follow-up visits (73%). The sample includes a total of 117 (78%) notes that indicate a diagnosis of AD, while 33 (22%) indicate aMCI. Mean (SD) MMSE score was 20.2 (7.1), representing the full range of possible scores. A majority of the MMSE tests were administered in English (82%). Eligible patients based on MMSE are 112 (75%), 106 (71%) and 76 (51%) respectively for the phases 1-3 trials in order. The sample includes 118 clinical visit notes of patients who were deemed eligible to participate in one, two, or all of the research protocols during that particular visit, showing many patients are eligibility for more than one study. Of these notes, 61% (n=71) indicates that the patient was eligible in all the three studies. A total of 32 clinical visits notes document visits with patients who are too cognitively impaired (i.e., MMSE < 16) to be considered for any of the trials.
Final model and concepts selection

A total of 5569 total unique concepts were extracted from the clinical notes for the initial corpus. After expert inspection by BI, a total of 18 UMLS semantic types were included to identify and select relevant concepts (Table 2). After filtering, 1775 unique concepts remained in the corpus. Table 3 shows concepts that were mentioned more than 90 times. The final model (Table 4) includes 40 features, including 39 concepts and age (standardized), with an alpha parameter of 0.25.

Exploration with dimensionality reduction

We intended to use the concepts extracted from the regression with Lasso modeling to generate the novel taxonomy through unsupervised clustering methods. Before doing so, we inspected potential patterns that may structurally exist in the data by mapping the data from a high-dimensional space to a two-dimensional space with points colored by
outcomes of interest (severity, study eligibility, provider, and language) using Uniform Manifold Approximation and Projection (UMAP). The dimensionality reduction embedding of the feature vector returned from the Lasso (i.e., the final model parameters) is not useful in discriminating between any of the useful outcomes of interest specific to clinical trial eligibility for a particular protocol (Figure 5). In fact, the plots that show the dimensionality reduction embedding using just the sparse feature vector returned from the model did not show any discernable clustering at all.

Figure 5. UMAP Projection of all feature concepts returned from the Lasso by clinical trial protocol eligibility: (a) phase 1 study (NCT03822208); (b) phase 2 study (NCT03282916); and, (c) phase 3 study (NCT03887455).

To explore further, embeddings were generated and visualized for not only the feature vector returned from the model, but also the vector of all relevant features and the input feature vector from the modeling step (Figure 6). A distinct cluster is noticeable when all features are included, and this is still the case for the embedding using only the features that go into the Lasso regression (i.e., after filtering based on semantic type, the cluster still emerged in the embedding). However, this distinct clustering is gone when only features from the final regression with Lasso model were included, suggesting that our model was able to smooth out this underlying structure (and remove concepts that might confound the results).

Figure 6. UMAP Projection of feature concepts by (a) dementia severity, (b) provider, and (c) language of MMSE administration.

After further investigation, the observed difference probably relates to the difference in provider (Figure 6b). The embedding plots suggest that the blue and the tan providers are outliers; it turns out that these two providers work together in one of the AD centers in the department where they see many of the Spanish-speaking patients (Figure 6c). These differences in concepts extracted by provider were not clear upon manual review of the charts; in fact, the charts seemed on the surface to resemble all of the others. When the two providers (who work together) were removed from the dataset, the natural clustering in the dimensionality reduction disappears. However, we decided to keep the two providers in the final analysis because this better represents real-world practice.
**Evaluation metrics**

The plots below (Figure 7) show the true MMSE score vs the MMSE score predicted by the model, for both training and test data. A perfectly accurate model would show dots along the red reference line y=x. Indeed, at higher MMSE scores, the model is fairly accurate and clustered around this reference line. At lower MMSE scores, the model is much further off with the prediction. Considering the R-squared value, the final model explains 60.1% of the variance in the training data and 31.8% of the variance in the test data.

Figure 8 shows the difference between the predicted and true MMSE score, and we again see that lower true MMSE scores were not predicted very well by the model for either the training or test data, but higher scores were not as far off. If the scores were fully accurate, the dots would line up on the red y=0 reference line.

It is to be expected that for both training and test data, lower scores would be predicted higher and higher scores would be predicted lower when compared to the ground truth. The training data has a Root Mean Square Error (RMSE) of 4.6 and the test data returns an RMSE of 5.0. While still a wide margin, a predicted score that is about 5 points off in either direction would still be helpful in prescreening records to accomplish the clinical task.

![Figure 7. True and predicted MMSE score, with Regression + Lasso](image)

**Final model concepts and novel taxonomy**

We constructed a novel taxonomy (Figure 9) by using iterative card sorting of the concepts identified in our model (Table 4) and evaluated its face validity among clinicians in aging and dementia practice. The taxonomy includes concepts within the domains of the MMSE (i.e., orientation, concentration, working memory, memory recall, language, and visuospatial), and concepts representing domains outside of MMSE that are incredibly important and relevant for determining cognitive status functioning decline in AD such as agitation and home environment. The final classes include memory and cognition, activities of daily living, mood and behavior, medical, and descriptors.

The negative coefficient means that if a concept is present, the MMSE score is lower, and a larger magnitude is associated with a larger drop in MMSE score. In our quality check, the following selected concepts were substantiated by an excerpt from clinical notes: concept “Usually Need Help from Another Person for Eating” from excerpt “would not let him (son) feed her”; concept “Unable to Feed Self” from “discussed feeding tube and palliative care”; concept “Has difficulty doing” from “recently having difficulty with calculation”; and concept “Better than Others” from “he thinks his memory is better than his peers”. Further, the standardized age is associated with lower MMSE, which is expected. There are two concepts in the descriptors category that fall under “Spatial Concept” semantic type (i.e., local and adjacent), two concepts under the “Finding” semantic type (i.e., unable and better than others), one concept under the “Therapeutic or Preventive Procedure” semantic type (i.e., change – procedure), and the rest under the “Functional Concept” semantic type.

Further analysis of the data via visualization revealed that the use of concepts, both present and negated, may vary across the levels of cognitive impairment (Figure 10). Concepts pertaining to activities of daily living (e.g., grooming)
were used more in clinical text of patients with severe cognitive impairment. Interestingly, “restlessness” was used across the level of cognitive impairment but increasingly so as the cognitive impairment progresses. Further, the negated concepts were mostly observed in the clinical texts of patients with no to mild cognitive impairment.

Figure 9. Subspecialized taxonomy for characterizing cognitive status of patients with aMCI or AD.

Discussion

The current study demonstrates that narrative text from outpatient clinical visit notes of patients diagnosed with aMCI and AD could be instrumental in indicating the level of cognitive impairment for AD patients. Consistent with the literature, we used a data-driven approach to derive five categories of concepts corresponding to MMSE scores: cognitive, functional, behavioral, medical, and descriptors. These findings provide an important, albeit preliminary, foundation for informing expansions of existing concepts related to a specific proxy (i.e., MMSE score).
Our findings regarding the content and classification of cognitive impairment concepts provide a preliminary understanding of potential challenges for using EHR notes in automated prescreening approaches. First, there are concepts that are frequently used with different meanings in different contexts. For example, the term “local” is used to describe the proximity of clinical care (e.g., local neurologist) or a symptom (e.g., local tenderness). Examining documentation patterns across varying points of care (e.g., follow-up visit) and expanding the analysis of terms to other neighboring terms may provide additional information for the disambiguation of these concepts. For example, the term “feed” may not refer to the patient’s ability to feed oneself but of forgetting to feed a pet, which is still critical in classifying the impairment as memory and cognition or activities of daily living but also different than other uses. Further, the frequency of the terms used varies across the level of cognitive impairment progresses. For example, terms related to the concepts “grooming” and “restlessness” are more frequently used in clinical notes of patients with severe cognitive dementia; conversely, the use of terms related to the concepts of “hallucinations” and “tremor” decreased from normal cognition to severe dementia.

Figure 10. Percent of clinical text with concepts across the level of cognitive impairment, by taxonomy category.

Provided the high prevalence, cost, and mortality associated with AD1—and the urgent goal of the National Alzheimer's Project Act’s (Public Law 111-375) National Plan to Address Alzheimer's Disease to prevent and effectively treat AD by 20252—meeting recruitment goals for AD clinical trials have important scientific, clinical, financial, ethical, and policy implications28. Study findings have the potential to improve recruitment rates for AD clinical research and subsequently accelerate further development of an efficacious disease-modifying treatment for AD. Availability of a specialized taxonomy commonly used in AD clinical care documentation has the potential to bolster eligibility prescreening approaches for clinical trial recruitment. Future work to further develop and refine the model across broader range of patients, providers, and institutions should focus on expanding the model’s capacity to utilize clinical text with symbolic knowledge representation such as building into the model ways to include and infer from relevant broader and narrower concepts. For example, the concept “hallucinations” has “behavioral/psychiatric manifestations” as a parent concept and “sensory manifestations” as a grandparent concept, which are useful to interrogate for future inclusion in the model; on the other hand, “substance withdrawal severity” and “hypocalcemia severity” would not be relevant; finally, “general symptom” may be useful but is very broad. The present study derives potential concepts for inclusion in future ontologies and phenotypes, which can serve as the foundation of developing clinical decision support for clinicians and research teams to identify cohorts for AD clinical research and focus their time and effort into other aspects of research and clinical care such as recruitment and patient education29. Future work should examine the predictive accuracy of the terms used in clinical text and how these maps to UMLS concepts in determining AD clinical trial eligibility across different patient samples and EHRs. It would also be interesting to develop a longitudinal account of disease with the approach to computational phenotyping described in this study.

Limitations

The study has some limitations. The first limitation is the use of retrospective data of patients with two specific diagnoses (aMCI and AD) documented in EHR notes by ten specialists in a single subspecialized clinical practice in a quaternary academic medical center. This design strengthens internal validity, which is important in this early stage.
Moreover, there may be local variation in the terminology used within this single clinical practice, and these findings may not be generalizable to other settings or other EHR systems. As there is no mandate for MMSE testing at any particular visit, each provider perceives and documents different information (particularly across provider type), including the MMSE score; some providers may skew towards new patients, initial visits notes may be written by a clinical fellow or nurse practitioner under the provider’s supervision, time spent with patients may vary widely, and the clinic was newly conducting telehealth visits due to the COVID-19 pandemic. Future research evaluating different data sources and settings is needed to understand whether and how documentation patterns specifying cognitive function vary across services and EHRs. Additionally, while the present study included important sociodemographic factors such as age and language, other relevant factors such as education and date of the previous MMSE were not included due to dispersed EHR phenotypes and fragmented EHR data. As such, future research should investigate these factors using a much larger and more representative corpus including various clinical texts including discharge summaries and clinical notes.

As this study explored concepts in the clinical visit notes of patients diagnosed with aMCI or AD, these concepts may only represent concepts that clinicians who subspecialize in aging and dementia are more accustomed to using. Future research is needed to determine whether the concepts in this taxonomy are consistently used by clinicians across a different range of specialties (e.g., general neurology, primary care) and diagnoses. We could also expand the data corpus to include notes from general medicine and could consider using pretrained embedding models as an alternate approach. The present study focused on identifying terms used by clinicians to describe cognitive symptoms based on MMSE. However, other comorbidities such as stroke, epilepsy, or other neurodegenerative diseases may also affect cognitive symptoms in addition to AD. Future prospective research should aim to identify terminology that may be unique for AD or AD alongside other comorbidities. Further, we did not look at the presence or absence of AD biomarkers result to further confirm the probable diagnosis, and the medications that the patients were taking during the MMSE testing, which may affect the patient’s performance. Finally, as this study represents an initial derivation of a subspecialized taxonomy from a gold-standard diagnostic group only, although the whole MMSE range was covered, it did not include matched controls. Further development and refinement of subspecialized taxonomy to characterize cognitive function will benefit from identification of common data features in the EHRs of patients with subjective cognitive complaints, which was not addressed in this study.

Conclusions

In this study, we introduced a subspecialized taxonomy based on concepts in clinical text to assist in characterizing cognitive impairment without using MMSE scores. Our work demonstrates the feasibility of subgrouping of patients using their EHR notes even when MMSE scores may not be directly available. By leveraging clinical narrative notes, a proxy of cognitive impairment was constructed using symbolic knowledge representation and computational modeling. This method could improve the efficiency and accuracy of cohort identification based on cognitive function for AD clinical research regardless of the presence of a recent MMSE score in the patient chart. We conclude that utilization of specialized taxonomy is a suitable approach to extract concepts from clinical notes and this approach may be more portable and generalizable than a purely computational approach and could possibly be used to infer the severity of cognitive impairment and provide interesting clinical insights. Future work is warranted to test how this approach may generalize to other domains for developing proxies for clinically relevant indicators or formal scores using narrative clinical notes and symbolic methods.

NetworkSIR and EnvironmentalSIR: Effective, Open-Source Epidemic Modeling in the Absence of Data

Abstract
The rapidly changing situation characterized by the COVID-19 pandemic highlighted a need for new epidemic modeling strategies. Due to an absence of computationally efficient models robust to paucity of reliable data, we developed NetworkSIR, a model capable of making predictions when only the approximate population density is known. We then extend NetworkSIR to capture the effect of indirect disease spread on the progression of an epidemic (EnvironmentalSIR).

Introduction
The COVID-19 pandemic has led to over two million deaths worldwide.1 While the recent emergency authorization of effective vaccines has signaled a potential end to the spread of SARS-CoV-2, the pandemic has emphasized the importance of understanding the mechanisms that drive epidemic development, to better manage future pandemics. Computer models and/or simulations can provide useful insights on disease spread in a given population such as predicting or modeling the effect of public health policies (such as self-quarantining) without having to enact them2.

While studying disease spread has traditionally been the domain of epidemiologists, public health experts and, more recently, machine learners, there are clear benefits to examining this issue through the lens of distributed systems (a subfield of computer science). The numerous agents within a distributed system can exploit the inherently parallel nature of disease modeling, allowing for massive increases in computational efficiency compared to traditional, serial methods. These advances in efficiency can allow researchers to perform larger and more complex simulations—which consider more complexities—yet require similar resources.

To demonstrate the utility of a distributed systems approach to modeling, we propose and justify a basic implementation of Kermack and McKendrick’s SIR1 (susceptible, infected, removed or recovered) model as a distributed system, dubbed NetworkSIR. We then highlight NetworkSIR’s extensibility by including a modification to create EnvironmentalSIR, which is able to capture a different phenomenon of interest, namely the indirect disease (without direct person to person contact) spread which occurs through objects or air. To further facilitate scientific research on this subject the source code of both models has been made publicly available under the GNU General Public License v3.1

Lastly, while the problem of studying disease spread has persisted for centuries, many of the ideas presented here are new. We believe that NetworkSIR is the first distributed mechanism of simulating disease, and EnvironmentalSIR is the first network-based model capable of capturing indirect disease spread as it is transmitted from the environment to a human3, as opposed to exclusively from human to human. Understanding the effect of environment-to-human based disease spread is particularly important, as it is not currently well understood in the context of computational epidemic modeling. Having a model that can elucidate the effect of such transmission could play a vital role in guiding policy decisions regarding visiting public spaces and restaurants during epidemics.

Previous Work
Kermack and McKendrick developed one of the first and most important population disease transmission models which was both simple and reasonably accurate. The proposed SIR model was compartmental in nature; the population of interest is partitioned into compartments, or categories, based on the characteristics of the population. Specifically, a population was partitioned into those who were ‘Susceptible’ to the disease, those who had become

1 Please refer to https://madisonpickering.github.io/publications_pdfs/NetworkSIR_EnvSIR_repoLinks.txt to access the code.
2 An example of disease spread through the environment to a human is disease spread by touching a surface with infectious material, then touching one’s mouth, nose, or eyes and becoming infected.
‘Infected’, and those who were ‘Removed’ from the population secondary to past infection, where “Removal” included death or immunity to the disease. Epidemics were then “simulated” by using differential equations to show the flow of individuals between compartments.

The SIR model describes the occurrence of an epidemic as depending on two factors:

1. The inherent “infectivity” of the disease
2. The population density of the susceptible population

As many disease-specific factors contributing to its “infectivity” are difficult or impossible to modify by humans, considerable research has been devoted to understanding the effect of non-homogeneous population density on epidemic spread for which it is necessary to understand human social structure. An Infected individual with a broad social network may infect more individuals (simulating the effect of a higher population density) than an individual who may only interact with a small number of contacts.

The tendency of humans to interact with others based on their own personal preferences is referred to as non-homogeneous mixing. Homogenous mixing in contrast considers that a contact between any two individuals occurs randomly, but uniformly, across the population. From a modeling perspective, the effect of non-homogeneous mixing is reduced as a population size approaches infinity, at which point homogenous mixing may be assumed. As we will focus only on the more common scenario of a non-infinite population size, we will similarly confine our discussion of previous work to three broad paradigms which each reject the homogenous mixing assumption.

Firstly, we discuss Cellular Automata based approaches, which build off the concept of Cellular Automata as first pioneered by John Von Neumann and Stanislaw Ulam. In this method, epidemiological simulations take place on some finite, two-dimensional grid, where each point or cell within the grid is represented as a finite state automaton. Each automaton can represent an individual or subpopulation, depending on the way the simulation is described. The automaton use the states (e.g., Susceptible or Infected or Removed) of a small number of their physical neighbors to derive their next state. This approach’s key limitation is its restricted capacity to incorporate non-random mixing. Typically, each individual or subpopulation is allowed to mix with either four or nine neighboring cells: the automaton’s Moore’s Neighborhood or Von Neumann Neighborhood.

In contrast, Bayesian Network approaches (of which we include Hidden Markov Models as a subset) are able to incorporate non-homogeneous mixing without any restrictions. These approaches typically model individuals as nodes in the Bayesian Network and include edges between individuals which represent their capacity to infect another. Only a node that has an edge to another node may directly infect that other node. A number of features (essentially, any recorded data the researcher thinks are important, for example age) are associated with each node, and infection is determined by making probabilistic predictions about the likelihood that a node will infect another. Using a series of these predictions, a Bayesian Network can simulate an epidemic with an impressive degree of specificity.

While Bayesian Network approaches are the most powerful in terms of realistic predictive ability, they also require a large amount of individual-level input to make these predictions. Furthermore, most operations (e.g., training, prediction) with Bayesian Networks are prohibitively computationally expensive as the network grows in size, limiting their current utility to very small scale simulations. Lastly, Bayesian Networks require that no cycles (loops) exist in their node topology. Despite these restrictions, Bayesian Network approaches can still produce impressive results.

Finally, we discuss Contact Network based approaches, which reject homogeneous mixing at a level between Bayesian Networks and Cellular Automata models. Like Bayesian Networks, Contact Networks model humans as nodes and require an edge between two nodes if one individual may potentially infect the other (assuming that one of those humans is infectious). As a result of defining interactions in this manner, Contact Network based models place no restrictions on the amount of non-homogenous mixing that can be represented. This potentially allows for very realistic simulations at an individual level, similar to Bayesian Network approaches. Furthermore, Contact Network based models are not inherently computationally prohibitive, since the asymptotic time complexity of simulating an epidemic is largely up to the researcher. Many researchers have attempted to adapt the SIR model to such a network due to the SIR model’s relative accuracy despite its simplicity. However, there remains little consensus on how exactly SIR should be adapted to a network. We thus propose NetworkSIR as a way to provide a common ground for researchers interested in epidemic modeling using Contact Networks.
NetworkSIR

The general idea behind NetworkSIR is to use the social structure of a population as input, then apply SIR dynamics with respect to that social structure. By social structure, we refer to humans and their daily close-proximity interactions (CPIs). In a divergence from traditional methods of adapting SIR dynamics to a network, we explicitly model the infectious material responsible for infection as small tokens called “agents”. For an Infected individual to infect a Susceptible individual, that Infected individual must pass an agent to the Susceptible individual along its edge. This mode of modeling infection was inspired by the rumor-spreading algorithm models proposed by Giakkoupis et. al. and its verisimilitude with viral or bacterial vectors.

NetworkSIR simulates an epidemic as follows:

1. **NetworkSIR** uses the social structure of a population of interest as input. This social structure is specified as a list of nodes and edges, where each node represents a human and each edge represents a close proximity interaction (CPI) between those two humans.
2. The entire population of interest is initialized as Susceptible, with the exception of a very small number of individuals who are Infected.
3. The simulation then occurs in a series of rounds, where each round is equivalent to some time period (e.g., a day). In each round, the following transitions occur:
   a. The individuals who are Infected have some probability to infect the nodes that they have edges with. This is done by passing agents from the Infected node along the node’s edges. The mechanism behind this is discussed in more detail later.
   b. A node that has been Infected transitions to being Recovered after some number of rounds, denoted as the Recovery Threshold.

The simulation ends when either no further infection is possible or a predetermined round limit has been reached. Figure 1 depicts a small sample simulation.

![Figure 1: Simulation of NetworkSIR With Three Individuals and Recovery Threshold = 2](image)

**Figure 1.** A sample simulation of NetworkSIR

It is impossible for further infection in the system to occur beyond the third round; once a node has been infected, it cannot become reinfelected. Consequently, once node A receives the agent passed to it by node B, it will simply discard it. Furthermore, Node C cannot directly interact with Node B, due to the lack of an edge between them. While it is not shown here, the simulation will actually run for another round until node B recovers for reasons related to computational efficiency. Intuitively speaking, it is less computationally intensive for each node to report if it is Recovered than for that node to perform a search on the nodes around it and determine if it is in some path that could result in further infection. Furthermore, each round only runs for as long as is required computationally. In a round where no infection is possible, the nodes will simply begin the round, nothing will happen, and then they will terminate.

A major shortcoming of Contact Network based models is the lack of consensus regarding the implementation of SIR dynamics within the network. This typically manifests as individual research groups defining their own equations for how to simulate the compartmental transition from Susceptible to Infected (the process of infection)
and the transition from Infected to Recovered. While this is not inherently problematic, the equations used to govern those transitions usually lack robust justification and source code is often not available\textsuperscript{6, 9, 10, 11, 12}. This makes comparison and evaluation among models difficult or impossible.

By providing extensive justification\textsuperscript{2} for the mechanisms that NetworkSIR uses to simulate an epidemic, we hope to inspire a “common ground” for Contact Network based models going forward. Specifically, we provide justification for the two transitions responsible for simulating SIR dynamics in NetworkSIR, based on real-world data.

**Transition Type 1: Infection**

Infection in NetworkSIR occurs when an Infected node sends an agent to a Susceptible node. But, how does an infected node determine which and how many node(s) it should send an agent to if it has more than one edge? Furthermore, by what mechanism should agents be created?

To answer these questions, we make the following two assumptions:

1. The probability of an Infected individual ‘x’ infecting a Susceptible individual ‘y’ correlates linearly and positively with the duration of the CPI of x and y. Mathematically, this gives the following equation:

\[ P(\text{infection}) = k \cdot (\text{CPI}_{\text{duration}}) \quad k > 0 \]

This roughly equates to the assumption that if two individuals x and y are in close contact for an extended period, then it is more likely that infection will occur than if they were in contact for a brief period. This additionally implies that each second (or other time unit) of a CPI is as dangerous as any other.

2. Every Infected node uses the same mechanism that drives infection. This does not mean that each Infected node will always infect the same number of people, but rather, an algorithm which accurately describes the mechanism of infection for one Infected node (taking as input that node's CPIs/social relations) will be applicable for all Infected nodes. This has the important consequence that only one algorithm must be developed, rather than a new algorithm for every individual node.

From the above assumptions, we conclude that if we can determine a mechanism by which one can determine the duration of a CPI, we would be able to determine (relative to the individual) the probability that the individual will infect another. This would make it possible to determine the likelihood that an individual would infect a given person in their social circle as opposed to infecting another. However, first we must determine the mechanism which determines the length of a CPI, given that a CPI occurs. Mathematically, we must first find, for any individual i:

\[ P_i(\text{CPI with duration } t | \text{CPI}) \quad \forall i \]

We identified two cases\textsuperscript{4} by which we can calculate this probability: using a probability distribution given necessary parameters, or by approximating it using regression analysis. To generate these statistics, we used a contact network consisting of over 700 individuals and their CPIs, along with the duration of those CPIs, as collected from a U.S. high school\textsuperscript{10}.

We began by graphing the P(CPI with duration t | CPI) at both the individual and population level for the data set to determine by visual inspection which probability distributions might create an appropriate fit. We included the Binomial, Poisson, and Geometric distributions in our analysis. Of the continuous probability distributions, we included the Gaussian/Normal distribution, as certain formulations of the Central Limit Theorem applied to discrete probability distributions will yield a Gaussian/Normal distribution. Of the distributions, only the Geometric distribution appropriately fit the graphed data. We then applied Pearson’s Chi-Squared Test for Goodness of Fit\textsuperscript{18} with the following hypotheses:

1. H0: individual i’s CPI durations are Geometric Random distributed
2. H1: individual i’s CPI durations are not Geometric Random distributed

\textsuperscript{3} Due to page count limitations, we cannot elaborate in as much detail as we would like and still discuss all our results. For more details, refer to chapter 3.3 of “NetworkSIR and EnvironmentalSIR: Two Simple Distributed Mechanisms for Modeling Epidemics”.

\textsuperscript{4} We note that this analysis is mathematically insufficient to constitute a proof as there is a third possible case: the probability might be better approximated with some other method. However, it is infeasible to try the literally infinite number of alternatives (neural networks, etc.) and evaluate their performance with respect to each other.
All tested individuals rejected $H_0$ by a very large margin, with $P = 0.001$. Thus, we can say with high certainty that each individual's CPI durations are not Geometric Random distributed. Furthermore, since several probability distributions were tested for goodness of fit, and the Geometric Random distribution created the best fit yet was still insufficient, we conclude that it is unlikely that an individual's CPI durations can be expressed natively as a probability distribution.

Regression analysis provided a better fit. We performed linear, logarithmic, exponential, polynomial, and power series regression. Of these, the power series yielded the best fit with an $R^2$ value of 0.8636 (Figure 2). Figure 2 was generated by calculating the probability of each individual $i$ having a CPI of a given duration, given that $i$ would have a CPI. Each discrete CPI (and its probability of occurring) has its own point in Figure 2. We recorded 19,789 CPIs and their respective probabilities.

![Figure 2. The probability of a CPI of a given duration occurring](https://via.placeholder.com/150)

Since we have found an appropriate way of calculating $P_i$ (CPI with duration $x$ | CPI) $\forall i$, we can now fully propose a method of calculating $P(\text{infection})$. Knowing $P(\text{infection})$ can be used to assign relative probabilities that an Infected individual $i$ will infect a Susceptible individual $x$ as opposed to Susceptible individual $y$, given that $i$ has CPIs with both $x$ and $y$. These relative probabilities can then be scaled (normalized) such that their sum is equal to one for each individual. In the larger context of the NetworkSIR simulation, we can assign these relative probabilities to the edges of each node resulting in a probabilistic infection dynamics consistent with real-life behavior. We refer to this process as edge-weighting, and the steps are as follows:

1. Generate some probability $y$ using a Uniform Random Distribution
2. Use the equation given by regression analysis to calculate the associated CPI for that duration. Rounding to the nearest hundredths place and solving for $x$ (CPI duration) yields $x = \left(\frac{0.06}{y}\right)^{\frac{1}{17}}$
3. Weight the edge such that it is equal to the CPI duration calculated in step 2
4. Normalize all edge weights for a node such that they sum up to 1

When a node sends an agent, the edge weights above are used to determine who to send the agent to. To determine when to send an agent, we use the parameter $P(\text{Stay})$, equal to the probability that an infected node will not send an agent in a given round. It should be noted that non-pharmaceutical interventions such as handwashing and wearing of masks would alter $P(\text{Stay})$ by increasing it. Finally, to address the issue of when an Infected node should generate an agent, we require that an Infected node should always have the opportunity to infect other nodes. Therefore, only in the case that an Infected node begins a round without any agents will an agent be generated.

**Transition Type 2: Recovery/Removal**

We utilize a scalar value denoted as the Recovery Threshold to determine when a node should recover. Specifically, a node recovers if it has been infected for a number of rounds greater than the Recovery Threshold. This is motivated by the following:
Variations in recovery time are largely dependent on individual-specific factors (such as age, comorbidities, etc.), and we have previously assumed that these data are unknown. Further, individuals suffering death have a shorter period to “Recovery” than those who recuperate.

Randomness is already present in the model through our defined mechanism of infection.

Using a Recovery Threshold prevents nodes from remaining Infected for arbitrarily long amounts of time.

The parameter “Recovery Threshold” is naturally captured. It is a common practice to note how long individuals on average require to recover during symptom monitoring or how long it takes to die.

Readers interested in more implementation details and pseudocode should refer to chapter 3.4 of “NetworkSIR and EnvironmentalSIR: Two Simple Distributed Mechanisms for Modeling Epidemics”.

Evaluation

We evaluate our performance using two measures: the ability to 1. capture SIR dynamics, and 2. to predict the total number of individuals infected over the course of a pandemic with reasonable accuracy. To evaluate the former, we execute NetworkSIR with parameters designed to infect every individual: \( P(\text{stay}) = 0.8 \), Recovery Threshold = 30, and five initially Infected individuals. NetworkSIR is run over the same contact network used earlier which consisted of 789 individuals from a U.S. high school.  

!["Ideal" SIR Graph](image)

**Figure 3.** NetworkSIR graph showing asymptotic behavior

The results in Figure 3 highlights NetworkSIR’s major benefit over SIR. NetworkSIR produces a more symmetric infection curve, caused by eliminating SIR’s probabilistic mechanism of recovery/removal. A typical SIR graph’s infection curve tapers off more slowly, which equates to the assumption that as a pandemic continues individuals will take longer to recover or die. This assumption is not supported by facts. Thus, we feel comfortable claiming that NetworkSIR maintains a useful application of SIR dynamics in a network.

We now evaluate NetworkSIR’s prediction accuracy. We used statistics obtained from seasonal influenza to provide parameters for our simulation. The Recovery Threshold was determined by data from Harvard Health\(^1\) and the WHO\(^2\), which yielded an average recovery threshold of 5, and \( P(\text{stay}) \) was set to 0.78. NetworkSIR was then run for 500 simulations, and yielded an average of 16.7 percent of the population infected. Data from the NIH indicates that the worldwide average epidemic size is approximately 9% of a given population, while in the US it tends to be closer to 20%.

Data from the WHO\(^2\) similarly provide an estimate of 5-15%. Due to the fact that schools are notoriously densely populated (and thus should theoretically tend to the upper limit of percentage infected) we deem NetworkSIR’s prediction of 16.7% reasonably accurate.

Running NetworkSIR on a much smaller network consisting of 34 individuals and 78 edges\(^3\) for 500 times with the same \( P(\text{stay}) \) and Recovery Threshold parameters (but only one initially infectious individual) yielded an average epidemic size of 10.5%. We consider this a reasonable estimate, as it remained well within NIH and WHO predictions and is lower than the estimate obtained from the high school contact network—which represented a population with a higher population density. As NetworkSIR was able to provide reasonably accurate predictions
given two inherently different populations, we find these early results to be promising indicators of NetworkSIR’s potential for predicting a pandemic’s course.

EnvironmentalSIR

A key advantage of modeling disease spread explicitly through agents is that the effect of environment-to-human disease spread can be examined—particularly the effect of high-contact surfaces. To examine this, we modify NetworkSIR to have a new compartment, “Environment”. Environment nodes cannot transition to any other compartments, but can still infect nodes. To reflect the fact that most infectious material cannot survive outside of a living host, we define a “Sanitation Threshold” for Environment nodes. After ‘Sanitation Threshold’ number of rounds have passed, any agents residing within the Environment node are removed. By varying the length of the Sanitation Threshold, the effect of sanitation frequency (or, differences in the ability of infectious material to survive on surfaces) can be examined. A sample simulation of EnvironmentalSIR is shown in figure 4.

![Figure 4. A sample simulation of EnvironmentalSIR](image)

Although no further infection is possible, the simulation will continue for another round (until node B recovers). No further infection is possible as D is sanitized in Round 3, removing the agent that was passed to it in Round 2, and as before, only Infected nodes can generate agents.

To summarize, Environmental Nodes essentially perform two actions: infection and sanitization (i.e., the removal of agents after Sanitation Threshold number of rounds have passed). While Environmental Nodes cannot directly generate agents, we allow them to probabilistically pass any agents they might have to the nodes they have edges with using the same mechanism as Infected nodes. Environment Nodes in the context of the network represent high-contact surfaces that multiple individuals are regularly in contact with. As such, an edge between a node (representing an individual) and an Environment Node (perhaps representing a grocery store card-reader) represents the potential capacity of that individual to become infected through contact with the Environment Node.

Results

Due to the lack of prior work examining the effect of indirect disease spread in the context of the SIR model, we are unable to discuss the predictive ability of EnvironmentalSIR to capture “ideal” SIR dynamics. Instead, we provide comparisons between EnvironmentalSIR and NetworkSIR when parameterized with the same values. In particular, we evaluate the effect of varying the Sanitation Threshold and the number of Environment Nodes on the resulting epidemic dynamics.

As before, we run the simulation 500 times and report on the resulting statistics. We again use the same high school contact network, but this time randomly choose ten individuals (per run) to represent Environment Nodes. We set the Sanitation Threshold to be equal to two rounds. This resulted in a final average epidemic size of 14.2%, a reduction of 2.5%. Increasing the Sanitation Threshold to 5 rounds and holding all else constant yielded an average
epidemic size of 14.6%, a 2% increase. However, there were frequent cases in which small, secondary outbreaks occurred. Figure 5 depicts an execution of the simulation in which this occurred.

![EnvironmentalSIR Graph With Repeated Outbreaks](image)

**Figure 5.** Multiple outbreaks caused by the introduction of Environment Nodes with infrequent sanitation.

Further increasing the Sanitation Threshold to ten rounds resulted in a final average epidemic size of 15%. However, the number of secondary outbreaks increased as well. We therefore conclude that the primary effect of infrequent sanitation is an increase in an epidemic’s duration, and a secondary effect includes small increases in outbreak severity.

Increasing the number of Environment Nodes to 50 and setting the Sanitation Threshold equal to five rounds resulted in an average epidemic size of 12.1%. We therefore conclude that the primary effect of introducing environment nodes is a decrease on the final epidemic size. Introducing any environment nodes at all also seems to result in more asymmetric infection curves.

This reduction in overall epidemic size could be due to our method of representing them in the simulation: nodes representing individuals are changed to represent environmental fixtures. This could potentially lower the population density in key areas. Furthermore, Environment Nodes cannot produce agents—they can only remove them. This behavior may also contribute to smaller average epidemics.

**Limitations and Future Work**

The broadest class of limitations include those inherited from the SIR model, as it serves as the basis for NetworkSIR and consequently, EnvironmentalSIR. Additionally, both NetworkSIR and EnvironmentalSIR assume no knowledge about individuals within the population of interest. As such, features such as individual-level comorbidities, age, etc are ignored. Additionally ignored are any features other than CPI duration that could affect the likelihood of an individual being infected. Drawing on to NetworkSIR’s strength in its extensibility, future work can focus on incorporating more features into NetworkSIR’s predictions for increased accuracy. Example avenues of future work include replacing our proposed mechanism of edge-weighting with MLE (Maximum Likelihood Estimation) or MAP (Maximum a Posteriori) estimates for increased accuracy. However, in its current form, NetworkSIR is best used as a mechanism to study the flow of infectious material between individuals in a population, or as a framework for more complex models.

Additionally, both NetworkSIR and EnvironmentalSIR would benefit from further validation using real-world data. In particular, the collection of contact networks which include interactions between humans and commonly-visited environments is necessary for EnvironmentalSIR’s validation. A limitation which occurred from the lack of such networks is the re-use of the algorithm for infection (used by Environment Nodes) as used by Infected nodes in NetworkSIR. It is likely that humans do not interact with environmental fixtures in the same way that they do other humans, which would make this algorithm reuse inappropriate. However, due to lack of data, the development of a more appropriate mechanism is difficult.
Finally, the collection of large-scale datasets which track with certainty individual-level disease spread is necessary for the validation of both NetworkSIR and EnvironmentalSIR. Current datasets of this type are limited largely by size and method of collection (anecdotal accounts). However, it is likely that such data will be available in the near future due to the massively increased research interest in contact-tracing (automated or otherwise).

**Conclusion**

Accurate predictive modeling of pandemics allows for good public health decision making. To manage novel pandemics from a public health perspective, researchers and public health officials must be able to model disease dissemination to predict resource utilization such as bed capacity, staff requirements, and personal protective equipment. More importantly, as we learn how non-pharmaceutical interventions affect transmission risk, we must be able to quickly re-run the prediction models to adjust the forecast, which necessitates computationally efficient models. Furthermore, only accurate models that reflect the projected disease spread can help politicians and officials to determine large scale interventions such as mandatory mask wearing and shut downs of public spaces. 19

In this paper we offer two new models of disease dissemination: NetworkSIR and EnvironmentalSIR. Validation results and the higher verisimilitude of the models with actual disease spread suggest that they may offer better prediction. Using Environmental nodes to transmit agents allows for modeling of viral agents which are transmitted from surfaces and through ventilation. By building models that encompass environmental spread not linked to direct human-to-human contact, we can better explain pandemics. We encourage others to further test and validate our models.

Abstract

Alterations in consciousness state are a defining characteristic of focal epileptic seizures. Consequently, understanding the complex changes in neurocognitive networks which underpin seizure-induced alterations in consciousness state is important for advancement in seizure classification. Comprehension of these changes are complicated by a lack of data standardization; however, the use of a common terminological system or ontology in a patient registry minimizes this issue. In this paper, we introduce an integrated knowledgebase called Epilepsy-Connect to improve the understanding of changes in consciousness states during focal seizures of pharmacoresistant epilepsy patients. This registry catalogues over 809 seizures from 70 patients at University Hospital’s Epilepsy Center who were undergoing stereotactic electroencephalography (SEEG) monitoring as part of an evaluation for surgical intervention. Although Epilepsy-Connect focuses on consciousness states, it aims to enable users to leverage data from an informatics platform to analyze epilepsy data in a streamlined manner.

Epilepsy-Connect is available at https://bmhinformatics.case.edu/Epilepsyconnect/login/.

1. Introduction

Epilepsy is a serious neurological disease that is defined as having at least two unprovoked seizures in a 24-hour time period and is the fourth leading non-communicable disease impacting global years lived with disability (YLD)[1], [2]. More than 52 million people worldwide are affected by epilepsy, resulting in 18.3 million global YLD[2]. Approximately one third of these people suffer from refractory or drug-resistant epilepsy, leaving them with uncontrolled seizures[3].

Epilepsy is a spectrum condition that broadly encompasses all seizure disorders, with alterations of consciousness during seizure events being a core component of epileptic seizures[4]. While successful treatment of epilepsy requires refined classification of the disorder, informative classification guidelines that focus on changes in consciousness state have been difficult to achieve. In 2017, the International League Against Epilepsy (ILAE) updated the definition of epilepsy to include several new focal and generalized seizure types[5]. Despite offering more granular classifiers such as awareness, these ILAE seizure classifications have been criticized for a lack of clarity and brevity[6]–[8]. The “Four-dimensional epilepsy classification” is an approach that aims to classify seizures based exclusively on ictal symptomatology, and it includes precise and detailed descriptions of the nature of changes in consciousness state[7], [9]. This proposed approach to use clinical features to better delineate focal seizures reduces the dependency on an abnormal, correctly interpreted, available electroencephalograph (EEG)[8].

A better understanding of the changes in consciousness state during seizures is essential for both improvement in treatment of epilepsy as well as potentially enhancing the safety of epilepsy patients during seizure events [4], [8], [10], [11]. In addition to limitations of existing classification systems with respect to consciousness state during epileptic seizures, the lack of standardization in case ascertainment, data collection methods, and data reporting methods also impedes advancement in epilepsy research related to consciousness. In this paper, we propose that the design and implementation of a patient registry focused on alterations of consciousness state in epilepsy using a common terminological system or ontology can address many of the data management challenges faced by clinical researchers [12]–[16]. Ontologies are knowledge reference models that often use description logic to represent the relationships between concepts or terms in a way that allows computational logical reasoning, which allows for mass integration and analysis of large amounts of heterogeneous data; this logic is widely used to enhance patient classification and other data analysis tasks [14], [16]. Therefore, ontologies can play a key role in managing multidimensional data from different sources in a consciousness focused patient registry.
Patient registries have become a common way to facilitate sharing comprehensive, diagnostic, condition-specific data in order to enhance clinical and scientific research [12]. There are several existing registries that cover various aspects of epilepsy, each providing unique insights into different aspects of therapies, rare variants, and general health related to epilepsy (Table 1). To the best of our knowledge, there is no existing registry that focuses on changes in consciousness states in epilepsy patients and the use of the registry data for computational analysis of the patient data to study changes in brain network topology during seizures. Furthermore, most existing epilepsy registries do not include publicly accessible data, making it difficult for researchers to perform exploratory data analysis or relate these highly specific findings to more general topics. To address this significant gap in the study of consciousness states in epilepsy patients, we introduce an integrated knowledgebase called Epilepsy-Connect that uses ontology for standardization of data in a new patient registry to study changes in consciousness states during epileptic seizures (https://bmhinformatics.case.edu/Epilepsyconnect). The broader objective of the Epilepsy-Connect informatics platform is to enable a greater understanding of the consciousness state system, ultimately improving diagnostic accuracy, patient care, and the prediction of surgical necessity and/or outcomes.

1.1 Background

**Significance of Consciousness State in Epilepsy Neurological Disorder.** Up to 70% of focal epilepsy patients do not have freedom from seizures despite optimal drug therapy [3]. However, surgery to resect the epileptogenic zone often does not result in seizure-free patients, and they continue to experience significant deterioration in their quality of life due to repeated seizures, including loss or change in consciousness state that endangers their safety [11], [24]. The analysis of changes in consciousness states during recurrent seizures has been suggested as a potential method to improve evaluation of patients for surgery [3], [24]. Consciousness is a comprehensive yet complicated term lacking one concrete definition [4], [25]. Consciousness, while not concretely defined, is believed to depend upon continuous integration and processing of information [4]. Interruptions in this continuous integration and processing of information—often presenting as changes in awareness, attention, arousal, responsiveness, ability to interact, and/or memory—are noted as alterations in consciousness state [4], [11]. Focal seizures span various degrees of impairments or alterations of consciousness, including: (1) no impairment, (2) observable motor or autonomic components, (3) sensory or psychic auras, (4) dyscognition, (5) dialepsis, (6) ictal delirium, (8) evolution to a bilateral, convulsive seizure, and (9) epileptic coma [4], [26].

Losses of, or alterations in, consciousness state in patients with epilepsy are complex phenomena that involve changes...
in neurocognitive networks such as the default mode network (DMN), salience network (SN), and central executive network (CEN)[27]–[30]. These impairments may be identified by various neurological characteristics and can be measured objectively by assessing a patient’s amnesia of events occurring during epileptic seizures and their responsiveness to external stimuli during epileptic seizure [4], [11]. Several studies have been conducted to link changes in consciousness to specific brain regions[11], [31], [32] and to changes in brain activity in several cortical regions and subcortical arousal systems[11], [27]–[30], [33], [34]. These studies, however, fail to distinguish between the various states of consciousness. Each state of consciousness has its own unique clinical presentation, and it has been noted that each state of consciousness has unique characteristics during a seizure. We propose to analyze signal recordings from refractory patients to characterize changes in brain network topology and correlate the changes to alterations in consciousness during seizure events using de-identified patient data from the Epilepsy Center at the University Hospitals Cleveland Medical Center (UH-CMC).

Epilepsy-Connect Patient Registry Data. The UH-CMC is a Tier 4 epilepsy center that conducts research on the causes and therapies of epilepsy with refractory epilepsy patients receiving care in the epilepsy monitoring unit (EMU). In the EMU, patients undergo continuous monitoring of brain activity for five days, including continuous video monitoring. During this period, anti-seizure medications are temporarily reduced or stopped in order to safely induce medically supervised seizures so that epileptologists may determine the epileptogenic zone and, by extension, determine the best course of therapy for the patient. Patients are monitored using intracranial electrodes that record stereotactic electroencephalography (SEEG) to localize seizure foci. We use de-identified patient data from the UH-CMC with Institutional Review Board (IRB) approval to populate the Epilepsy-Connect patient registry.

Network Analysis of SEEG Data for Characterizing Alterations of Consciousness State in Epilepsy Patients. It is well understood that focal seizures originate within networks where initial activation is limited to one cerebral hemisphere[26], [35]. Current focal epilepsy models acknowledge that the epileptogenic zone is a distributed network involving inter-regional anatomo-functional relationships among brain areas[24], [36]. These networks have not been fully characterized yet, and research for more accurate prediction of surgical intervention outcomes using these networks is ongoing[24], [36].

One increasingly popular body of research has emphasized the utility of network analysis methods that model epileptic seizure networks as graph models consisting of brain locations as nodes and the interaction between them as edges in a graph to understand each of these potential network mechanisms[37]. Network topology has been used to study general changes in ictal network properties spanning the duration of the seizure[38], [39] or at seizure onset[40]. Research has even considered changes in interictal network topology[37], [38], [41], [42]. While there is an abundance of literature focused on developing general understandings of epilepsy networks, little is known about the relationship between these networks and the differences in the various impaired states of consciousness.

The Epilepsy-Connect knowledgebase aims to serve as an integrated neuroinformatics resource with a patient registry and network analysis tools, which can be directly applied to the patient data. The Epilepsy-Connect knowledgebase features a query interface that allows users to create patient cohorts based on specific inclusion/exclusion criteria. In the next section, we describe the implementation details of the Epilepsy-Connect knowledgebase, including the workflow used to populate the registry, the development of the informatics component, and the functionalities currently supported by this integrated neuroinformatics tool.

2. Methods

The Epilepsy-Connect knowledgebase was developed in close collaboration with clinicians at the UH-CMC to support clinical research together with patient care. Figure 1 shows the workflow used in the development of the Epilepsy-Connect knowledgebase. The three primary objectives of the Epilepsy-Connect knowledgebase are:
1. Support the creation of a patient registry using standardized terminology modeled in a widely used epilepsy-focused ontology [16];

2. Enable researchers to perform patient-cohort queries over the patient registry data for hypothesis development and validation related to alteration of consciousness state in pharmacoresistant epilepsy patients who undergo evaluation for surgical evaluation; and

3. Support users to manage their cohort queries and query results, which can be used for data sharing as well as dissemination of their study results.

2.1 The architecture and development of the Epilepsy-Connect platform. The Epilepsy-Connect platform consists of a set of modules that support: (1) creation of a cohort query using a visual query interface, and (2) management of user information, including query history. The current version of Epilepsy-Connect has been developed using the Django web application framework, which uses the Python programming language and features a large number of libraries and modules that support variety of data processing and analysis tasks including access to ontology files. The architecture of Epilepsy-Connect allows it to integrate and manage data from the UH-CMC using software modules for data pre-processing and conversion to a common data model following the well-known Extract Transform Load (ETL) approach. We note that as part of the data processing step, multiple terms in the study data conform to the ontology classes in the Epilepsy Ontology, which facilitates the standardization of the data terms in the patient registry module of the platform.

The Epilepsy-Connect platform uses the Model View Template (MVT) approach with data in the registry component managed using an object relational data model, the user interface is managed by the View component, and the user interaction with various features of the software is mediated by the Template, which conforms to the Django framework. The Epilepsy-Connect platform is accessed via a web browser with role-based access control (RBAC) with users assigned to a user group. The access to data in the registry component is governed by the UH-CMC IRB with a data user agreement (DUA) required for download of the data. Users follow an intuitive query process to create a study cohort using a visual query composition process (results are discussed in Section 3).

2.2 Study Data. At present, the Epilepsy-Connect registry hosts de-identified retrospective patient data from UH-CMC who were evaluated for surgical intervention. The preoperative evaluation data were gathered from each patient’s discharge summary following invasive EEG/video evaluation. This data was split into patient demographics, medical history, seizure etiology, medical imaging records and findings, neuropsychological testing information, and clinically observed representations of patient alterations of consciousness. Further, de-identified SEEG recordings for each patient are processed using an in-house signal processing workflow called the NeuroIntegrative Connectivity (NIC) tool to segment and transform signal data stored in the European Data Format (EDF) to a Javascript Object Notation (JSON) format called Cloudwave Signal Format (CSF) [43], [44]. The SEEG recordings are analyzed by the UH-CMC clinicians during EEG reading sessions to determine seizure details and define ictal and interictal periods. Further, clinicians also note the specific electrode contact involved in seizure events, which are used as input parameters for the computational neuroscience workflow used in this project to characterize topological changes associated with change in consciousness state of these patients. The seizure details, ictal time periods, and the list of electrode contacts together with other relevant patient details are stored in the
Epilepsy-Connect knowledge as part of the ETL process.

Summary statistics of the data were calculated in R (version 4.0.4). A total of 70 patients, ranging from the age of 15 to 69 (median age of 35), were included in the registry. Table 2 shows a summary of the patient demographics. The number of males and females included was approximately equal, and age did not differ significantly between the sexes ($p = 0.97$, $\chi^2 = 0.001$). A total of 809 seizures were analyzed for the registry. The seizures for one patient were excluded from this calculation since the patient was reported to have had “one seizure every two minutes” over multiple days within the study. Of these seventy participants, sixty-one reported having at least one seizure with an alteration of consciousness. Forty-two patients were reported to have had an aura during at least one seizure; twenty-seven patients experienced dialepsis during at least one seizure; six patients presented with dyscognition in at least one seizure; and thirty-one patients had at least one seizure without any alterations of consciousness. Access to the patient registry data through the Epilepsy-Connect query interface is available as a “guest user” and a “registered user”. A registered user account will be created after the user has completed the data user agreement with IRB approval. A registered user has full access to the Epilepsy-Connect knowledgebase; however, a “guest user” can explore a restricted set of data elements through the user interface.

2.3. Epilepsy Ontology and Standardization of Terms. The Epilepsy-Connect uses the Epilepsy Ontology (listed in the National Center for Biomedical Ontologies as the Epilepsy and Seizure Ontology, EpSO) as a reference ontology to standardize the storage and querying of data [16]. The Epilepsy Ontology has been iteratively developed using input from multiple epilepsy domain experts as part of the ILAE Big Data task force to comprehensively model various aspects of epilepsy and seizures, including genetics, neuropathology, medication, and brain anatomy. Epilepsy Ontology uses the description-logic-based Web Ontology Language (OWL) to construct a class hierarchy, link together the ontology classes using properties, and apply sophisticated class-level restrictions to model epilepsy information at a fine-level of granularity. The Epilepsy Ontology uses ontology-engineering best practices to re-use existing ontology terms from the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT), the Gene Ontology, RxNorm for drug information, and the Foundational Model of Anatomy (FMA) for modeling brain regions. A phased approach was used to extend the Epilepsy Ontology for use in the Epilepsy-Connect project.

In the first phase, we enumerated all the data elements in the Epilepsy-Connect registry, which can be broadly classified into six categories of patient evaluation results (e.g., etiology, neurological review, and family history); results of neurological exam (e.g., memory, attention, motor, and reflexes); details of imaging procedures (e.g., imaging modality and status); seizure events (e.g., start and end of seizure events, onset and end frequency); alterations of consciousness state (e.g., aura, dialeptic, or apraxia); and details of alterations of consciousness events (e.g., post-seizure memory retention, fine distal movement). In the next phase, we modeled these data elements in the Epilepsy Ontology, for example Figure 2 shows a part of the class hierarchy describing EEG patterns. These ontology terms are being used in the Epilepsy-Connect project for both annotation of database as well as to support the functionalities of the user interface. In particular, we are integrating the Epilepsy Ontology in the user interface to support patient cohort queries using the ontology-based database access (OBDA) framework. The use of OBDA will allow users to leverage semantic matching of query terms to information in the patient registry without being constrained by string matching only. At present, the Epilepsy-Connect query interface uses the ontology terms to create a customized database for supporting the query composition task using drop-down menu values. The use of the Epilepsy Ontology in the patient registry will also enable easier sharing of data using common terminology for data annotation.

Network Analysis of SEEG Data using Patient Cohort Query. In addition to supporting patient cohort queries, the Epilepsy-Connect knowledgebase is being integrated with a network analysis tool called the Neuro-Integrative Connectivity (NIC) platform, which was developed in our prior work[43]. The NIC platform converts SEEG European Data Format (EDF) files into Cloudwave Signal Format (CSF) files, a JavaScript Object Notation (JSON) based human-readable format previously developed by our lab[44]. Once files have been converted, the NIC tool may be used to investigate statistical correlations of brain functional connectivity. Users are able to choose between Pearson Correlation[45], Mean Phase Coherence[46], and Non-linear correlation[47] for their measurement(s) of correlation. Furthermore, the NIC workflow allows users to analyze the change in network graph topology throughout seizures via methods in algebraic topology. Outputs include the clustering coefficient, Betti numbers, characteristic path length, and global efficiency. The NIC tool is available for download at https://bmhinformatics.case.edu/nicworkflow/accounts/login/.

After the user creates a study cohort using the Epilepsy-Connect user interface, the NIC tool will be able to be invoked to process and compute network measures over the SEEG data. At present, we created a cohort with patients with two seizures for further analysis. The corresponding SEEG files were processed using the NIC platform to characterize the network characteristics of the epileptic seizures, including global and local connectivity with corresponding disruption of the small-world network topology, which is a characteristic of brain network in healthy subjects. In the next section, we describe the results generated by the Epilepsy-Connect knowledgebase via the user interface.

3. Results

Epilepsy-Connect User Interface. The Epilepsy-Connect user interface consists of an intuitive query composition module (Figure 3), which supports both drop-down menu values as well as a “Drag-and-drop” feature. Using a stepwise process, users can select at least one variable from a list of curated patient cohort variables. Variables provide a drop-down list of factors which can be used to impose search criteria limits; numeric variables will provide sliders whereas qualitative responses will allow for radio button selection. At this time, queries are limited to “OR” logic. Once a user has completed a query, they will be directed to the results page to view their results. Restricted access users will have the option at this point to download the resulting dataset in a comma separated values (CSV) format. For an example of functionality, we have chosen to illustrate the query criteria that a patient had at least one dialeptic seizure (Figure 4).

Additional features have been implemented for restricted access users. Users with a registered account will be able to review the data in the registry as a whole by visiting the “data” tab in the upper right-hand corner of the page. Furthermore, they will be able to revisit their prior queries, by utilizing the “history” tab in the upper right-hand corner of the page.
4. Discussion & Limitations

We created an integrated knowledgebase called Epilepsy-Connect to improve the understanding of changes in consciousness states during focal seizures of pharmacoresistant epilepsy patients. This registry catalogues over 809 seizures from 70 patients at the Epilepsy Monitoring Unit within University Hospital’s Epilepsy Center who were undergoing SEEG monitoring as part of an evaluation for surgical intervention. Public use data for the registry includes information on general patient demographics, clinical symptoms that patients experienced during at least one of their seizures, and the alterations of consciousness that patients experienced during at least one of their seizures. We propose to deploy Epilepsy-Connect in the EMU of UH-CMC to support clinical research and improve patient care.

The broader objective of the Epilepsy-Connect informatics platform is to enable greater understanding of the consciousness state system that could be useful in improving diagnostic accuracy and patient care, as well as predicting surgical necessity and/or outcomes. To demonstrate and validate the use of Epilepsy-Connect for this purpose, we composed a simple query of the public access data to examine patients who had experienced at least one diaphaptic seizure during the recorded evaluation. The resulting cohort included six patients. While the results of this case study are enlightening, further analysis is needed to fully comprehend the complexities of the various networks associated with alterations of consciousness states. Comparisons across the selected cohort could reveal network changes that occur during seizures in which a patient presents with diaphapsis. Moreover, comparisons across multiple cohorts could foster understanding of network changes that occur during any seizure-induced alteration of consciousness state.

Although Epilepsy-Connect was designed with a focus on consciousness states, it includes a large range of data that can be utilized to explore epilepsy from several perspectives. Epilepsy-Connect’s standardized and comparable data collection makes it ideal for sharing comprehensive diagnostic data in order to improve research into epilepsy treatment methods and new intervention techniques, while still providing unique insights into seizure-induced alterations of consciousness states[12]-[16]. In an effort to make Epilepsy-Connect more universal, future releases are expected to add information such as weighted diffusion tensor imaging results for further connectome analysis, patient surgery decisions and outcomes, and additional patient neuropsychological testing. Furthermore, the modular architecture of the registry allows for queries to be easily modified, thus streamlining data collection procedures for any interested investigators.
5. Conclusions

Alterations of consciousness state are important in defining epileptic seizures[6]–[8], [10], and developing comprehension of seizure-induced changes to consciousness state is essential for improving seizure classification[8], [10]. One aspect of this is to understand the complex changes in neurocognitive networks which underpin alterations of consciousness states during epileptic seizures[27]–[30]. However, this is not easy, as the lack of standardization in case ascertainment, data collection methods, and data reporting methods tend to make data difficult to compare or validate across studies[12]–[15]. Patient registries work to minimize these issues[12]. In this paper, we introduced an integrated knowledgebase called Epilepsy-Connect that supports standardized and comparable data collection of patients with refractory focal epilepsy, and showed one potential use case for improving the understanding of changes in consciousness states during epileptic seizures. Although Epilepsy-Connect was designed with a focus on consciousness states, it aims to enable users to leverage data from an informatics platform to analyze epilepsy data in a streamlined manner in order to bolster scientific advancement.

Investigating Health Information Technology Usage by Sociodemographic Subpopulations to Increase Community Engagement in Healthcare: An Analysis of the Health Information National Trends Survey

Geetanjali Rajamani, BS1, Lianne Kurina, PhD1,2, Lisa Goldman Rosas, PhD, MPH2
1Department of Human Biology and 2School of Medicine, Stanford University, CA

Abstract

It is well known that the US is plagued by health inequities: unjust differences in morbidity and mortality rates by sociodemographic factors. A potential method to address such inequities lies in utilizing health information technologies (HIT) to reach under-resourced populations and increase their involvement in healthcare. Previous researchers have done just this, using HIT tools to engage under-resourced communities and improve outcomes. However, it is unclear how HIT usage varies by sociodemographic characteristics. This study investigated this question through analysis of the Health Information National Trends Survey (HINTS) and proposed tailored HIT interventions for specific subpopulations. Internet, smartphone, and wearable device usage were analyzed by age, race/ethnicity, educational attainment, and income; purposes of HIT usage were assessed; and logistic regression models were conducted to determine associations between purposes of HIT usage and sociodemographic predictors. Results showed that Black/African American, Latinx, and Asian populations all had significantly increased use of health videos, while participants with lower educational attainment had significantly decreased use of many HIT tools. Thus, this study highlights effective interventions for specific racial/ethnic populations and showcases a need for HIT tools inclusive towards low education populations to increase their engagement in healthcare and reduce inequities.

Introduction

There exist many health inequities in the United States – significant differences in morbidity and mortality rates by social factors such as race, socioeconomic status (SES), and educational attainment. For example, African Americans make up 13% of the US population but account for 42% of new HIV diagnoses, and Latinx make up 18% of the population and account for 27% of new diagnoses. American Indian/Alaska Natives (AIAN) are twice as likely to have diabetes as whites. In the COVID-19 pandemic, minorities disproportionately bear the burden of COVID-19 cases, hospitalizations, and deaths. Such inequities arise from a complex combination of factors, including lack of access to adequate/affordable care, low health literacy rates, racism, and various systemic injustices. Solutions to address these inequities are of the utmost importance, not only to improve the health of the nation, but also to serve social justice in healthcare.

In today’s digital world, technology is becoming rapidly integrated with many aspects of life, including healthcare. Health information technology (HIT) is a prominent field; a variety of apps exist to help with disease management; the electronic health record (EHR) collects health data from thousands of patients electronically; and even virtual reality is being used to treat mental health disorders. Thus, a potential solution to addressing health inequities may also be found in the realm of HIT. Specifically, HIT can be utilized to reach under-resourced populations, provide them with access to health information and health care, and reduce suboptimal outcomes for these populations.

Review of Relevant Research

Previous research has shown that HIT can be used as a form of community engagement to involve sets of under-resourced communities, rather than just individuals, to be invested in their own healthcare and is a powerful strategy to reduce health inequities. For example, a review study by Kranz et al. (2018) found that when safety net clinics – serving under-resourced populations – utilized HIT for coordinating appointments/transportation with patients, facilitating communication with providers, and a host of other purposes, patient outcomes such as hemoglobin A1c, maternal and child health, and adult screening practices improved.

However, there is much room for expansion in the literature regarding how HIT usage varies by demographic characteristics. A study by Mackert et al. (2016) examined how HIT usage varies by health literacy of participants. They found that those with an “adequate” health literacy level or higher were more likely to use fitness apps, nutrition apps, activity trackers, and patient portals than those with a “less than adequate” health literacy level, suggesting that current HIT tools must be modified in order to cater to low health literacy communities. A study by Wang et al. (2019) analyzed HIT usage patterns of older adults (average age 70 years), finding that although few are currently using...
mobile technologies, many are open to the idea. Overall, these studies show that although researchers have examined how certain subpopulations utilize HIT – such as health literate adults and older individuals – few studies exist regarding how HIT usage generally varies across a variety of subgroups.

**Project Aims**

It is unknown exactly what sociodemographic factors are correlated with HIT usage – i.e. do some groups use smartphone-based technology more and do others use web-based technology more? Having a better understanding of what sociodemographic factors are correlated with HIT usage will help better tailor studies regarding which modality of technology should be used to engage a specific group of people. This increased engagement can potentially lead to increased prevention of chronic diseases, increased screening rates in under-resourced communities, and overall reduced inequities and improved health.

This study aims to address this gap by analyzing whether and how sociodemographic factors such as race/ethnicity, education, and total income are associated with HIT-related usage factors, including access to internet, smartphone usage, use of an electronic wearable device, and more. The specific questions investigated were:

- How do rates of smartphone, internet, and wearable device usage vary across sociodemographic groups (race/ethnicity, income, education)?
- What are the methods in which HIT is used in healthcare to help with decisions and communications (e.g. texts with providers, health apps, health videos, etc.)?
- Are there differences in use of health and wellness apps by sociodemographic status (race/ethnicity, income, education)?

This study will thus help understand what modalities of HIT are best for which sociodemographic groups (and thus guide future interventions) and provide a better picture of the role of technology as a potential strategy to address health inequities.

**Methods**

To determine how HIT usage varies by sociodemographic factors, the Health Information National Trends Survey (HINTS), sponsored by the National Cancer Institute (NCI), was utilized.

**Sample**

The HINTS survey was developed by the NCI to better understand the rapidly evolving field of health communication, which includes HIT. HINTS is a cross-sectional survey of a nationally representative sample of American adults, administered regularly since 2003, and HINTS data are publicly available. This survey instrument consists of a total of 129 close-ended questions organized into 14 sections, and all data are quantitative. The data are de-identified and made available for public use by adhering to standards for analysis and reporting. The target population is adults age 18 years and above. For this study, HINTS 5 (Cycle 3) was utilized, collected from January-May 2019 (N=5438). Detailed sampling strategies and survey design methodologies are available in the HINTS 5, Cycle 3 methodology report.

**Measures: Sociodemographic Factors**

The following sociodemographic variables, taken from Section O of the HINTS questionnaire, were included in analyses: age; highest grade or level of schooling; Hispanic/Latino/Spanish origin; race; annual income. For the purposes of this study, the race and ethnicity variables were combined and are presented as Non-Hispanic White, Non-Hispanic Black, Hispanic/Latinx, Asian and Other (including AIAN, Pacific Islander, and multiple races). Educational attainment categories were also combined and are presented as: high school degree or less, some post-high school education, college degree and postgraduate studies.

**Measures: HIT Usage**

Table 1 lists the HIT usage variables (section B) of the HINTS questionnaire that were included in analyses, along with their response options. A total of 11 questions were included, of which 3 questions pertain to internet use, 5 inquire about smartphone ownership and usage, and 3 relate to electronic wearable device use.

<tr>
<td>B11: Would you be willing to share health data from your wearable device with your health care provider? Your family or friends?</td>
<td>Yes; No</td>
</tr>
</tbody>
</table>

Data Analysis

Data analysis was conducted using the software Stata/IC 16.1 (StataCorp LLC, TX, USA). First, univariate analyses were conducted to understand the purposes of HIT usage. Among those who indicated they were internet users, analyses were performed to determine how many used internet for: looking up cancer information; sharing health information on social media; participating in online health forums; and watching YouTube health videos (Figure 1). Among those who indicated they were smartphone users, analyses were performed to determine how many used smartphones for: looking up health information; buying medicines online; communicating with health care providers; tracking health care costs; looking up medical test results; making health care appointments; looking up information regarding harms of e-cigarettes; using health/wellness apps; tracking progress on health-related goals; making decisions on treatment plans; and sending/receiving texts from providers (Figure 2). Finally, among those who indicated they were electronic wearable device users, analyses were performed to determine how many use these devices: every day; almost every day; 1-2 times per week; less than once per week; not in the past month; and how many would be willing to share data with providers or family/friends (Figure 3).
Next, bivariate analyses were conducted to examine the relationship between HIT usage and sociodemographic variables. Whether a participant uses internet or not was analyzed by age, a combined ethnicity/race variable, education, and income categories (Table 2). Similarly, smartphone usage was analyzed by the same demographic variables (Table 3), as was electronic wearable device usage (Table 4). Chi-squared tests and two-tailed t-tests were conducted to determine the significance of these various relationships.

Finally, four separate multivariate logistic regression models were conducted to understand how some purposes of HIT usage (mentioned in Figures 1-3) vary by sociodemographic predictors. Specifically, smartphone use for engaging with health and wellness apps, internet use for watching YouTube health videos, smartphones to look up health information, and smartphones to communicate with providers were each examined separately, with age, ethnicity/race, education, and income as predictors (Table 5). These four variables were chosen for the regression models because they were the most commonly reported forms of HIT usage.

Results

Sociodemographic Analysis of Internet Users & Purposes of Usage

Table 2 summarizes the sociodemographic factors of participants who reported using internet (N=4322) versus those who reported not using internet (N=1074). The average age of internet users was 54.1 years (SD 16.4), while the average age of non-internet users was 68.6 years (SD 13.7) – a significant difference (p<0.0001). More non-Hispanic whites and Asians report using internet compared to non-Hispanic Blacks and Hispanic/Latinx populations; more educated people report using internet compared to less educated populations; and more people in higher income brackets report using internet compared to those in lower income brackets (p for all comparisons <0.0001).

Figure 1 shows how many internet users: watch health-related YouTube videos (37.97%), look up cancer information (21.70%), share health information on social media (14.14%), and participate in online health forums (8.38%).

**Sociodemographic Analysis of Smartphone Users & Purposes of Usage**

Table 3 summarizes the sociodemographic factors of participants who reported using smartphones (N=4172) versus those who reported not using smartphones (N=1121). The average age of smartphone users was 53.4 years (SD 16.2), while the average age of non-users was 69.5 years (SD 13.2) – a significant difference (p<0.0001). More Asians and people who reported “other” races report using smartphones compared to other racial/ethnic populations; more educated people report using smartphones compared to less educated populations; and more people in higher income brackets report using smartphones compared to those in lower income brackets (p for all comparisons <0.0001).

Synthesis of Key Findings

Results show that there was a significant difference in the racial/ethnic composition of internet users: 87.3% of non-Hispanic whites report being users, while only 74.3% of non-Hispanic Blacks and 72.5% of Latinx report being users ($\chi^2=134.53, p<0.0001$). The differences by educational attainment are also striking: only 54.4% of people with a high school degree or less are internet users, while 91.9% of college graduates and 95.3% of post-graduates are users ($\chi^2=816.87, p<0.0001$). As income bracket increases, so does internet usage: only 55.9% of people earning less than $9999 per year are users, whereas 96.6% of people earning $200,000+ are users ($\chi^2=635.08, p<0.0001$).

Next, consider smartphone owners: 90.1% of Asians report owning a smartphone, as do 81.7% of non-Hispanic whites, compared to 75.6% of non-Hispanic Blacks ($\chi^2=28.05, p<0.0001$). Again, as education increases, so does smartphone ownership: only 59.4% of people with a high school degree or less report owning smartphones, compared to 91.6% of people with a postgraduate degree ($\chi^2=456.83, p<0.0001$). A similar trend is seen with income: only 56.1% of people earning less than $9999 per year own a smartphone, while 97.8% of people earning $200,000+ own a smartphone ($\chi^2=566.16, p<0.0001$).
The final HIT type examined, electronic wearable devices, also showed significant differences in racial/ethnic composition of users: Asians (29.2%) and non-Hispanic whites (26%) are the groups with the highest rates of electronic wearable device ownership ($\chi^2=11.17$, $p<0.025$). Once again, the trends by educational attainment and income are extremely clear: 34.8% of postgraduates own such a device, compared to just 10.3% of people with a high school degree or less ($\chi^2=245.88$, $p<0.0001$); and almost half of people earning over $200,000 per year (49.9%) own such a device, compared to just 10.2% of people in the lowest bracket ($\chi^2=403.70$, $p<0.0001$).

In terms of the purposes of internet usage, many participants reported watching YouTube health-related videos (38%), followed by looking up cancer information (21.7%) as a second common purpose. For smartphone users, the vast majority (80.2%) reported using their device to look up health information, and many also reported using it for engaging with health/wellness apps (54.9%), communicating with a provider (50%), making appointments with a health care provider (48.2%), and looking up medical test results (47.4%). Finally, most electronic wearable device users use their device every day (48.9%) or almost every day (20.3%) and are more willing to share device data with providers (80.6%) rather than family and friends (66.7%).

Discussion

As previously mentioned, HIT is a powerful tool to engage not just individuals, but also communities in their own health care. It is important to understand how HIT community engagement strategies can be leveraged to reduce health inequities. The multivariate logistic regression models ran as part of this study can help tailor HIT community engagement strategies to specific sociodemographic groups. Some of the most common purposes of HIT usage (namely, health/wellness apps, YouTube health videos, looking up health information, and communicating with providers) were examined against sociodemographic predictors.

Non-Hispanic Blacks reported a 37% increased odds of using health/wellness apps ($p=0.005$) and a 54% increased odds of watching YouTube health videos ($p<0.0001$) compared to non-Hispanic whites, controlling for age, education, and income. Thus, perhaps HIT engagement strategies that capitalize on apps and videos tailored to this population can help further engage Black/African American communities. Similarly, Hispanic/Latinx populations reported a 61% increased odds of watching YouTube health videos ($p<0.0001$), but a 24% decreased odds of looking up health information ($p=0.039$) and communicating with providers ($p=0.009$) as compared to non-Hispanic whites, controlling for age, education, and income. Thus, for engaging Latinx communities, videos may prove to be a more successful strategy as compared to websites or methods of communication with providers. Finally, note that Asians have a 2.47 times increased odds of watching YouTube health videos ($p<0.0001$) as compared to non-Hispanic whites, controlling for age, education, and income – again suggesting that videos could be a powerful engagement strategy for this community.

One of the most striking findings from this study is the correlation between educational attainment and HIT usage. Specifically, participants with a high school degree or less have a 53% decreased odds of using health/wellness apps ($p<0.0001$), a 57% decreased odds of watching YouTube health videos ($p<0.0001$), a 77% decreased odds of looking up health information ($p<0.0001$), and a 71% decreased odds of communicating with their providers ($p<0.0001$) as compared to postgraduates, controlling for age, race/ethnicity, and income. This makes intuitive sense, as people in this population may not have as much access to these tools and/or knowledge on how to effectively utilize them. This is a very important finding, as it shows that, with status quo HIT tools, a key population of interest – those with low educational attainment – cannot be reached. Significant work must be done to tailor HIT tools to cater to populations with lower health literacy and education rates in order to engage these populations in healthcare, improve health outcomes, and work towards reducing health inequity.

Finally, consider income status and HIT usage. As income bracket decreases, so does HIT usage: those earning $9999 per year or less have a 70% decreased odds of using health/wellness apps ($p<0.0001$), a 47% decreased odds of looking up health information ($p=0.023$), and a 77% decreased odds of communicating with their providers ($p<0.0001$) as compared to those earning $200,000+ per year, controlling for age, race/ethnicity, and educational attainment. This makes sense, given the close relationship between income and educational attainment. Again, these data show that HIT tools must be modified to cater to socioeconomically disadvantaged populations.

Overall, these regression analyses show promising avenues in which HIT community engagement strategies can be tailored for specific populations. By using methodologies that are better suited for certain sociodemographic groups (e.g. more health apps for Black/African American populations, and more health videos for Black, Latinx, and Asian populations), more members will likely participate in HIT usage. Furthermore, this study highlights a need to create more HIT tools inclusive towards populations with low educational attainment and socioeconomic status.
Based on the findings of this investigation, further research must be done to determine if these tailored HIT engagement strategies are indeed effective. The study results will guide future researchers in determining which forms of HIT they should utilize for which sociodemographic groups. It is important to determine if using these tailored strategies does indeed yield better community engagement results, as then these interventions can be implemented at a population-level to work towards achieving health equity.

**Limitations**

It is important to consider some of the limitations of this study. First, the HINTS survey data are cross-sectional, and thus the results of this study indicate correlation rather than causation. Second, the HINTS survey had a relatively low response rate (about 30%) and hence some non-response bias may have been introduced into the data. Finally, there are some limitations to evaluating HIT usage and fully understanding the many ways in which HIT can be used through a population-based survey, which does not go into depth regarding the individual nuances in HIT usage.

**Conclusion**

Overall, this study examines how HIT usage varies by sociodemographic factors through analysis of the HINTS dataset in order to propose tailored technological interventions for various subpopulations. Previous research has shown the value of HIT tools in engaging under-resourced communities in health care and combating health inequities. While prior researchers have designed various HIT interventions and tested them on specific subpopulations, this study will provide guidance for future researchers on which interventions may be best suited for certain sociodemographic groups. Further research must be conducted to determine if these tailored interventions do indeed increase community engagement and can serve as a modality towards achieving health equity.

DL4Burn: Burn Surgical Candidacy Prediction using Multimodal Deep Learning

Abstract

Burn wounds are most commonly evaluated through visual inspection to determine surgical candidacy, taking into account burn depth and individualized patient factors. This process, though cost effective, is subjective and varies by provider experience. Deep learning models can assist in burn wound surgical candidacy with predictions based on the wound and patient characteristics. To this end, we present a multimodal deep learning approach and a complementary mobile application – DL4Burn – for predicting burn surgical candidacy, to emulate the multi-factored approach used by clinicians. Specifically, we propose a ResNet50-based multimodal model and validate it using retrospectively obtained patient burn images, demographic, and injury data.

1 Introduction

An estimated 40,000 burns require inpatient admission each year, 30,000 of which are treated at the limited number of burn centers across the country¹. Accurate determination of burn depth is critical for treatment management, in particular surgical decision making, which may impact patient morbidity and mortality². Visual inspection is the most widely used method, which has an accuracy of 64-76% for experienced burn surgeons, a 50% accuracy for inexperienced clinicians, and a tendency of providers to overestimate burn depth³–⁸. Inaccurate burn evaluation poses risks to the patient and the healthcare system. On one hand where overestimation of burn depth leads to unnecessary surgeries and a high rate of inappropriate burn center referrals³,⁸, underestimation leads to delayed surgical management, prolonged healing times, and increased risk for hypertrophic scarring and contractures³,⁸.

Currently there exists a body of work supporting the use of machine learning (ML) in various areas of burn wound diagnosis and management. Few studies have investigated ML models to predict burn wound surgical candidacy. These studies typically use a support vector machine (SVM) model and remain in the investigative stages³,⁶,⁹. Additionally, existing machine learning models predict with a target based only on a wound’s burn depth and associated healing time. A shortcoming of this strategy is the inability to account for the inherent surgical risks as well as patient and injury variables clinicians use in their decision to operate².

We propose a multimodal approach to better emulate the clinical decision making process. We input photographs with patient demographic and injury data to improve the model’s predictive capabilities. We further present our concept for delivering this technology in the form of a mobile application. We seek to translate this technology into a mobile application given the versatility, convenience, and accessibility of hand-held devices as they become more frequently used in the healthcare setting. The overall architecture of the DL4Burn is shown in Fig. 1. The specific contributions of our work are as follows.

• Multimodal Deep learning for Burn image surgical candidacy. We propose a deep learning-based surgical evaluation model which utilizes expert medical opinion along with a deep learning-based model to analyze the images and the multimodal meta-data (such as patient information, first responder and physician’s analysis) to predict the surgical candidacy of a burn wound.

∗Authors contributed equally. Contact corresponding authors Sirisha Rambhatla at sirishar@usc.edu and Samantha Huang at huangsm@usc.edu.
Figure 1: Overview of DL4Burn – a Multimodal Deep learning approach for burn surgical candidacy prediction. Panel (a) shows the multimodal deep learning model specifics. In panel (b) we illustrate the cloud-based workflow of the iOS application being used in the field.

- **Interpretable Assistive Solution.** In addition to providing learning-based recommendations, our method analyzes the outcomes via a state-of-the-art interpretability method to provide insights into the decision-making process of the learning model, and to assist medical evaluations in a trustworthy fashion.

- **DL4Burn iOS Application.** Complementary to the technical contributions, we also introduce the DL4Burn iOS mobile application to be used in the field for burn image and meta-data acquisition, triage, and analysis of images in real-time. This tool will help to accelerate data acquisition and the deep learning model learning, while providing burn surgical candidacy outcomes.

1.1 Related Works

1.1.1 Burn inspection and candidacy evaluation by clinicians

The decision to undergo surgical management is a multi-factorial process often individualized by patient\(^2,10\). Generally, surgeons evaluate the burn depth and percent total body surface area (%TBSA) burned to determine the wound’s healing potential, which is then used to determine if the wound should undergo surgical intervention\(^10,11\). Deep partial to full thickness burns are expected to take greater than three weeks to heal and are therefore surgically managed\(^10,11\). Superficial to superficial partial thickness burns are expected to heal within seven days to two weeks and are non-operatively managed\(^10,11\).

To determine burn depth, clinicians most commonly rely upon visual evaluation, inspecting for color, texture, and capillary refill as well as the presence or absence of sensory loss\(^11,12\). This process is subjective, varied by provider experience, and becomes especially difficult when deciphering mixed partial thickness burns\(^12\). This is especially critical given the differentiation of these burn depths is a baseline for deciding whether or not to operate on a wound\(^12\). As such, there is a need for a more objective method to assist in burn diagnosis and management.

1.1.2 Deep learning for medical imaging

Deep learning has been applied to many areas of medical imaging as an assistive tool for providers. Examples include chest x-ray imaging to detect lung nodules and histologic imaging for identifying high risk breast cancer\(^13\). In burn research, machine learning has been used on various imaging modalities in order to classify burn depth and determine a wound’s surgical candidacy. Specifically, machine learning has been used to classify burn depth from photographic, infrared, and spectroscopic imaging, which is then used to further classify wounds as surgical or non-surgical\(^3,6,9,14–16\). As such, the machine learning models are designed to classify surgical candidacy based on the predicted burn depth. For example, wounds classified as deep partial thickness to full thickness are labeled as surgical wounds while superficial and superficial partial thickness wounds are labeled as non-surgical\(^14,15\).
These studies employ several different machine learning techniques in order to determine burn depth, and by proxy, wounds that would require surgery. Here, Serrano et al. and Yadav et al. used support vector machine (SVM) and feature selection to translate visual cues used by clinicians, like color and texture, into mathematical models.\textsuperscript{9,14} Wang et al. instead, used a ResNet-50 based model to classify wounds by healing time.\textsuperscript{15} Findings from these studies have been promising, with an accuracy ranging from 79%-100% in predicting surgical candidacy, however these have been evaluated on relatively small datasets.\textsuperscript{3,6,9}

It must be noted that a shortcoming of these strategies is the reliance on a simplified view of burn diagnosis – using burn depth and the associated healing times as a proxy for determining burn surgical candidacy. In practice, the decision to operate depends not only on burn depth, but also on individualized patient factors and the inherent risks of surgery.\textsuperscript{2} For instance, patient age influences skin thickness and therefore thermal protection; while pre-existing comorbidities impact the ongoing injury pathophysiology and surgical risks.\textsuperscript{10} Injury characteristics such as the %TBSA burned and presence of sepsis impact thermoregulation, immune responses, and inflammatory cascades, prompting the need to balance aggressive fluid resuscitation with appropriately timed surgical intervention.\textsuperscript{2,10} Additionally, burn surgeons often require multiple evaluations over the initial days of injury to assess for the wound’s evolution and evaluate for areas of healing.\textsuperscript{12} Therefore, a method to evaluate wounds through different time points and a multimodal deep learning model which considers multiple information sources will be a more reliable approach for burn evaluation.\textsuperscript{17}

2 Methodology

We begin by describing our data collection methodology, and then present the proposed multimodal approach.

2.1 Data Collection

We conducted a retrospective chart review at the Southern California Regional Burn Center at LAC+USC on patients admitted between January 2015 and December 2016. Inclusion criteria were patients greater than 18 years at the time of injury, with any form of burn injury, and with photographs taken of their burn wounds during their admission. Available burn wound images without patient identifying data (e.g., eyes, birth marks, tattoos) were uploaded securely to our database. We collected data on patient demographics, injury characteristics, treatment characteristics, and outcomes. The photos were renamed with record number, anatomic location, and post burn day. We recorded these labels in a separate log, where each image was matched with patient injury, treatment, and eventual outcomes data, resulting in a dataset consisting of 174 labelled images requiring (class 1) and 226 images not requiring (class 0) surgical intervention. Note that here the outcome data indicates if the wound eventually required surgery. We treat this outcome as the gold standard. Thus the task is to predict the final outcome (requiring or not requiring surgery) from an image and other characteristics recorded at the time the patient was admitted.

In addition to the images, the features such as age, race (white, black, hispanic, asian), gender (male, female), comorbidities (diabetes mellitus, hypertension, chronic kidney disease, coronary artery disease, congestive heart failure, hyperlipidemia, cerebral vascular accident, liver failure or cirrhosis, psychiatric illness, obesity, chronic obstructive pulmonary disease), anatomic location of burn (arms, hands, thighs, legs, feet, face/head, neck, chest/torso, breasts, back, genitals, buttocks, perineum), mechanism of injury (scald, contact, flame, electrical, chemical, dermatologic), burn depth (superficial, superficial partial thickness, deep partial thickness, full thickness), %TBSA, presence of inhalation injury, presence of wound conversion, and post burn day (PBD), were also collected.

2.2 Preprocessing

We process the data collected to form the multimodal dataset \( D = \{x_i, y_i\}_{i=1}^N \), where \( x_i = \{x_{i}^{\text{Im}}, x_{i}^{\text{Tab}}\} \) denotes the multimodal data samples consisting of images \( x_{i}^{\text{Im}} \) and tabular data \( x_{i}^{\text{Tab}} \), and \( y_i \) denotes the target labels for surgical candidacy, in the following way.

**Image Preprocessing.** Since our retrospective data had inconsistent image sizes, we trained the model using randomly cropped and rotated burn images, which makes the learned model robust to scale and orientation of the burn region. Specifically, we randomly rotate the images \([[-30^\circ,30^\circ]]\), center crop and add random horizontal flips, before we normalize each image, \( x_{i}^{\text{Im}} \) for all \( i \in \{1,\ldots,N\} \). During training, we further randomly crop images in each epoch to
further improve the robustness.

**Tabular Data Preprocessing.** For the tabular data, we encode the categorical data (race, comorbidities, anatomic location of burn, mechanism of injury, burn depth) using one-hot coding. Here, we use a vector of all zeros to indicate a missing entry. We use the binary labels for gender, presence of inhalation injury, presence of wound conversion, and PBD variables. The variables age, burn depth, %TBSA are denoted by their float values, where 0 indicates a missing entry. The resulting features are concatenated to form a vector $x_{i}^{\text{Tab}} \in \mathbb{R}^{62}$, denoting the tabular information.

### 2.3 Multimodal Deep Learning for Burn Wound Evaluation

Multimodal Deep Learning aims to leverage all available information (potentially from varied sources, i.e. multiple modalities) to improve the performance on a machine learning task\textsuperscript{17}. Multimodal information has been effectively used in medical domains such as cervical dysplasia diagnosis\textsuperscript{19,20}, Alzheimer’s disease progression\textsuperscript{21,22} and skin lesion classification\textsuperscript{23}. Adding these multimodal features observed during medical screening improves the prediction accuracy by mimicking the real-world diagnostic procedure, wherein a multitude of factors are considered in decision making. To leverage these, we propose a multimodal deep learning model to predict burn surgical candidacy. Further, we also explain the imaging-based predictions using state-of-the-art interpretability techniques to reveal the decision making process of the deep learning network, critical to assisting clinicians in practice.

The proposed multimodal deep learning architecture for burn evaluation – DL4Burn – shown in Fig. 1 (a), uses two neural networks to arrive at the representations for the image and the tabular data separately. The choice of these neural networks depends on the data they process. For instance, in this paper, we use a deep convolutional neural network (CNN) to process the images and a multi-layer perceptron (with $\tanh(\cdot)$ activation) for the tabular data. We fuse these networks by concatenating the appropriately shaped inner-layer representations, and then pass this through a multi layer perceptron model (with $\tanh(\cdot)$ activation). We obtain the final classification result by using a softmax layer, which outputs the class probabilities\textsuperscript{†}.

### 2.4 Model Specifics and Training

Since the collected burn image dataset is relatively small as compared to the images required to train a deep neural network\textsuperscript{18}, we use ResNet-50 model pre-trained on ImageNet dataset in place of the deep convolutional neural network with three additional trainable multi-layer perceptron layers (with 2048, 1000 and 256 neurons), resulting in a representation of dimension 256\textsuperscript{24}. Next, we learn the representation corresponding to $x_{i}^{\text{Tab}} \in \mathbb{R}^{62}$ using a 2-layer multi layer perceptron each with 32 neurons, resulting in a size 32 representation. We then concatenate these image and tabular representations to form a 288 length vector, and pass it through a 2-layer multi-layer perceptron model containing 128 and 2 neurons respectively, and finally through a softmax layer to calculate the class probabilities. We train the model using stochastic gradient descent optimizer with a learning rate of 0.01 and momentum of 0.9, over 400 epochs with a batch size of 50 using the Cross Entropy Loss function. Overall architecture is shown in Fig. 1 (a).

### 2.5 Interpretability

The decisions made by Neural network-based learning models are fairly opaque and are not interpretable as such. As a result, it may not be clear why a certain prediction was made and what contributed to this specific decision. This is a major issue in healthcare applications, where practitioners need to know which factors contributed to a decision to make an informed choice. To build explainability we leverage a state-of-the-art blackbox model interpretability method in order to build a reliable and robust burn surgical candidacy application\textsuperscript{25}.

### 2.6 Baselines

We compared the performance of DL4Burn with support vector machine (SVM) and neural network-based baselines. Specifically, we use SVM trained on classifier on Histogram of Oriented Gradients (HOG) features\textsuperscript{26} and SVM trained

---

\textsuperscript{†}Class probabilities refer to the probability that a sample belongs to a certain class. In our binary classification setting, this represents the probability that a data sample belongs to class 1.

2.7 Metrics

We report the performance in terms of the area under the curve (AUC) metric, which is a popular metric for evaluating the performance of imbalanced dataset. Specifically, the AUC metric evaluates the area under the Receiver Operating Characteristic (ROC) curve between the True Positive Rate (TPR) and the False Positive Rate (FPR). To construct the curve, we threshold the predicted class probabilities (Section 2.3) at different thresholds between [0, 1], evaluating TPR and FPR at each of these. The AUC metric is especially suited for imbalanced datasets since it measures how good a classifier is at detecting in-class data samples (TPR) while rejecting ones that are out-of-class (FPR). In addition, we also report the accuracy for each of the models. For the best performing models – ResNet-50-based model and DL4Burn (both neural network-based methods) – we also perform and report average and best, AUC and accuracy across 5-fold cross-validation, respectively.

3 Analysis of Results

The AUC and Accuracy results for the proposed and the baseline methods are shown in Table 1. We note that handcrafted features-based techniques perform very poorly on the given dataset. This highlights the need to learn the features from data, which is supported by the results of the neural network-based models. Further, we observe the benefit of using multimodal data for predicting burn surgical candidacy from the performance of the unimodal ResNet-50-based baseline and DL4Burn. Specifically, in Table 2 we show the detailed results between the unimodal (image-only) and multimodal deep learning models. Here, we note the superior performance of the proposed multimodal approach as compared to the unimodal ResNet-50-based baseline. This shows that additional observations made by medical professionals are critical for improving the performance of the deep learning model. It is worth noting that DL4Burn surpasses the human evaluator by a large margin, underscoring applicability of DL4Burn in real-world clinical applications.

Furthermore, we explain the predictions made using the ResNet-50 models for images using Archipelago in Fig. 2. For each image, Archipelago explains how the main effects, and the interactions (the pixels which interact with each other) contribute to the final prediction. Here, the colored patches show if they support (green), are against (red), or are neutral (no color), for a given classification result. These explanations can be leveraged by the physicians to evaluate the surgical candidacy, and aids in the transparency of the learned deep learning model.

4 DL4Burn iOS App

Complementary to the proposed multi-modal deep learning model for burn wound evaluation, we present the prototype of our DL4Burn iOS application, which is an assistive tool designed to aid physicians in burn evaluation and triage. Our DL4Burn iOS app seeks to provide an efficient, cost effective, and reliable adjunct for determining a burn wound’s surgical candidacy. Given the accessibility of mobile phones and their increasingly common use in healthcare settings,
we anticipate its utility in busy emergency rooms, burn unit, and pre-hospital settings. As such, our iOS app has the potential to reduce healthcare errors, their associated costs, as well as streamline the delivery of burn care.

4.1 Functionalities

The functionalities of the app consist of a physician-based interface that enables them to upload burn images and patient demographic and injury data in order to track and manage burn patients. This is a cloud based app, in which uploaded data will be stored in the Google Firebase cloud (Fig. 1) or other cloud-based services. Here, we plan to use the Google Firebase, for its secured cloud-based storage service for mobile application development and deployment. Specifically, for HIPPA compliance and security, we utilize its built-in security authentication and authorization‡.

To begin, the main screen of the app prompts physicians to sign up or log in with their credentials (Fig. 3(a)). Once they are logged in, the app takes the user to a portal in which they add or select from existing patient profiles. Here they can either view the patient’s existing data or upload new data (Fig. 3(b)). To capture a new image for a patient, physicians can select ‘Camera’ on the navigation bar, where they will be able to take a photo and enter the associated patient demographic and injury data (Fig. 3(c)). A random string is generated to uniquely identify each image. This same randomly generated string is used as a key to store details about the patient as well in the real-time database. Screenshots for Google storage and Google Real-time database are given in Fig. 4. Once the image and data are uploaded, the information is stored on the cloud database and immediately fetched into the app. The physician can toggle to the ‘Users’ tab to view the uploaded image at any time (Fig. 3(d)).

We anticipate physicians will be able to capture burn wound images and injury data throughout a patient’s treatment period in order to more closely monitor the wound while also further training the deep learning model. As such, our iOS app enables physicians to keep an organized and photographic record of a wound’s progression and store this data for future evaluations in the treatment process. Simultaneously, these data points will further boast the predictive capacities and inform future applications of our deep learning model.

‡See https://firebase.google.com/docs/storage/security for details.
Figure 3: Overview of DL4Burn landing screens and Camera tool in the iOS app. Panel (a)-(d) show the registration/log in page, and the main landing screen of the app, camera functionality to capture image and enter patient details, and the main landing screen of the app with the image just uploaded, respectively.

5 Discussion

Summary. Determining whether a burn wound will require surgery is an important step in the management of burn patients. Appropriate timing of surgery is critical for optimizing patient outcomes, minimizing the risk for hypertrophic scarring and contractures, and minimizing healing time and hospital length of stay. Conversely, correctly identifying surgical burn wounds spares patients from unnecessary surgeries, their associated risks and healthcare costs.

Incumbent on the surgical decision-making process is an accurate burn wound evaluation. Clinicians most commonly utilize visual inspection to determine burn depth, using it as an estimator for healing time. Notably, the accuracy of this method ranges from 50-76% and is dependent on clinician experience. Burn depth and the associated healing time is further used to determine treatment strategy. Superficial to superficial partial thickness burns are considered nonsurgical wounds and deep partial thickness to full thickness burns are considered surgical wounds. Existing machine learning literature takes advantage of this classification method, designing models that determine burn depth and in turn surgical candidacy. These models have achieved accuracies of greater than 80%, demonstrating the potential role for machine learning as an adjunct for burn diagnosis.

However despite this success, the decision to operate is less opaque than simply determining burn depth. Clinicians must also consider the surgical risks, patient factors, and associated injury characteristics to decide whether to operate. Therefore our proposed multimodal approach addresses these limitations by leveraging patient demographic and injury data with photographic images, a process that assimilates more to that of clinicians. Multimodal deep learning involves the integration of data from more than one domain, used to improve classification by integrating information from each data source. In this study, we demonstrated that a multimodal approach can effectively combine the available information and physician input to provide superior performance as compared to a single domain approach.

Limitations and Future Work. As with any study, it is important to consider the limitations. The results presented in this work were based on a relatively small dataset, which may have led to slight overfitting. To counter this, we plan to leverage the proposed DL4Burn mobile application to scale data collection and hence improve model generalization. Next, due to the retrospective nature of our study, we understand that our data is dependent upon the accurate and complete documentation in the records. As such, the current multimodal features formed in our analysis were drawn from the evaluations of medical professionals available in the charts. Our future work will focus on extracting these features from prospectively obtained data and observations entered through the application. Next, in this work we utilize the final outcome, i.e. if the wound eventually required surgery or not. Specifically, our procedure relies on
Figure 4: Overview of data stored in Google Firebase. Panel (a) and (b) show the image stored in Google Storage and the data about patient along with the image description and url of the image stored in real-time database, respectively.

these final assessment as opposed to initial assessments, since initial assessments are more likely to be incorrect. In our future studies, we plan to record initial assessments to analyze how clinicians’ recommendations change over time. Furthermore, it would also be interesting to equip the learning algorithm with specific domain knowledge used by clinicians to evaluate and improve surgical candidacy.

Another line of work can also study the counterfactuals and effect of interventions. To enable such analysis, we plan to add functionality to track wound progression and interventions over time. This feature can also be used to assist remote assessment of wounds and monitoring surgical candidacy on-the-fly.

Finally, the COVID-19 pandemic has also highlighted the need to develop tele-medicine capabilities for burn wound monitoring. Motivated from this, we are also planning to develop an interface for patients wherein medical professionals can track wound progression remotely. We also seek to analyze successive images from patients to track wound healing, progression, and scarring outcomes so that we may improve and inform future iterations of the software.

Conclusions. Burn wound surgical candidacy involves complex decision making which needs to be customized for each patient, making it particularly challenging to standardize. In a number of cases, the decision to operate (or not operate) may result in long-term medical complications. As a result, there is a need to accurately predict surgical candidacy based on historical patient records to improve patient outcomes. The proposed DL4Burn model and mobile application leverage the expert analysis along with burn images to build reliable multimodal deep learning-based assistive tool for surgeons to improve decision making and patient care.

6 Acknowledgments

The authors would like to graciously acknowledge Joshua Lin, Megha K. Sheth, and Justin Dang for their contribution towards data collection and annotation. The analysis was conducted after receiving approval from our institutional review boards (IRB) number HS-21-00201.

Development of an Online Contraceptive Decision Aid for College Women

Molly Redman; Jenny Brian, PhD; Dongwen Wang, PhD
Arizona State University, Tempe, Arizona

Abstract

Lack of knowledge in highly efficient contraceptive methods led to low rates of adoption and misuse of these methods by young women. The existing online tools for contraceptive decisions have flaws. To address this critical need, we developed a prototype online contraception decision aid for college women. For this purpose, we conducted a focus group interview for needs assessment. We designed a scoring system to provide accurate and customized recommendations based on a user's preferences. We implemented the tool with specific functions to collect users' needs and preferences in selecting specific contraceptive methods, to present the customized recommendations, to provide side-by-side comparison of all contraceptive methods, and to recommend additional resources. Preliminary data seem to indicate positive evaluations of the tool. Future work is required to examine the generalizability of the findings and to have full implementations of the tool for real world use.

Introduction

Background

Birth control, commonly referred to as contraception, is defined as any medication or device to prevent pregnancy. There are a variety of contraceptive methods, such as condoms, birth control pills, and intrauterine devices (IUDs), which can be administered in different fashions. Some methods are highly effective at preventing pregnancy, while others are not due to their nature or high probability of user error. Many methods can be used simultaneously with condoms as extra protection against pregnancy, HIV, and other sexually transmitted infections (STIs). Beyond pregnancy prevention, contraceptive methods are beneficial in other aspects of women's health, including regulation of hormones, management of periods, and control of hormonal acne.

Each birth control method is different. Even the same method may work differently for each individual woman. Previous studies have shown that lack of knowledge and awareness of highly efficient contraceptive methods results in their low rates of adoption and misuse, especially in young women. Despite having a higher fail rate compared to other methods, the birth control pill is the most commonly prescribed method among college women. Approximately 77% of this population have reported using birth control pills as their primary choice for contraception. Yet there are many other available methods.

There are two popular online contraceptive decision aids – the Planned Parenthood Birth Control Quiz and the Bedsider Comparison Matrix. The Planned Parenthood tool consists of a short quiz that evaluates a user’s preferences, lifestyle, and opinions on selected methods. At the conclusion of the quiz, the tool recommends three birth control methods that account for the user’s inputs. There are also videos that serve as additional educational resources for those interested in learning more about the recommendations. The Bedsider Comparison Matrix is a large grid that allows a user to compare and contrast many different contraceptive methods at the same time, based on criteria such as “prevents pregnancy” and “party ready.” There is another feature called “Build Your Own” that allows the user to compare up to three different methods at one time. This feature enables the user to learn more about methods that they are specifically interested in.

Preliminary Study on Accuracy and Usability of the Existing Online Tools for Contraceptive Decision

We conducted a preliminary study to assess the accuracy and usability of the tools provided by Planned Parenthood and Bedsider. Here accuracy reflects how well the tool’s recommendation complies with what is expected, i.e., an accurate recommendation would suggest a method that fits what a user has identified as the most important needs and preferences. Meanwhile, usability refers to how easily the tool allows for a user to receive the recommendation, including components such as navigation, layout, and general graphic design. The research aim of this preliminary study was to evaluate the two existing online tools for contraceptive decision, identify any gaps in accuracy (only applied to the Planned Parenthood tool) and usability, and if so, propose potential improvements.

For this purpose, we conducted a literature review on birth control usage and usability heuristics. We then performed a usability walkthrough for both tools to examine whether they were user friendly. Lastly, we developed a set of test
cases that enumerated the possible combinations of decision factors such as to provide a quantitative evaluation on the accuracy of the Planned Parenthood quiz.

We found that the language used for the Bedsider matrix was understandable by both experienced and inexperienced users. Furthermore, there was consistent use of symbols across the platform, therefore allowing for easy transition between pages. However, the tool heavily relied on these symbols and did not provide labels to clearly indicate their meaning. As a result, there was a heavy reliance on recall rather than recognition, a flaw in usability. The information provided in the Bedsider tool was clear. However, there was no opportunity to create a customized result based on user needs, which was another limitation.

In contrast, the Planned Parenthood quiz had a focus on providing customized recommendations to a user. There were many additional information sections throughout the quiz to help the user understand the rationale of certain questions. However, as the user progressing through the quiz, there was no opportunity to go back to correct a mistake. Furthermore, the recommendations at the end did not always accurately reflect the needs or preferences of the user.

To assess the accuracy of the Planned Parenthood quiz, we developed a set of 200 test cases with all possible combinations of the decision factors. We applied the quiz to these 200 test cases, manually reviewed the recommendations generated for each, and examined: (1) the adherence to CDC guidelines; and (2) the accurate reflection of user’s preferences. Of the 200 test cases, 174 (87%) adhered to the CDC guidelines. Among the 177 test cases with an expression of strong user preferences, only 108 (61%) of the recommendations accurately reflected them.

These results have revealed that: (1) the Planned Parenthood quiz and the Bedsider’s matrix each has its own usability flaws; and (2) there is a gap in accuracy of the recommendations generated by the Planned Parenthood tool in fitting an individual’s preferences.

Study Objectives

To address the issues identified from the above preliminary research, we decided to launch a study to develop a new birth control decision aid, My Contraceptive Choice (MCC), with the following aims: (1) generating accurate recommendations that comply with CDC guidelines and individual user’s preferences; (2) presenting clear and concise information; and (3) providing user control in navigation and the opportunity to correct mistakes. We selected to focus on college women as the target user population of the MCC tool. Here college women are defined as females between the age of 18 and 24 years old and currently attending a four-year public university. This user population has major needs in contraception and yet, as discussed earlier, presented knowledge gaps in selecting the appropriate methods. We report in this paper the development process for the MCC tool. The evaluation of the MCC tool is ongoing. We will report the details of the evaluation study and the results in the future.

Methods

The study started with a focus group interview for the target users to solicit their inputs on the factors they considered when choosing a contraceptive method as well as the desired functions for a new tool to assist their decision making. These inputs were then used to guide the development of the MCC tool.

Due to the COVID-19 pandemic, we decided to conduct the focus group interview online through Zoom. For this purpose, we sought the potential participants for the focus group through the student email lists at the Arizona State University (ASU), obtained consent, and recruited ten female students who were between 18 and 24 years old. Each participant received a $35 Amazon gift card as a compensation for the two-hour focus group session. The ASU IRB approved this study.

We prepared a series of questions for the focus group participants, including: (1) the types of birth control methods they used regularly; (2) selection of specific methods; (3) experiences of using specific methods; and (4) feedback on the two existing online tools for contraceptive method selection (Bedsider and Planned Parenthood). We recorded the focus group session through Zoom. For data analysis, we reviewed the transcript for sentiments that were heavily agreed on with regard to specific questions. We noted the phrases or ideas that were repeated multiple times. We paid special attention to the factors that impacted the participants’ decision making as well as their opinions (either positive or negative) on specific features of the two existing tools.

The design of the new online tool MCC was guided by the CDC guidelines and other related medical literature, the results from the preliminary study on the two existing tools, and the findings from the focus group. Specifically, we envisioned that the MCC tool should provide three important functions: (1) customized recommendations based
on a user’s needs and preferences; (2) side-by-side comparison of multiple contraceptive methods such as to facilitate a user’s decision making; and (3) links to additional resources for further education on specific contraceptive methods, purchase of specific devices, or clinics for medical consultations. For the function described in (1), we relied on the CDC guidelines, the other related literature, and the findings from the focus group interview to select/organize the specific factors and to design an algorithm for customized decision aid. For the function described in (2), we reused certain features from the Bedsider tool deemed to be user friendly, and meanwhile added or revised other features such as to address the usability issues identified from the preliminary study and the focus group. For the function described in (3), we reorganized the existing resources listed on the Bedsider and Planned Parenthood tools, and included additional resources as suggested by the focus group participants.

The initial implementation of the MCC tool was for proof of concept. We thus focused primarily on the user side. For this purpose, we designed the MCC as a client-side web application, based on Hypertext Markup Language (HTML), Cascading Style Sheets (CSS), and JavaScript functions. We present the details on implementation of the MCC tool in the next section.

**Results**

*Findings from the Focus Group Interview*

The focus group included participants with various experiences in use of contraception methods, ranging from inexperienced to users of multiple contraceptive methods including condoms, IUDs, and birth control pills. The motivations behind using these specific methods were primarily for pregnancy prevention, regulation of hormones, and/or management of menstruation and its side effects. Some participants used the dual method (condom + either IUD or birth control pill) for extra protection, while others selected to use only one method at a time. Furthermore, many participants agreed that they felt comfortable using their respective contraceptive methods because their close family members or friends had positive experiences using the same methods.

The participants indicated that they wished they were aware of certain side effects and complications prior to starting a contraceptive method. They agreed that much of the information and resources they received previously were hard to understand and not very helpful. A common side effect participants reported experiencing with contraceptive methods, especially the birth control pill, was weight gain or the difficulty to lose weight. Other medical conditions participants reported as side effects from their contraceptive methods included high blood pressure/hypertension, anxiety, and depression. Although these side effects were hard to manage, some participants said they would still use the same method but wished to be more educated.

However, not all side effects discussed were negative. Many participants agreed that being on the pill reduced their signs and symptoms of acne, a frequently seen medical condition in this population. Additionally, other participants stated that their contraceptive methods helped manage painful menstruation side effects and some even reported having their periods stop altogether. Some participants expressed that they liked the latter side effect, while others did not want this result. Additionally, two participants used their birth control methods to maintain health conditions such as polycystic ovary syndrome (PCOS) or endometriosis.

After taking the Planned Parenthood Birth Control Quiz, the majority of the participants expressed dissatisfaction in their recommendations. From the accuracy perspective, the recommendations did not seem to reflect their inputs on specific needs or preferences expressed during the quiz. The star rating system used by the tool to indicate how well a method fitting for an individual seemed to be somewhat cryptic, as many participants received the maximum number of stars for recommendations of multiple methods but were unsure which fit them better. In regard to the questions asked in the quiz portion, participants were not sure why some questions were needed as they did not seem to have a clear impact to the final recommendation. Including these questions made the quiz long and repetitive, and therefore difficult to remain engaged in.

The participants indicated that the Bedsider matrix was confusing and difficult to decipher at the first glance. They agreed that there was a steep learning curve to understand the purpose of the tool and to use it efficiently. However, once this phase passed, the information was very useful and easy to understand. The “Build Your Own” feature of the matrix was also confusing to many and did not seem that helpful when attempting to compare different methods. One of the largest usability issues was the difficulty in remembering the meaning of specific symbols, which we noted in the preliminary study.

When discussing the development of MCC, participants strongly agreed that they would like to see a mixture of Planned Parenthood’s quiz and Bedsider’s matrix. They wished for a decision aid tool that utilized their inputs to
create customized recommendations, but also wanted the ability to compare and contrast to other methods on a general scale. They also wished for features that clearly demonstrated how their inputs were used to make the recommendations and how the methods fit them as an individual.

Implementation of MCC – Gathering Data of User Needs and Preferences

Based on the CDC guideline, additional medical literatures, the preliminary study on the two existing online tools, and the findings from the focus group, we decided to organize the three main functions of MCC in a sequential order, i.e., recommendations of contraceptive methods with customization to user needs, side-by-side comparison of all contraceptive methods, and additional resources. To use the MCC tool, one can start at the homepage with a brief introduction on the purpose of the tool. From there the tool can be launched.

The MCC tool focuses on a list of contraceptive methods relevant to the target user population of college women, including condom, the copper IUD, the hormonal IUD, the ring, the mini pill, the combination pill, the implant, the patch, the shot, and fertility awareness method (FAM)². The customized recommendations are based on users’ preferences in selecting contraceptive methods, prior experiences in using specific ones, users’ medical history with potential interferences with certain methods, and additional factors that may impact the selection. To solicit the user inputs from these aspects, we have designed four distinct pages - Personal Preferences, User Experiences, Medical History, and Additional Factors, each with a set of questions.

On the Personal Preferences page, we use four Likert Scales (very unimportant, unimportant, neutral, important, and very important) to determine a user’s priorities on specific features of a contraceptive method. These features include cost effectiveness, preventing pregnancy, managing periods and side effects, and (low) possibility of weight gain. A screenshot of the Personal Preferences page is shown in Figure 1.

![Personal Preferences Page](image1.png)

**Figure 1.** A screenshot of the Preferences Page of MCC.

On the User Experiences page, users have the opportunity to indicate the specific methods they have used before. By selecting a specific method used before, users can further indicate the past experience (negative, neutral, or positive) and whether they are considering using it again in the future. A screenshot of the User Experiences page is shown in Figure 2.

On the Medical History page, users can express concerns on a list of their medical conditions (acne and breakouts, blood clotting disorders, depression or anxiety, hypertension or high blood pressure, polycystic ovary syndrome (PCOS) or endometriosis, and treatment of sexually transmitted infections (STIs)) that may interfere with use of specific contraceptive methods. A screenshot of the Medical History page is shown in Figure 3.

On the Additional Factors page, there are three additional questions: (1) how comfortable the user feels with the insertion of a foreign body in vagina (very uncomfortable, uncomfortable, neutral, comfortable, or very comfortable); (2) the level of hormones that the user feels most comfortable using (no hormones, one hormone, two hormones, or don’t know/no preference); and (3) how often the user wants to maintain the birth control methods (daily, weekly, monthly, yearly, or don’t know/no preference). A screenshot of the Additional Factors page is shown in Figure 4.
Figure 2. A screenshot of the User Experiences page of MCC.

Figure 3. A screenshot of the Medical History page of MCC.

Scoring System to Provide Customized Recommendations for the Top Ranked Contraceptive Methods

To provide customized recommendations for the contraceptive methods that fit with a specific user’s needs or preferences, we have developed a numerical scoring system. This scoring system assigns scores to each contraceptive method based on a user’s answers to the questions on the above four pages. As the user moves from one question to the next, the scores for each contraceptive method are added up. After completion of the data collection on user needs and preferences, the three contraceptive methods with the top scores are the recommendations to the user. We discuss the details of this scoring system next.

On the Personal Preferences page, each question focuses on a specific feature for decision, i.e., cost effectiveness, preventing pregnancy, managing periods and side effects, and (low) possibility of weight gain. Only the contraceptive methods in compliance with that feature are scored. Here, the methods that are considered cost-effective include condom, FAM, mini pill, combination pill, the patch, and the ring. Methods that are good at preventing pregnancy include condom, mini pill, combination pill, the ring, the implant, copper IUD, and hormonal IUD. Methods that help reduce periods and their side effects include mini pill, combination pill, the ring, the implant, and hormonal IUD. Methods that have a low possibility of weight gain include condom, FAM, and copper IUD. For a specific question on a particular feature, a relevant method is awarded a point of -2, -1, 0, +1, or +2, corresponding to the user’s answer as very unimportant, unimportant, neutral, important, or very important, respectively. For example, if a user’s response to the question on low possibility of weight gain is important, the three relevant methods, condom, FAM, and copper IUD each is awarded +1 point.

On the User Experiences page, if a user has a positive experience for a specific contraceptive method, that method is awarded +8 points, which is equivalent to the maximum positive points of all their preferences combined from the previous page. In other words, a positive experience for a specific method overrides all the previous opinions against it. An additional +2 points are rewarded if the user indicates to use the method again. If a user has a negative experience for a specific method, that method is awarded -8 points, i.e., overriding all the previous preferences for it. If a user has no interest in using a method again, it will be removed from the final recommendation list altogether.

On the Medical History page, if a user has checked acne and breakouts or polycystic ovary syndrome (PCOS) or endometriosis, each contraceptive method that can help address these concerns, including the combination pill, the patch, and the ring, is awarded +2 points. The other medical conditions may lead to potential contraindications when selecting specific methods. Therefore, if a user has expressed concerns on one of those medical conditions, all its contraindicating birth control methods will be removed from the final recommendation list. Specifically, for blood clotting disorders, depression or anxiety, and hypertension or high blood pressure, the contraindicating methods include the combination pill, the patch, and the ring. For treatment of sexually transmitted diseases (STIs), the contraindicating methods include hormonal IUD and copper IUD.

On the Additional Factors page, the scoring for the first question (how comfortable with the insertion of a foreign body in the vagina) is similar to the Likert Scale system used for the questions on the Personal Preferences page. Specifically, a relevant method (hormonal IUD, copper IUD, and the ring) is awarded a point of -2, -1, 0, +1, or +2, if the answer to the question is very uncomfortable, uncomfortable, neutral, comfortable, or very comfortable, respectively. For the scoring of the second question (level of hormones), each of the relevant method for a specific answer (no hormone, one hormone, or two hormones) are awarded +2 points. The relevant methods for no hormone are condom, FAM, and copper IUD; the relevant method for one hormone are the implant, the mini pill, the shot, and the hormonal IUD; and the relevant methods for two hormones are the patch, the combination pill, and the ring. For scoring of the final question (frequency to maintain a method), each of the relevant method for a specific answer (daily, weekly, monthly, or yearly) is awarded +2 points. Here the methods that must be maintained every day are condom, FAM, the mini pill, and combination pill; the methods that must be maintained on a weekly basis are the patch and the ring; the method that is maintained on a monthly schedule is the shot; and the methods that must be maintained on a multi-year schedule are the implant, the copper IUD, and the hormonal IUD.

After the scorings for each of the questions on the four pages are completed, every contraceptive method now has a total score. The MCC tool generates a list of recommendations based on the top three methods with the highest scores that match with a user’s preferences, prior experiences, medical conditions, and other needs. The complete algorithm is illustrated in Figure 5.
Figure 5. The algorithm of the scoring system to make customized recommendations.
Graphical Presentation of the Recommended Contraceptive Methods and Side-by-Side Comparison of All Methods

The feedback from the focus group interview indicated that the users preferred a tool with both the customized recommendations and the side-by-side comparisons of all contraceptive methods. When designing the function to present the customized recommendations, we decided to merge it with the side-by-side comparison of all methods to achieve efficiency. For this purpose, we divided the customized recommendations into two segments (pages), i.e., a graphical presentation and a detailed description in text.

Immediately after users have completed the quiz (the first four pages), they are directed to the first segment of the presentation, which uses a tabular design similar to Bedsider’s matrix. The columns of this table include all the contraceptive methods, while the rows list the major factors considered by young women when selecting a birth control method. Each cell of this table is filled with either a green checkmark (yes), a red cross-mark (no), or a gray circle (sometimes/maybe), indicating how well the corresponding method (column) matches with the factor (row). In the same table, the columns corresponding to the top three recommended contraceptive methods are highlighted in blue color. Meanwhile, the rows corresponding to the factors deemed as important to a specific user (based on the user’s inputs from the previous four pages) are bolded. The user can also hover the mouse over a specific cell to learn more about the corresponding contraceptive method from the tooltip. A screenshot of this page is shown in Figure 6.

**Figure 6.** The customized recommendations are combined with the side-by-side comparison of different methods.

Details of the Recommended Contraceptive Methods and Additional Resources

The second segment of the results section displays the details of the customized recommendations for a user. For this purpose, we organize the top three recommended methods in separate columns, each containing the detailed information pertaining to what the method is, how it fits the user, how to use the method, as well as resources for further education and finding a pharmacy/clinic. In the section to explain how a method fits the user, the system dynamically generates bullet points based on the user’s inputs. For example, if a user wants a method that is very good at preventing pregnancy, a bullet point will show up here indicating how effective the selected method can address this need. A screenshot of this segment is shown in Figure 7.

The last function of MCC that we envisioned was to provide additional resources for all contraceptive methods. Since this part is similar to the last section of the recommendations described above, we decided to merge the function of Additional Resources with the previous segment as an appendix. This appendix includes all contraceptive methods, each with two sections of additional resources: (1) the Information section links to the Planned Parenthood and Bedsider websites for more educational resources; and (2) the Find a Pharmacy or Clinic section links to sites to locate a pharmacy/clinic or to make a purchase online.

Evaluation of MCC

The evaluation of the MCC tool is ongoing. The preliminary results from an online survey of 150 users indicated that: (1) 112 (75%) believed that the recommendations they received were appropriate and reflected their personal preferences; and (2) 136 (91%) thought that the layout of MCC made it easy to navigate the tool. We will report the details of the evaluation study and the complete results in a future paper.
Discussion

In design of the MCC tool, we have obtained important insights from the focus group participants with regard to why they use specific contraceptive methods. Specifically, we have found that the most important factors considered by a college woman when selecting a contraceptive method are cost effectiveness, pregnancy prevention, management of periods and their side effects, and little weight change. Neither Planned Parenthood nor Bedsider has included the last factor of little weight change in its tool, but it is indeed an important consideration by many college women.

The focus group members unanimously agreed that MCC should combine the best aspects of Planned Parenthood’s quiz (customized recommendations) and Bedsider’s matrix (side-by-side comparison). Our design directly reflected this request. In collection of users’ needs and preferences, we included additional factors, such as the potential concerning medical conditions, which were not in the Planned Parenthood quiz. On the Recommendation Page, we emulated Bedsider’s matrix but made significant revisions, including: (1) removed factors that typically were not applied to the targeting user population, such as can be used while breastfeeding; (2) removed methods that seemed outdated or inefficient, such as the diaphragm and withdrawal; (3) highlighted the top three recommendations based on a user’s needs and preferences; and (4) highlighted the factors deemed to be important for a specific user. We therefore achieved the goal to combine the customized recommendation and side-by-side comparison to show the pros and cons of each method with an efficient design.

A primary focus of the MCC design was to ensure that: (1) the user had the opportunity to indicate their previous experiences with birth control methods, and (2) the tool’s recommendations of specific methods should reflect the user’s experiences. While the Planned Parenthood quiz was supposed to have a similar feature, the focus group feedback and test case data both suggested that the feature did not work. We therefore designed an algorithm that combined the numerical scoring and hard rules for this purpose. If a user had good experiences using a specific contraceptive method, the system would award +8 points to that method. On the other hand, if a user had bad experiences using a method and would not consider using it again, the system would exclude that method from the final recommendations. It seems this strategy is able to provide customized recommendations, as indicated by the preliminary data from the online survey. Detailed analysis is needed here, and we expect to report the complete results in a future paper.

We have made the navigation of the MCC tool easy by using the “continue” and “back” buttons on each page. A user can go back to a previous page to review and correct any mistakes in data entry. The preliminary data seemed to indicate that users had very positive feeling on navigation.

There are a few limitations in this study. First, the focus group participants were recruited from ASU’s College of Health Solutions and Barrett Honors College. Many students in these two colleges study in health-related disciplines, and thus may have more knowledge on birth control. In addition, the focus group approach has its intrinsic limitations, such as small sample size and participant’s reluctance to express opinions different from the majority. Generalization of the findings, such as the preferred structure and language used for the tool, from this focus group to other populations should be further studied. Second, in development of the algorithm, we did not consider insurance coverage when assigning the cost-effective methods. When designating the methods with low possibility of weight...
gain, we took a conservative approach to exclude the methods with controversial evidence\(^\text{15,16}\). The scoring system, in particular, the weight for a specific factor, was based on heuristics. The robustness of the recommendations generated by the MCC tool therefore should be further tested. In the ongoing evaluation study, we have included quantitative measures on performance of the system based on simulated test cases. We will report the results in a future study. Third, the current implementation of the MCC tool is for proof of concept, focusing only on the client side. Full implementation of the system is needed to capture the actual use of the tool in real world. This could be another direction for future work.

**Conclusion**

We have successfully developed a prototype of the MCC tool to help college women select birth control methods. We have leveraged the inputs from a focus group, integrated certain useful features from two existing tools, and built an efficient, easy-to-navigate system. We have designed a scoring system for customized recommendations of contraceptive methods that are based on users’ needs and preferences. Preliminary data from an ongoing study seem to indicate positive evaluations of the tool. Future work is required to examine the generalizability of the findings to other populations and to have full implementations of the tool for real world use.

**Acknowledgements**

The Barrett Honors College at ASU provided funding support for this honors thesis research by the first author. We thank the students who participated in the focus group for their contributions to this study.

Comparing Scribed and Non-scribed Outpatient Progress Notes

1Oregon Health & Science University, Portland, OR

Abstract

Working with scribes can reduce provider documentation time, but few studies have examined how scribes affect clinical notes. In this retrospective cross-sectional study, we examine over 50,000 outpatient progress notes written with and without scribe assistance by 70 providers across 27 specialties in 2017-2018. We find scribed notes were consistently longer than those written without scribe assistance, with most additional text coming from note templates. Scribed notes were also more likely to contain certain templated lists, such as the patient’s medications or past medical history. However, there was significant variation in how working with scribes affected a provider’s mix of typed, templated, and copied note text, suggesting providers adapt their documentation workflows to varying degrees when working with scribes. These results suggest working with scribes may contribute to note bloat, but that providers’ individual documentation workflows, including their note templates, may have a large impact on scribed note contents.

Introduction

In the decade since the HITECH Act catalyzed electronic health record (EHR) adoption in the United States,1 there has been growing concern that providers spend too much time documenting patient care.2 The typical primary care physician now spends as much time in front of their EHR as with patients,3,4 and there is growing evidence that more EHR time, especially after work, contributes to higher rates of physician burnout.5,6,7 There is an urgent need to reduce EHR burden,8 which has led many physicians to employ medical scribes—clerical staff who help document patient care.9 Scribes are often primarily employed to document exam room conversations in clinical notes, but scribes may also perform a wider range of tasks based on their clinical training or the provider with whom they work.10 Many scribes are students with little prior medical experience, though some have prior training as nurses, technicians, or medical assistants and thus have license to perform some clinical as well as clerical tasks.

Prior work has found that working with scribes often reduces provider documentation time while increasing physician satisfaction and clinic volumes.11,12 Yet, few studies have examined how working with scribes affects clinical notes themselves. One study found provider’s perceptions of chart quality and accuracy increased when working with scribes,13 while another found scribed notes in primary care clinics were of slightly higher quality when measured on the PDQI-9 scale.14 However, other work found too much variability between raters to use the PDQI-9 to evaluate scribed note quality in emergency medicine.15 Likewise, one simulation study found significant variation between scribes in the completeness, quality, and accuracy of their notes.16 More evidence is needed to assess how employing scribes affects the contents of clinical notes. In particular, there is a need to assess the variation of scribe impact across providers and specialties to help illuminate best practices for collaboratively documenting patient care. Most prior work has instead examined scribes working with a handful of providers in a single specialty.10

This retrospective cross-sectional study aims to help fill this knowledge gap by examining how scribed notes differ from those written without scribe assistance. Since scribes often focus on exam room interactions, we hypothesize:

1. H1: Scribed notes are longer than notes written without scribe assistance
2. H2: Scribed notes contain more manually typed text, but similar amounts of copied and templated text

To test these hypotheses, this study examines over 50,000 notes written by 70 providers in 27 specialties across 2017-2018, both with and without scribe assistance. We find scribed notes are significantly longer, containing more manually typed text, but also more templated and copied text. We also find substantial variation between providers in how working with scribes affected their mix of typed, templated, and copied note text. Together, these findings suggest working with scribes may contribute to note bloat, but that providers’ individual documentation workflows and note templates may have a large impact on the contents—and thus the quality and accuracy—of scribed notes.
Methods

This research was conducted at Oregon Health & Science University, a large academic medical center in Portland, Oregon. OHSU implemented a commercial EHR for billing, documentation, and practice management starting in 2005 (Epic Systems, Verona WI) and has used the same EHR since. After piloting scribe use in Obstetrics & Gynecology for several years, OHSU implemented a university-wide scribe program in 2015. Rather than employ scribes through an external scribe service, the program is managed by OHSU and primarily employs students seeking additional medical experience before embarking on further training (e.g., medical school) rather than individuals with prior clinical training (e.g., technicians, medical assistants). This research was approved by OHSU’s Institutional Review Board which granted a waiver of informed consent for analysis of EHR data and metadata.

Data Collection

To examine how notes written with scribe assistance differ from those written without, we first identified which providers worked with scribes during the years of 2017 and 2018. To do so, we obtained a list of all EHR user IDs for scribes employed by OHSU’s scribe program from its inception in 2015 until July 2020. We then used this list to identify all outpatient encounters in 2017 and 2018 where a scribe edited the patient’s record. From this list of encounters, we identified providers who had worked with a scribe for at least 100 encounters during the study period. To get a sample of notes written by these providers, we leveraged an existing corpus of 200,000 randomly-selected patient records covering the decade from 2009 to 2018. From this corpus we collected all notes written in 2017 and 2018 by providers who regularly worked with scribes as identified above. In addition, we collected demographic data about each encounter such as the billed level of service, patient age, the patient’s assigned sex, and the patient’s self-described race and ethnicity. To look at how notes were written in more detail, we also collected EHR metadata describing how much of each note had been entered via manual typing, copy-pasting, or a note template, as well as which EHR user entered that text. Providers with fewer than 20 scribed notes or 20 non-scribed notes in the corpus were excluded from analysis to ensure a sufficient number of notes of each type for comparison.

Measures

The primary measures employed in this study were note length, the source of note text, and the presence of certain lists of templated patient data. Note length was measured in characters as tracked by the EHR. The source of note text was measured using EHR metadata to count how many of a note’s characters were typed manually, copy-pasted, or inserted with a template. Since this metadata tracks which user entered text via each method, we calculated what proportion of each note’s characters were entered by the primary provider for the encounter, the scribe, or another member of the care team. Finally, we used regular expression matching to identify whether each note contained highly-structured data lists inserted into the note using a template. For example, whether a note contained an imported problem list could be determined by checking if the note contained the text ”Patient Active Problem List” which appears at the start of every list imported using our institution’s standard problem list data link.

Data Analysis

Differences in patient and encounter demographics between scribed and non-scribed visits were evaluated using $\chi^2$ tests. We report mean note lengths and the mean number of characters attributable to each source of note text to ensure component values (i.e., characters of manually typed, templated, and copied text) sum to the average note length. The observed data are not independent (e.g., the lengths of notes written by the same provider are correlated) so we use mixed-effect linear models to assess the association of working with a scribe with 1) note lengths, 2) the number of characters attributable to each text source, and 3) the proportion of notes containing each type of templated patient data list. These models control for the provider as a random effect and the encounter year, patient age, patient assigned sex, patient self-described race, patient self-described ethnicity, and billed level of service as fixed effects. We only report model estimates for the modeled associations with scribe presence as all other model factors were included not to test a specific hypothesis, but to control for potential disparities. Working with a scribe was considered to be significantly associated with an increase or decrease in each of the modeled measures if the model’s p-value for scribe presence was <.05. Variation in how scribes affected different provider’s documentation workflows was also explored by plotting how much longer or shorter scribed notes were than non-scribed notes for each provider. All analyses were performed in Python (v. 3.7.6), using the statsmodels library for statistical modeling.
Results

We identified 89,084 encounters in 2017-2018 where a scribe employed by OHSU’s scribe program had edited the patient’s record. Limiting this list of encounters to office visits, providers who worked with scribes for at least 100 visits over the study period, and visits where only one scribe edited the record left 73,061 potential scribed visits for inclusion in the study. Of these, note data from the randomly sampled records were available for 28,473 scribed visits (39% of potential scribed visits) as well as 24,653 visits conducted by the same providers without a scribe present. This sample excluded 2,718 notes from 14 providers with fewer than 20 scribed or 20 non-scribed notes in the corpus. In total 53,126 visits conducted by 70 providers in 27 different specialties were included in the study (Table 1).

Scribed vs Non-Scribed Visits

There were significant differences in patient and encounter demographics for visits documented with and without scribe assistance for which notes were available. Visits with a scribe present were more likely to have been conducted in 2018 rather than 2017 (p<.001), potentially reflecting the increasing use of the scribe program over time, and were more likely to have been billed at a higher level of service (p<.001) (Table 2). Scribed visits were also more likely to have been for older, non-hispanic, and female patients, which may reflect that physicians in Obstetrics and Gynecology were among the first to work with scribes at OHSU and still among the most frequent users of scribes (Table 1).

Note Length

Notes written with the assistance of scribes were significantly longer than those written without scribe assistance. In our sample, the mean note written with a scribe was 6,062 characters long whereas the mean note written without a scribe was 4,430 characters in length. However, this observed difference also reflects differences in the kinds of visits conducted with and without scribes, with some providers and specialties employing scribes at most visits, and others less frequently (Table 1). Controlling for variation in note lengths by provider, patient age, sex, race, ethnicity, encounter year, and billed level of service, notes written with the assistance of scribes were found to be 989 characters longer than those written without scribes (p<.001, 938 to 1,040 95% CI). This represents a 22% increase in length from the average non-scribed note. The association of scribe use with increasing note length varied by provider. While 61 of the 70 observed providers wrote longer notes when working with a scribe—in one case over 4,000 characters longer on average—9 providers wrote shorter notes when working with scribes (Figure 1).

Text Source

The source of note text was significantly different between scribed and non-scribed visits (Figure 2). Controlling for variation in note length by provider, patient age, sex, race, ethnicity, encounter year, and billed level of service, providers wrote an average of 2,024 fewer characters when working with a scribe (p<.001, 1,983 to 2,065 95% CI), and members of the care team other than the provider or the scribe (e.g., residents, technicians, medical assistants) wrote 1,186 fewer characters (p<.001, 1,148 to 1,224 95% CI). Meanwhile, the overall mix of text entered by any
author included significantly more text from all three sources, including 272 more characters of manually typed text ($p < .001, 256 to 289 95\% \text{ CI}$), 112 more of copied text ($p < .001, 86 to 137 95\% \text{ CI}$), and 606 additional characters of templated text ($p < .001, 567 to 644 95\% \text{ CI}$).

$^a$ Includes encounters without level of service specified, or billed with a code lacking the typical 1-5 office visit code levels.

Figure 1: Difference in mean note length between notes written with and without scribes, by provider.
Figure 2: Mean number of note characters by source of note text and author for notes written with and without scribes.

**Templated Data Lists**

Scribed notes were observed to include certain highly structured lists of patient data more often. For example, scribed notes were more than twice as likely to include an imported patient problem list (29.5 vs. 12.6% of notes) and 10 times as likely to include a list of reviewed lab results (11.1 vs. 1.1%). However, these differences as well as the difference in how often notes included a structured allergy list (47.8 vs. 36.5%) were not significant when controlling for factors such as the provider, patient age, sex, race, ethnicity, encounter year, and billed level of service. That is, the observed differences in how often these items were included in the note were driven more by the changing practices of a few providers than being a consistent difference across all providers. By contrast, scribed notes were significantly more likely to include medication lists as well as structured lists of past medical, past surgical, and family history (Table 3).

Table 3: Percent of scribed and non-scribed notes containing certain templated lists of patient data. Parameter estimates and p-values are given for the scribe factor in mixed-effect models of each list’s presence.

Variation by Provider

Lastly, to examine variation by provider and specialty, we plotted the mean difference in note length, both overall and by text source, for the nine providers with the greatest increase and the greatest decrease in note lengths when working with a scribe, as well as all providers in the four specialties with the most scribed encounters (Figures 3 & 4). Providers did not display a consistent trend but varied in whether most of the additional (or decreased) text was manually typed, templated or copied. For example, while several providers had large increases in templated and manually typed text, for other providers the increase in note length was almost entirely attributable to additional copied text. While trends were more apparent when providers were grouped by specialty, not all providers in the same specialty exhibited the same trends (Figure 4).
**Figure 3:** Average (mean) difference in source of note text for providers with the largest increase and largest decrease in note length between notes written with and without scribe assistance.

**Figure 4:** Average (mean) difference in source of note text between notes written with and without scribe assistance for providers in the four specialties with the most study encounters.
Discussion

This study was designed to test two primary hypotheses: 1) that scribed notes were longer than non-scribed notes and 2) that scribed notes contained more manually entered text, but not more templated or copied text. In addition, it began to explore the variation in how providers adapted their documentation workflows to working with a scribe.

Longer Scribed Notes

We find strong support for the first hypothesis. After controlling for variation by patient, provider, and encounter characteristics, we find scribed notes were 989 characters longer than those written without scribe assistance—equivalent to about 150 words of additional text. There are a number of reasons why scribed notes may be longer, including scribes manually typing more detailed patient histories or including templated attestations of their contribution to the note. Scribed notes may also be capturing more detailed information to support higher levels of billing, though the models employed in this study already control for the propensity of scribed visits to be billed at higher levels of service. Whatever the precise cause, the observed difference in note length raises the concern that while scribes may save physician time, they may also contribute to note bloat. While 1,000 extra characters in a single note may seem a small increase, it translates to a 22% increase in length over the average non-scribed note. Multiplied across the 20 or more notes a provider may write in a single day—or that another physician may need to scan during chart review—the accumulated additional text may profoundly affect EHR burden. With clinical notes in the United States already 4-times longer than those in other countries, care must be taken not to bloat notes further.

Source of Text in Scribed Notes

Beyond observing differences in note lengths, this study was also designed to investigate how text was entered into scribed and non-scribed notes. We find evidence supporting part of our second hypothesis; that scribed notes would contain more manually entered text, but not more templated or copied text. Scribed notes did indeed contain more manually typed text (272 characters), but also more copied and templated text (112 and 606 additional characters respectively). The overall difference in lengths between scribed and non-scribed notes thus appears to be driven more by note templates than manually typed text. And despite the risks of copying note text to patient safety and note quality, we see an increase in the amount of copied note text when working with a scribe. Invoking templates and copy-pasting prior notes may help scribes document consistently, and quickly adapt to the preferences of different providers. However it may also propagate outdated or erroneous findings, as when copying a prior assessment and plan, or using a template to generate a review of systems with default findings that were not actually observed.

Trends were also apparent in shifting note authorship. As might be expected, providers wrote substantially less text in scribed notes, entering fewer than half the characters they would in a typical note written without scribe assistance. Yet, they still entered a non-trivial amount of text. Scribes also contributed substantial amounts of text, with just the scribe contribution to the average scribed note being longer than the entire average non-scribed note. We also observed substantially less text being entered into scribed notes by authors other than the provider or scribe. While data are not presented here, a post-hoc analysis revealed at least part of this drop was due to medical residents writing large portions of non-scribed notes for some providers, but rarely doing so when a scribe was present. This may reflect some providers not electing to employ scribes during resident-led clinics. Beyond demonstrating changing patterns of note authorship, these data highlight the highly collaborative nature of note writing during both scribed and non-scribed visits.

Variation Amongst Providers and Specialties

In addition to testing our two primary hypotheses, this study was also designed to observe variation in how providers adapted their documentation workflows to working with a scribe. Figures 3 & 4 demonstrate the varying impact, even within specialties, that working with a scribe had on how providers drafted their notes. While some providers included substantially more templated and manually written text when working with a scribe, others included dramatically more copied text but only marginally more (or sometimes less) manually typed or templated text. Still other providers reduced the amount of text included in their notes from all three sources of manual typing, copying, and templates. There are likely many individual changes to documentation workflows underlying these observed differences. Providers with large increases in copied note text for scribed visits may have adopted a workflow where the
scribe copies entire sections of prior notes (e.g., history of present illness, assessment and plan) and pastes them into
the current note. Dramatic increases in the amount of templated text may be a result of providers creating entirely new
note templates for scribes to use which import more data lists such as medications or past medical history to help the
provider review the patient’s case.

Future work is needed to observe differences in documentation workflows more directly and to determine which ways
of working with scribes are most efficient, effective, and safe.23 There is existing evidence that provider’s individual
preferences, differences in EHR design, and having multiple ways to enter the same information can drive variation in
provider’s documentation.24 These differences can lead to variation in the completeness of patient records, and may
contribute to patient harm if data are incorrect or difficult to find. While more research on scribed documentation
workflows is needed, it is clear from the evidence collected in this study that working with a scribe does not have one
consistent impact on documentation workflows, but varies from provider to provider.

Implications for Research, Training, and Design

Conclusion

This study demonstrates a strong association between working with scribes and writing longer notes. After controlling for factors such as patient, provider, and encounter characteristics, scribed notes were found to have 989 more characters than notes written without scribe assistance, or roughly 150 additional words. While a portion of this additional text came from manually typed text, the majority came from additional templated text. This study also demonstrates substantial variation in how providers adapted their documentation workflows when working with scribes, as demonstrated by changes to the amount of text incorporated into their notes from manual typing, templates, and copy-pasting. These results suggest working with scribes may contribute to note bloat, but that provider’s individual documentation workflows, including the design of their note templates, may have a large impact on the contents of scribed notes and ultimately the accuracy, quality, and utility of scribed documentation.

Abstract

The majority of prostate cancer survivors do not meet physical activity (PA) recommendations. Although technology has shown to promote PA, engagement has been a challenge. This mixed method study characterizes survivors’ needs and preferences for digital walking programs. Through focus groups and surveys, we engaged prostate cancer support groups to describe PA motivators and barriers, interest in improving PA, and preferences for design features of a future digital walking program. Identified motivators (peers, positive thinking) and barriers (health issues) reflect PA needs that impact engagement. The most preferred features include: (1) well-curated, specific content, (2) individualized feedback from trusted sources, (3) moderated peer discussion, and (4) support from small teams and peer mentors. These findings inform digital PA programs that survivors will find engaging and can promote PA.

Introduction

Prostate cancer is the second most common cancer in men with 1 in 8 diagnosed during his lifetime.1 With an estimated 248,530 new cases of prostate cancer in 20211 and a 5-year relative survival rate of 98%2, more than 3.1 M men in the United States are prostate cancer survivors3. Given the high disease burden of prostate cancer there is a need to identify strategies to improve quality of life among cancer survivors. Regular physical activity (PA) improves fitness, vitality and quality of life among cancer survivors4-6, delays cancer progression7, and reduces the risk of prostate cancer mortality8. Despite the protective benefits of PA for prostate cancer survivorship 85% of prostate cancer survivors report not meeting PA recommendations9.

Even though traditional supervised exercise programs show effectiveness in improving PA for prostate cancer survivors,10 barriers including cost, lack of time and support, access to facilities, and exercise partners, as well as disease-specific barriers like treatment side effects (e.g., urinary incontinence, fatigue) can limit engagement in these programs11-12. There is an opportunity to leverage engaging digital technologies in distance-based programs that bring support to survivors in their own neighborhoods and communities as a feasible low cost alternative.

Digital PA programs provide the opportunity to deliver behavior change techniques13,14 (e.g., goal setting, feedback, social support) via an easy to access, low cost and scalable modality. Digital PA programs that use technologies like fitness trackers, mobile phones, social media have been shown to promote PA among prostate cancer survivors15-17. Yet, lack of adherence and sustained engagement in these digital interventions by prostate cancer survivors limits the effectiveness of these interventions17-19. Thus, a major gap in prior research is how to design digital PA programs that prostate cancer patients will find engaging and want to use. There is a need to understand what type of digital technology appeals most to prostate cancer survivors and how to package existing behavior change features in these digital tools to promote PA.

To address this gap, we engaged prostate cancer survivors and their loved ones in focus groups to understand their needs and preferences for digital walking interventions. We particularly focused on walking as it is one of the most accessible forms of PA that requires no training and might be sustainable throughout a patient’s life. The purpose of this study was to characterize the user needs and design preferences of digital walking programs that leverage fitness trackers and social media features for prostate cancer survivors. Findings offer guidance to inform the design of supportive PA content, self-tracking features, and peer support elements of digital tools that can promote walking.

Methods

We conducted a concurrent mixed methods20 study with focus groups and surveys. Study procedures were approved by the University of Washington Institutional Review Board. We recruited from prostate cancer support groups in the Seattle metropolitan area from July to August 2018 for focus groups conducted at regularly scheduled support group meetings. Each focus group lasted for 60-90 minutes, was moderated by a team member and comprised 3 parts.
First, the moderated led group discussion on perceived benefits and barriers of walking. Participants wrote down ideas to the question “If you had a magic wand what is that one thing that would help you walk more?”. The moderator collected these “magic wand” ideas marked on index cards and read examples aloud to ground group discussion on PA motivators and barriers. This discussion helped to establish and characterize user needs for digital PA programs.

Second, the facilitator introduced the design concept of a digital walking program that incorporated a fitness tracker (i.e., Fitbit) and a social media-based platform (i.e., Facebook) to increase step count. The features of the digital walking program were designed based on best practice and evidence-based recommendations\textsuperscript{13,14,21} to facilitate personalized goal tracking, feedback, and social support. We collected qualitative data on design features participants prefer across 4 sets of options presented through mock interfaces: content, PA feedback, group discussion, and teamwork (Figure 1). Participants discussed likes and dislikes about these feature and ways each could be improved.

Third, after the focus group, participants completed an optional exit survey to report participant characteristics (i.e., demographics, technology experience), interest in improving PA (not at all interested, somewhat interested, very interested), and importance of each design feature (not important, less important, more important, most important).

![Figure 1. Mock interfaces for design features: A) Content, B) PA feedback, C) group discussion, and d) teamwork](image)

**Data analysis**

Focus group sessions were audio recorded and transcribed for qualitative analysis. Two members of the research team took notes during each session to supplement transcripts. We deductively coded this data with a high-level a priori coding schema: PA motivators, PA barriers, and preferences for each of the 4 features (i.e., content, PA feedback, group discussion, and teamwork). A team member (SS) analyzed transcripts using the coding schema in Dedoose\textsuperscript{22}. The researchers (AL and SS) met during the coding process to discuss sub-codes and refine coding categories.

We quantitatively analyzed survey data with SPSS 26.0 (SPSS Inc). We used descriptive statistics to summarize participant characteristics, interest in using digital PA programs, and preferred design features based on ratings of importance. We used inferential statistics to compare interest level and preferences for design features across all participants and among the 3 focus group sessions. We used Friedman tests ($X^2$) to assess differences across participants and Kruskal Wallis tests (H) to assess differences among groups. We used Dunn tests (Z)\textsuperscript{23} with a Bonferroni adjustment for post hoc pairwise comparisons for significant results.

**Results**

1. Participants
Across the 3 focus groups (FG1, FG2, FG3), we engaged 61 members of prostate cancer support groups, of whom 49 responded to the survey (80%). Table 1 summarizes the characteristics of survey respondents who were predominantly older white males, college educated or greater, and 44 reported having been diagnosed within 4 months to 21 years (mean = 7 SD=6). Respondents who were prostate cancer survivors indicated a range of treatments (e.g., radiation, cryotherapy, cyber knife). Of the 5 respondents who did not report having a prostate cancer diagnosis, three identified as a spouse, and one as a caregiver, and one did not report their role. The majority of respondents reported using the internet and smartphones, but less than half reported using social media and less than one quarter reported using a fitness tracker.

2. Motivators and Barriers to PA

Across focus groups a range of “magic wand” ideas surfaced. Table 2 summarizes a few of these ideas. We categorized ideas as technology-based (e.g., reminders, virtual competitions), peer support (e.g., walking buddy, coach), and other ideas, such as “a zapper”.

As the group discussed these magic wand ideas, participants described individual experiences with PA and key PA motivators and barriers surfaced, which we summarize below.

**PA motivators:** Participants expressed both internal and external motivators for PA. Participants told us that considering PA as likable and fun is an important internal motivator for PA. For example:

“Let’s start with basics – what do you like to do? I like to go for a walks and runs in forests, I like to move in beautiful places….If you are happy when you are walking, you are in magic land. So that’s what I do. I walk the trails and the cliffs… and I wouldn’t miss it for the world. So that’s like we get things turned around just get the tools that makes it work. What works for us and what’s suits our nature.” (FG 3)

“Nobody likes boring exercises! It needs to be made fun and it could be anything from dance classes to you know going on group walks or things like that….rather than that just going to the gym and going for a walk there are...
...a lot of other things you can do to get the exercise that are a lot more fun at the same time. Sometimes people don’t connect fun activities with exercise you don’t even know. But it is.” (FG 3)

Participants also indicated that personal characteristics, like fear of failure, serve as internal motivators:

“...I hated failing. That [failure] was more of a push than the rewards for being successful.” (FG2)

Another participant expressed the value of positive attitude and thinking as an internal PA motivator:

“...Positive attitude is probably the basic for my good health... There are a lot of opportunities for good health like health clubs, there are things that people can do that don’t get enough exposure. People get on a positive line of thought and those problems start to get away if you start doing what’s best for you.” (FG 3)

In addition to internal motivators, participants also indicated external motivators from others. Advice from healthcare providers was a key motivator for many, for example, participants shared:

“My doctor told me that I can start hormone therapy and one of the side effects is that it weakens your structural system, and so you need to do some basic strength exercise to combat that down. Well that was the only motivation I needed, it’s just that.” (FG 2)

“I asked the surgeon “what’s the best exercise I can do”? He said “Walking. You need to walk”. And then he added “Not just walk but you’ve got to press yourself.” (FG 2)

Peers were also described as external motivators for PA. For example, participants told us:

“The people that I know, or I’ve come to know, at the YMCA that work out at the same time I do. And they’ve become friends. And I look forward to seeing them... they are friends. I feel like letting them down if I didn’t [go].” (FG 2)

“I think the strongest motivation or motivator would be other people in the group. I don’t know if one of them is not feeling well, the others might go “we missed you.” (FG 1)

Finally, participants indicated the importance of family for motivating them to get more PA:

“My wife is on Fitbit she gets these badges for walking across and stuff like that. She’s competed against other family members for a while. There was a kind of competition and things you know.” (FG 2)

PA barriers: Participants focused on health factors that negatively impact PA, such as recovering from medical procedures or health conditions. For example, participants told us:

“When you have something happen like surgery or an acute event it’s like you lose a lot of ground and need a lot of support on the way back.” (FG 3)

1072
“if someone has irritable bowel it makes it a challenge to head outside without having facilities nearby.” (FG 1)

3. Interest in improving PA

Figure 2 summarizes interest level of survey respondents by focus group. Across all participants, there was high interest in “Improving my PA level” (mean=2.6, SD=0.6), but less interest in “Using technology to improve my PA level” (mean=2.0, SD=0.6), “Using a Fitbit tracker to improve PA level” (mean=1.8, SD=0.7), or “Using a Facebook group to improve my PA level” (mean=1.5, SD=0.6). Across all participants, this interest varied significantly ($\chi^2 (3) = 77.50, p<0.001$). Post hoc pairwise comparisons show significantly greater interest in “Improving my PA level” than improving PA level by (1) using technology ($Z=0.967, p<0.002$), (2) using Fitbit ($Z=1.272, p<0.001$), or (3) using a Facebook group ($Z=1.804, p<0.001$). We also found significantly greater interest across all participants in using technology to improve PA level than using a Facebook group to improve PA level ($Z=0.837, p=0.011$).

Figure 2: Interest in four options for improving PA by focus group (1 = “Not at all interested”; 3 = “Very Interested”)

Among the three focus groups, there was a significant difference in interest for using a Facebook group to improve PA level ($H(2) = 11.367, p = 0.003$). Post hoc pairwise comparison indicated this difference was between FG2 and FG3 ($Z=15.167, p = 0.004$). There were no other significant differences among focus groups.

Group discussion supported these differences and provided insight into participants’ somewhat guarded interest in technologies like Fitbit trackers and Facebook. Use of these technologies was generally low (Table 1) but not universal. One participant expressed challenges with using technology for PA because:

“The technology changes so quickly” (FG 3)

Other participants shared negative experiences and challenges with wearable devices:

“I had a Fitbit and it really helped me walk. But it fell apart in less than a year.” (FG 1)

“If you ride a bike for an hour, you get this many calories burned. If you walk for an hour, you get this many calories burned - when it is quite different when you’re going up that big hill or down that big hill. So, I like a little bit more finding ways of getting a little bit more specific.” (FG 2)

Some participants who were not social media users expressed disinterest:

“I don’t want to participate in a Facebook which I don’t belong to now.” (FG 2)

However, other participants liked the idea of using technology to track PA data, schedule PA, and for reminders. Participants also expressed interest in using technology for self-monitoring:
“So you can do self-evaluation of where you are at... A bunch of data there that he [referring to a coach] compares to your age group. If there was something similar where you could do your own self-evaluation will be helpful.” (FG 3)

Some participants also liked being part of an online group. For example, one participant stated:

“Even in this group I mean there is probably 6 or so different categories of pace or style or even interest. I mean if we can network with real people, that’s the motivation that people like this go for I think...” (FG1)

4. Preferred design features of digital walking programs

Figure 3 summarizes survey respondents’ mean importance ratings for the nine design options categorized by content, PA feedback, discussion and teamwork. Across all participants, there was a significant difference in perceived importance across the nine design options ($X^2 = 126.301, p <0.001$). Post hoc comparisons (Table 2) indicate that some features, such as “accessing posts with educational information”, were rated significantly more important than “receiving feedback via posts from group members” ($z=2.024, p=0.029$), “starting my own discussion” ($z=3.024,p<0.001$), “competing for badges” ($z=4.866,p<0.001$), “comparing step count on a leaderboard” ($z=3.866,p<0.001$), and “working with a team towards a step goal” ($z=2.813, p=0.011$). In contrast, “competing for badges” was rated less important than all other options except “starting my own discussions” ($Z=3.044 p=0.084$).

![Figure 3: Participant importance of social media features by focus group](chart)

We describe quantitative differences and qualitative comments that support differences within the four sets of options categorized by content, PA feedback, discussion and teamwork below.

**Table 2:** p values of pairwise comparisons of content options across all survey respondents (n=49)
Across all participants, the highest rated feature on average was “accessing posts with educational content” (mean = 3.2 out of 5, SD= 0.7). However, there were a not significant difference between importance of this option and “receiving supporting posts from peers” (mean = 2.6, SD= 0.9). Among focus groups, there was a significant difference in importance of “receiving supportive posts from peers” (H(2) = 14.615, p < 0.001). Post hoc comparisons found this difference was between FG2 and FG3 (z= -3.141, p = 0.005) and between FG1 and FG3 (z= -3.354, p = 0.002).

Focus group discussion helps explain and further define these design preferences. Participants indicated that they preferred receiving authoritative information from researchers, coaches, mentors, and clinicians. They expressed interest in receiving quality information that was well curated. Participants also expressed greater interest in receiving information that was specific to prostate cancer than general PA information.

“Well curated, authoritative, interesting content is key.” (P48, FG3)

“When I first got diagnosed with prostate cancer that’s what I did it [referring to finding information on google] and you get all kinds of information too much, perhaps if it was something like this that’s more directed it could be more useful” (FG 3)

Other types of information participants preferred related to personalized exercise, activities, healthy diet and recipes, and goal setting.

**PA feedback options:** Overall, participants rated the importance of “receiving feedback via private messages from the researcher” (mean = 2.7, SD=1.0) higher than “receiving feedback via posts from group members” (mean = 2.3, SD =0.9), but this difference was not significant. Among focus groups there was a significant difference in importance of “receiving feedback via posts from group members” (H(2) = 11.076, p = 0.004). Post hoc comparisons found this difference was between FG2 and FG3 (Z=-3.302, p = 0.003).

Through discussion, participants further describe these preferences. Some indicated that rather than receiving PA feedback from strangers (e.g., people on social media they do not know) they would prefer receiving feedback either from an “accountability partner”, such as a “moderator”, “coach”, or “matched peer”. Participants expressed a preference for in-person meetings to get to know other participants, such a peer support person, before joining a social
media-based PA program. Some felt that meeting in-person could help build trust, shared goals, and motivate progress toward PA goals.

“So it should be someone we know, we like and trust - it takes about a meeting or two probably.”(FG1)

“I think the strongest motivation or motivator would be other people in the group. I don’t know if one of them is not feeling well the other might go “we missed you”.” (FG1)

Some participants were also open to receiving automated feedback from technology:

“Just some kind of feedback that ‘You made it!’ doesn’t need to come from a person”(FG 2)

**Discussion options:** Across all participants, the importance of “having a researcher moderate discussions” (mean = 2.7, SD =0.9) was rated significantly higher than “starting my own discussions” (mean = 2.0, SD =0.8) (z=3.286, p=0.037). There were no significant differences among focus groups for these two discussion options.

Despite the quantitative preference for moderated over self-initiated discussions from surveys, focus group discussion indicated that participants preferred a combination of moderated and peer discussion. They were interested in discussing with a group they were familiar with who shared a similar situation. Many participants indicated that the support group they were currently a part of provided them with opportunities for discussion and a similar group discussion online might be similarly beneficial.

“We can always use more data and information and that’s the stuff we would like to see. Research thoughts about what we can do better and mitigate any of the side effects and to work on not having again those kind of stuff but food not to eat, what foods to eat more of, dietary concerns if those things are proven to be effective and helpful.” (FG2)

**Teamwork options:** Across all participants, the importance of “working with a team toward step goals” (mean = 2.3, SD = 1.0) was rated higher than “comparing your step count on a leaderboard” (mean = 1.6, SD=0.8), which was rated higher than “competing for badges” (mean = 1.2 , SD=0.4). There was a significant difference between competing for badges and working with a team towards a step goal (Z = -4.436, p<0.001). There was no significant difference among focus groups for any of the 3 teamwork options.

Focus group discussion further describes these preferences. Most participants were not interested in competing with one another, which they attributed to age. Some participants indicated they were a little competitive, while most others indicated that they were only interested in competing with themselves and not against others. Thus, participants expressed little interest in competing for badges or comparing goals on a leaderboard for rewards and incentives.

“I could care less if John Doe who I don’t know has 10 million steps doesn’t do me.. it's not going to motivate me any further”” (FG 2)

“FGP (female) - I think competing for badges is not for our age group maybe for younger age group but just did you make your goal yeah did you set a goal did you make your goal if you did give yourself a pat on the back if you did great” (FG 3)

In contrast to competition, rewards, and incentives, participants expressed much greater interest in working with a team towards PA goals, sharing experiences, mentoring each other and motivating each other. Participants preferred closed groups with opportunities to socialize, learn from each other, share information, and find exercise partners or walking buddies.

“The only part about the teams, the last one, ‘working with the team towards step goals’ is if there is a way to set up a team where we can help each other and things more kind of like a mentorship type stuff if somebody is really struggling is there a role I can play to help that person in that process by being a team member with them and maybe that would help them. I might look at that.” (FG 2)

**Discussion**

Few studies have examined prostate cancer survivors’ needs and design preferences for digital walking programs, despite their potential. Through this concurrent mixed methods study, members of prostate cancer support groups offered valuable input that informs development of digital walking programs that have potential to engage users and thus promote PA. The qualitative data from the focus groups helped with interpretation of the quantitative survey data and provided context to the results. Findings are important because prostate cancer survivors need PA support and experience barriers to program access and meeting national PA recommendations. Yet there has been little in the way
of design guidance for engaging digital programs for this population. Our findings offer a first step by providing this
design guidance based on the perspectives of prostate cancer survivors.

Our findings indicate that prostate cancer survivors express an interest in overcoming exercise barriers and improving
their PA. When designing any digital program for this group it is valuable to consider features that reduce barriers and
enhance internal motivators (e.g., fun, positive thinking) and offer connections with external motivators, such as
providers, family, and peers. Even though the participants indicated moderate interest using technology to improve
PA in surveys they also provided a range of technology based magic wand ideas to help them walk more (e.g.,
reminders, virtual community etc.). When designing interventions for prostate cancer survivors, care should be taken
to address low technology use and guarded technology interests. Consider utilizing technology that is easy to use and
simple for participants to perform desired functions (e.g., tracking data, setting reminders).

Based on our findings we recommend that a digital walking program for prostate cancer survivors be designed to: 1)
provide well curated and specific content - both authoritative material from professionals and experiential material
from peers; 2) provide individualized feedback (e.g., how one is doing relative to one’s own goals) based on tracked
data or advice from a trusted, experienced source; 3) provide capabilities for a moderated discussion and the ability to
facilitate discussions with peers (e.g., “Has anyone else dealt with the problem I am experiencing?”); and 4) enable
users to work with peers to share interests, motivate each other, and find walking partners rather than compete. Our
results indicate that a well-designed digital walking program that combines fitness trackers with social features (e.g
find walking partners, motivate each other) could potentially increase access to and extend the reach of PA programs
that better support survivors.

Facilitating behavior change for PA is multifaceted and complex. The behavior change intervention literature indicates
that goal setting, feedback, self-monitoring, and social support (i.e. a combination of personal, interpersonal and
environmental factors) should be considered when designing digital behavior change interventions for older adults.24
Yet care needs to be taken to match the behavior change technique to design features that users prefer and most likely
to use. For example, our results indicate that participants lacked interest in competing for badges, even though these
types of digital rewards are a feature that has been shown as beneficial in young adult cancer survivors.24, 25 Our
findings offer a first step by offering guidance for design of engaging digital programs for prostate cancer survivors.

Findings should be evaluated in the context of some limitations. We conducted 3 focus groups in a single metropolitan
area that limit could generalizability of findings. We explored the potential of designing engaging digital technology
to promote PA in a sample that was low in both social media use and fitness tracker use. Lack of experience may have
limited the ability for participants to imagine using these features. In addition, limitations like having certain dominant
individuals in a group and other response biases that are inherent in focus groups might have influenced the data.
Future work should extend the study to a broader audience, such as prostate cancer survivors who do not have access
to support groups, diverse patients with respect to education, race ethnicity, and include more caregivers and friends.
Future research should also evaluate feasibility and effectiveness of a digital walking program designed for prostate
cancer survivors. Despite these limitations, our study has several strengths that include directly engaging future
technology users and our mixed methods approach. Conducting focus groups at existing support group meetings,
where participants regularly meet and are socially connected, facilitated a rich conversation and sharing of ideas.

Conclusion

Given the need to increase PA in prostate cancer survivors but lack of guidance for well-designed digital PA programs
to facilitate behavior change, our findings characterize needs and design preferences for digital walking programs.
Participants expressed interest in improving PA and expressed preferences for design of specific features for program
content, PA feedback, discussion, and teamwork. Digital walking programs that are designed to meet these needs and
preferences could enhance engagement by facilitating an accessible, convenient, and scalable solution for improving
PA among prostate cancer survivors.

Abstract

Radiology reports are a rich resource for advancing deep learning applications for medical images, facilitating the generation of large-scale annotated image databases. Although the ambiguity and subtlety of natural language poses a significant challenge to information extraction from radiology reports. Thyroid Imaging Reporting and Data Systems (TI-RADS) has been proposed as a system to standardize ultrasound imaging reports for thyroid cancer screening and diagnosis, through the implementation of structured templates and a standardized thyroid nodule malignancy risk scoring system; however there remains significant variation in radiologist practice when it comes to diagnostic thyroid ultrasound interpretation and reporting. In this work, we propose a computerized approach using a contextual embedding and fusion strategy for the large-scale inference of TI-RADS final assessment categories from narrative ultrasound (US) reports. The proposed model has achieved high accuracy on an internal data set, and high performance scores on an external validation dataset.

1 Introduction

Thyroid nodules are very common, with a reported prevalence of 33% to 68% in the healthy population.1 Despite the high prevalence of thyroid nodules, only 1.2-12% are malignant. Diagnostic thyroid ultrasound is critical for nodule detection and characterization. Diagnostic thyroid ultrasounds are used to determine whether a thyroid nodule has features suspicious for malignancy, in which case an ultrasound-guided fine needle aspiration or surgical thyroidecstasy may be indicated for further work-up and management. The Thyroid Imaging Reporting and Data System (TI-RADS) and the American Thyroid Association (ATA), released by the American College of Radiology (ACR), are two existing reporting systems that standardize reporting lexicon, risk stratification, and management guidelines for thyroid nodules. There is significant variation in radiologist practice when it comes to diagnostic thyroid ultrasound interpretation and reporting, due to the existence of these two risk stratification systems, and the frequent use of narrative non-structured reporting. The TI-RADS system, more recently developed, categorizes thyroid nodules with one of five labels based on malignancy risk: TR1-benign, TR2-not suspicious, TR3-mildly suspicious, TR4-moderately suspicious, TR5-highly suspicious; guiding nodule management.

Our hypothesis is that an artificial intelligence (AI) system can be developed to automate the assessment of thyroid nodule malignancy risk from thyroid ultrasound images. To achieve this goal, the machine-learning system would need to be developed to label large numbers of longitudinal imaging examinations using the standardized terminology of TI-RADS reporting system. Subsequently, these annotated exams would be used to train an AI algorithm that can extract thyroid nodule risk directly from the US images, and display risk scores to the interpreting radiologists for verification. Such a system has the potential to reduce practice variation between the radiologists in assessing thyroid nodule risk from US images, streamline imaging workflow, and improve billing processes, through automated TI-RADS coding of the radiology reports. A standardized thyroid nodule database may also help population health and nodule surveillance, and be utilized for secondary analysis including subpopulation evaluation.

Text classification is an important part of Natural Language Processing (NLP). The underlying goal of text classification is to associate a given text string with one or more categories. This association is based on different characteristics of the text string (content, terms, context), under predefined classification taxonomy. Effective text feature selection is one of the biggest challenges faced in NLP and it is a crucial step towards designing a NLP algorithm with better efficiency and performance. The information extraction and text classification aspects of NLP can play a key role in
improving workflow efficiency in medical institutions.

The NLP-based automated inference of TI-RADS category from semi-structured radiology reports is an important first step towards developing an automated AI system to extract thyroid nodule malignancy risk directly from US imaging studies. The lack of standardized radiology reports poses a challenge for NLP-based algorithms. Furthermore, the diversity of the medical language space combined with its very specific terminology increases the difficulty of NLP-based medical text classification. For example, when describing a TI-RADS nodule scored as 3 (mildly suspicious), many domain-specific terms can be used, like: solid, hyperechoic, hypoechoic, isoechoic, and many others. These different TI-RADS descriptors can also be seen with different TI-RADS categories, as the TI-RADS system takes into account the malignancy risk of multiple different imaging characteristics and sums them up.

Several studies have explored the use of machine learning and NLP-based methodology for information extraction, or more specifically, for automated score-based classification of medical reports.\textsuperscript{2-7} Dorothy et. al.\textsuperscript{8} utilized NLP to extract BI-RADS final assessment categories from radiology reports. Sergio et. al.\textsuperscript{9} developed a machine-learning pipeline, using Support Vector Machine (SVM), for the automated extraction of Breast imaging-reporting and data system (BI-RADS) categories from breast radiology reports. Banerjee et. al.\textsuperscript{10} utilized machine learning to infer Liver Imaging Reporting and Data System (LI-RADS) scores, a malignancy risk-stratification system for liver lesions, from structured and unstructured reports through NLP-based transfer learning based on an established LI-RADS ultrasound (US) report database. With the rapid development of deep learning, a variety of novel NLP models and methods have emerged with improved performance, including text classification methods based on word vector models. As examples, Kim et al\textsuperscript{11} applied convolutional neural networks (CNN)\textsuperscript{12} for sentence classification tasks. Lee et al\textsuperscript{13} developed an NLP pipeline by combining recurrent neural networks (RNN) and convolutional neural networks (CNN) to classify short text strings. Zhou et al\textsuperscript{14} interpolated the idea of 2-dimensional maximum pooling operation to create a bidirectional long-term and short-term memory network (BILSTM), enabling the extraction of text features in the temporal and spatial dimensions during a downstream task.

In contrast to the previous approaches, recent advances in NLP techniques can be leveraged for better text classification by exploiting Transformers Encoder-Decoder\textsuperscript{15} word representations. The Bidirectional Encoder Representations from Transformers (BERT) model\textsuperscript{16} proposed by Google utilizes a self-attention mechanism transformer,\textsuperscript{15} and is a context-preserving NLP technique. BERT models outperformed previously published NLP models like word2vec,\textsuperscript{17,18} which were based on context-independent embeddings. This is because BERT can represent words or sequences in a way that captures the contextual information, causing the same sequence of words to have different representations when they appear in different contexts. However, most of the published work in BERT-based text classification in medicine uses only single source text data, while often multi-source data integration is needed for comprehensive representation of a single data point.

In this work, we propose a semi-supervised NLP pipeline for TI-RADS reports that combines BERT contextualized representations with patient demographic information as well as comorbidities, in order to create an ensemble late fusion classification model.\textsuperscript{19} The concatenation of these vectors representations are utilized in a machine-learning setting for inferring TI-RADS of all nodules from semi-unstructured reports based on the five TI-RADS final assessment categories. For this study, we experimented with a set of text featurization methods and multiple traditional machine learning and deep learning models, and compared their performance on three independent datasets.

2 Methods

Figure 1 presents the core processing blocks of the proposed pipeline. The pipeline combines the ‘FINDINGS’ documented in the radiology reports with the ‘CLINICAL INDICATION’ (Past nodule history information from patient) and ‘DEMOGRAPHIC INFORMATION’ (Age, Gender, Race) of the patient to construct an ensemble late fusion classification model.\textsuperscript{19} This fusion model mimics the radiologist’s workflow for scoring a study by adding the necessary additional information. Each processing block is described in the following section.
In order to perform the study and validate the model and results, we collected the following three non-overlapping corpora of ultrasound radiology reports of thyroid nodule screening from two academic healthcare institutions.

Corpus 1. Semi-Structured reports from EUH - With the approval of Emory University Institutional Review Board (IRB), a total of 665 thyroid cancer screening ultrasounds(US) reports from unique patients were extracted from the clinical data warehouse of Emory University Hospital (EUH) between July 2017 and March 2020. The mean age of the sample is 59(+/-14), 81% female, 48% white, 32% African American, 10% Asian, and 10% Others. These reports are written following a strict template, and contain standard sections such as: "HISTORY", "CLINICAL INDICATION", "FINDINGS", and "IMPRESSIONS". Although these reports can be written in a structured and semi-structured format, in this work we are interested on working with semi-unstructured reports, since extraction of scores from structured TI-RADS formatted reports is a trivial task. However, extraction of TI-RADS scores from semi-unstructured reports is challenging since they are documented in free-text and radiologists do not consult any particular vocabulary or taxonomy when describing and scoring each nodule. For this study, 627 of the 665 reports were categorized as semi-structured.

Corpus 2. Prospective Semi-Structured reports from EUH - Similar to corpus 1, a total of 290 thyroid cancer screening ultrasounds(US) reports from unique patients were extracted from the clinical data warehouse of Emory University Hospital (EUH) from April 2020 to October 2020. The mean age of the sample is 59(+/-14), 78% female, 49% white, 38% African American, 5% Asian, and 8% Others. The purpose of collecting a different corpus, from
the most up to date studies available to us, is to test the generalizability of the proposed model. Following the same criteria as corpus 1, we were able to identify 221 out of 290 as semi-unstructured reports.

**Corpus 3. Semi-Structured reports from SHC** - In order to test the generalizability of our algorithm on an external dataset, we have collected over 177 semi-unstructured TI-RADS radiology reports in collaboration with Stanford Healthcare (SHC) acquired between Jan 2015 - Dec 2017. The mean age of the sample is 41(±12), 58% female, 52% white, 25% Asian, and 3% African American. Similar to the EUH dataset, we parsed the reports and extracted the TI-RADS score assigned by the original reader, and after extraction we dropped the code from the text for evaluation of our NLP algorithm.

### 2.2 Report splitter

A TI-RADS report may contain information about multiple nodules. According to the ACR recommendation, radiologists should add detail characteristics of each nodule found, e.g., size, shape, composition, margin, echogenicity. In order to separate each nodule and its corresponding characteristics, we developed a python-based segmentation algorithm for the Finding section of the radiology report using regular expressions to identify key words indicative of a nodule, while maintaining dependencies between anatomical entities. Finally, we combined multiple sentences to formulate the description of nodules. In order to stop label-leakage, we excluded the Impression section of the reports since the final TI-RADS score is often reported explicitly in the impression. The Findings section includes only the characteristics of the nodule abnormalities and therefore, it does not leak any information regarding the TI-RADS final assessment classes.

In order to evaluate the performance of our segmentation algorithm, we manually segmented 50 random reports from Corpus 1. A total of 87 TI-RADS nodules were extracted, with label distribution of: TR1: 13, TR2: 17, TR3: 28, TR4: 21, TR5: 8. Our segmentation was able to identify and extract all 87 nodules correctly. When dealing with free-text reports, the full nodule description can be hard to identify since a nodule can be described in different sentences and paragraphs. Our algorithm was able to correctly extract 82 nodules and their full description, achieving an accuracy of 94%. The partial text description extracted from the 6 remaining nodules were considered satisfactory to identify the TI-RADS category of the nodule.

Once we segmented each EUH report, we identified 1,006 TI-RADS nodules from Corpus 1 and 597 TI-RADS nodules from Corpus 2. A total of 450 unique words were found, with nodule descriptors ranging between 3 to 45 words, with a mean report size of 15 and standard deviation of 6. As for SHC dataset, we were able to extract 177 nodules and their corresponding descriptors. A total of 390 unique words were presented and report size ranged from 4 to 60 words with a mean of 19 and standard deviation of 10. Figure 2 shows the distribution of TI-RADS labels from the EUH (Corpus 1 & Corpus 2) and SHC(Corpus 3) dataset. Given that our study includes the US screening population, the distribution is highly uneven, with very few representative reports with TI-RADS 5 (highly suspicious) and a high number of reports with TI-RADS score of 3 and 4 (mild to moderate suspicion). In addition to ‘FINDING’, we segmented and extracted the ‘CLINICAL INDICATION’ section from the radiology reports when present in the text report.

### 2.3 Text cleaning & preprocessing

We use pre-processing when constructing out baseline models, to reduce the feature-space and get better data generalization. However, the following steps were not applied with Bidirectional Encoder Representations from Transformers (BERT) models. Data pre-processing has been shown to improve the quality of extracted text features. In this work, we transformed the segmented data through a series of standard pre-processing techniques. This was accomplished by applying a conversion to lowercase, removal of stop words (e.g. ‘a’, ‘an’, ‘are’, etc.), removal of low-frequency (< 50) words, and removal of unwanted terms and phrases. We used the Natural Language Tool Kit (NLTK) library to obtain the list of stop words. We discarded identifying details of radiologist, clinicians, patients, and TI-RADS scores from the reports. While we applied a stemming and lemmatization technique for most of the baseline models, only lemmatization was applied to the original version of words when dealing with machine and deep learning models. This is because such models involve some kind of word textual embedding, and we are dealing with pre-trained embeddings, which were trained with original version of the words.
In addition to the usual standard text pre-processing, we also applied some specific pre-processing techniques for radiology domain. When dealing with radiology reports, there are some crucial information embedded in numbers and symbols, such as: measurements, percentage, shape, and others. Thus, it’s crucial to our system to be able to read and understand such information since those are critical information for obtaining the final scoring. We converted all numbers into character strings, e.g., ‘22’ is then mapped to ‘twenty two’. Furthermore, we also preserved all mathematical symbols, like: ‘>’, ‘%’, by converting them to character strings as well, e.g., ‘greater than’ and ‘percentage’.

2.4 Text Featurization and Discriminative models

Baseline Models: (1) BoW/tf-idf + Logistic Regression; (2) BoW/tf-idf + Random Forest; (3) BoW/tf-idf + XGBoost - We designed our baseline models with traditional NLP text representation, i.e., bag-of-word and tf-idf. We experimented with Logistic Regression, Random Forest and Extreme Gradient Boosting based classifiers with feature representation to form a comparative baseline for our deep learning based TI-RADS score prediction models.

Semantic Embedding and Classifier: (4) word2vec pre-trained/self-trained + Logistic Regression; (5) word2vec pre-trained/self-trained + Random Forest; (6) word2vec pre-trained/self-trained + XGBoost - For a more comparative text featurization approach, we applied Word2Vec which is a semantic embedding based neural network which generates a non-sparse numeric representation of the documents. This representation partially alleviates the problem of limited vocabulary faced by traditional bag-of-words and tf-idf models which simply ignore any relevant out-of-vocabulary words and preserve the semantics of the words while generating the numeric representations. To generate these embeddings representation, we computed the average corresponding vectors of all nodule description words. In our analysis, we experimented word2vec model with and without transfer learning strategy, which we call pre-trained and self-trained word2vec, respectively. For transfer learning, a word2vec model trained on the Google News dataset is fine-tuned with EUH radiology reports. We also experimented training our own version of word2vec over EUH reports. We used the skip-gram model with a vector length of 300, a window width of 5, and default settings for all other parameters. No vectors were built for terms occurring fewer than 6 times in the corpus.

Sequential and Convolutional Deep Learning Models: (6) LSTM (random initialization); (7) LSTM (word2vec initialization); (8) 1DCNN (random initialization); and (9) 1DCNN (word2vec initialization) - We experimented with sequential models - Long short-term memory (LSTM) and One-dimensional convolutional neural networks (1D-CNN). LSTM and 1D-CNN models usually include an Embedding layer as the first layer of the model. The objective of this layer is to learn a vector representation of each word in the training vocabulary set. In both approaches, we have experimented with two different variations, i) random initialization and ii) initialization with word2vec model weights. In the second approach, instead of initializing the model with random weights, we take the word2vec representation of the word as an input. This approach enables the model to take advantage of unlabeled data present in the form of unstructured radiology reports and learn semantic context beforehand. At the same time, the model is able to fine-tune the word-embedding layer for the particular language space while training the prediction model for TI-RADS score prediction. To address the variation in the size of the radiology reports, we used padding with a maximum report length of 30 words.

BERT Ensemble Classification Model - One of the biggest challenges with employing word2vec and tf-idf for radiology report parsing is how to handle unknown, out-of-vocabulary (OOV), and similar words (abbreviations, acronyms). In radiology reports, the use of synonyms and related words are widely used, depending on the preferred style of radiologist. This is a challenge because particular words may be used infrequently in a large radiology report corpus, even when it is collected from the same institution. BERT architectures have been devised to consider the context for each occurrence of a given word, providing a sub-word contextualized word embedding representation that will be different according to the sentence and its meaning. We are using BERT-Base Uncased model with a fully connected layer on top to fine-tune the whole model to a TI-RADS downstream classification task. Our implementation is built using the PyTorchTransformers library by huggingface. We trained the BERT model using an AdamW optimiser with a learning rate set to $10^{-5}$. For each experiment set, the training was run with an early-stopping patience of 100 epochs. The optimal model was then used to produce the reported results. The maximum
Figure 3: Fusion-BERT Classification System. The output probabilities of the three independent models and concatenated and fed into a logistic regression meta-learner.

sequence length was set at 128 and the batch size at 32. The model architecture and training phase are illustrated on Figure 3. In our preprocessing, a “[CLS]” symbol is added before input texts. It is used by the transformer to extract features from texts and encode global information. The output of highest hidden layer at the “[CLS]” position is taken as a sentence-level feature. Subsequently, a fully connected layer is used to output text classification probability values.

2.5 Fusion Model

Our goal is to build a supervised fusion model classifier to automatically recognize the TI-RADS categorization of the nodule. First, we trained three independent models: (1) nodule data classifier: takes a vector representation of the nodule data as input; We select the vectorization scheme that performed optimally for text report classification. (2) EHR classifier: Takes a concatenation of vectors representation as one-hot-encoding of the demographic information of the patient (Age, Gender(Male/Female), and Race (African American, Asian, White, Others, Unknown); (3) Clinical Indication classifier: Takes a vector representation as tf-idf of the clinical indication(history of patient) as input. BERT\textsuperscript{16} performed optimally over all the text vectorization models and was used to build the nodule data classifier, while Random Forest classifier was applied on EHR and Clinical Indication. Next, we create a late fusion-model that concatenate the output probabilities of the 3 models: BERT + nodule description; Random Forest + patient demographic information; and Random Forest + patient clinical indication. Finally, we add a meta-learner as a last layer, a standard non-parametric Logistic Regression classifier in its default configurations (stochastic average gradient solver, intercept scaling = 1, $l_2$ penalty). The reason behind adding a meta-learner is to allow the fusion-model to learn the relevance of each independent model for TI-RADS score prediction. The fusion-model is illustrated in figure 3.

2.6 Statistical Validation

We collected over 848 semi-structured EUH radiology reports (Corpus 1 and Corpus 2) for which we were able to segment 1006 and 597 nodules for our retrospective dataset and prospective dataset respectively (see Sec. 2.1, 2.2). We leveraged this set of nodules to train, test and validate our model, by randomly splitting our corpus 1 into 805 (80%) for training and 201 (20%) for testing purpose. In our second set of experiments, we expanded the scope of the work to include external validation with Stanford SHC dataset (corpus 3). We were able to extract and segment 177 nodules from SHC radiology reports. To evaluate our model, we applied four standard statistical metrics commonly used to validate NLP inference and for deep learning classification tasks. They are Accuracy, Precision, Recall and F1 score. F1 is the standard metric for this task; it is calculated as the harmonic average of the precision and recall. We also reported two addition evaluation measures, 1-margin Accuracy and 1-margin F1 score. Both measures consider a prediction to be correct if it differs from its ground truth by a margin of less than or
equal to 1. Such predictions are useful for clinical purposes because the descriptors for adjacent TI-RADS categories are often overlapping (e.g., TR 3 and TR 4, mild and moderate malignancy). Moreover, while agreement for the indication to biopsy was substantial to near-perfect, lower interobserver agreement has been observed between readers for neighbouring TI-RADS categories.

### 2.7 Interface Design

We developed a user-friendly graphical user interface (GUI) for our system to upload data and obtain prediction results in batch. The interface can handle a single nodule classification as well as prediction over multiple reports stored in a single file. For a single nodule prediction, the user can input a nodule description and the application will predict the output with the highest probability. In this module, the application also gives the probability of all categories, giving a better indication and explanation to the user. The user can also load a complete radiology report and perform classification on all nodules at once. Once the file is loaded, our application automatically segments every report to extract all nodules. Figure 4 illustrates an example of our Interface when loading a file with US radiology reports. Figure 4(a), and also with a single nodule description in Figure 4(b).

### 3 Experiments and Results

**Internal hold-out test data:** Simple baseline models like tf-idf performed very poorly as the thyroid ultrasound report dataset had a complex vocabulary and a very sparse language space. Traditional machine learning models combined with neural network semantic embeddings, like word2vec, had the best baseline performance for TI-RADS score prediction. Pre-trained word2vec models are trained using a large generic text corpus (like the Google News dataset), and leverage optimal embeddings when fine-tuning a language space for medical clinical notes through transfer learning. Given the highly specialized text domain of thyroid ultrasound reports, the combination of self-trained word2vec which was trained from scratch on a large amount of EUH radiology thyroid ultrasound data and Random Forest achieved a F1 score of 0.875, an increase of 1% when compared with the pre-trained word2vec model, becoming a hard baseline to outperform. However, BERT achieved an even greater F1 performance of 0.96 on Corpus 1 hold-out test set, with an improvement of 11.5% when comparing with self-trained word2vec model + Random Forest. The proposed pipeline, an Ensemble Fusion-BERT, was able to outperform BERT itself, showing an improvement of 2%. This illustrates how our model can mimic the radiologist’s workflow of scoring a TI-RADS nodule by adding the necessary additional information if needed. Table 2 summarizes class-wise Precision, Recall, F1-score, and 1-Margin metric of the proposed Ensemble Fusion-BERT model. Table 2 also illustrates the performance of the Fusion-BERT model on each class label for the: i) Corpus 1 - Test set; ii) Corpus 2 - Prospective Validation; and iii) Corpus 3 - SHC external validation. 1-margin metrics are also included. In addition, to present the class-level comparative performance in a more interpretable manner, the corresponding confusion matrices are displayed in graphical form in Figure 5. The numeric values in the confusion matrices show how many nodules were correctly classified as well as
how many were misclassified.

**Internal Prospective Validation:** 597 thyroid nodule description modules of the most recent thyroid US reports from April 2020 to October 2020 (see Sec. 2.1) were used to test the generalizability of the model. Our hypotheses is that most recent reports use different template structures and lexicon, which may result in an overall lower performance, since our model was trained on report data starting from 2017, prior to the implementation of the TI-RADS scoring system and template at our institution. While our model was able to achieve a F1 score of 0.97 on the Corpus 1 test set, it achieved a slightly lower F1 score of 0.89 on Corpus 2 (Prospective Validation Set). However, when using 1-Margin metrics the performance of our model on both, the test and validation sets, yield a F1 score of 0.99. This suggests that even though our model had a slight drop of performance on the prospective data, it is still applicable for curating a large-scale labeled imaging dataset with acceptable accuracy.

**External validation (EV) - SHC Dataset:** New participant level data from SHC, external to those used for model development and testing, were used to assess the reliability of our model’s predictions at a different institution. This is a very important step to validate a model to a potentially non-generalizable problem, where the model can only perform well on the same dataset it was trained. As seen from the classification results in Table 2, our proposed model demonstrated successful generalization on the Stanford SHC radiology reports (Corpus 3) with an average F1 score of 0.85, and 1-Margin F1 score of 0.94.

4 Conclusion

In this work, we experimented with a wide variety of natural language processing and text mining techniques to process the text of thyroid US reports so that machine-learning techniques can be applied to them for TI-RADS score inference. We propose an effective late fusion model for thyroid score extraction which tackles the complex radiology language space using a bi-directional transformer model, which takes into account relevant patient clinical history and demographics. We evaluated our model by testing its performance over a prospective and external cohort. Being trained on a single institution’s data, our model performed exceptionally well for our own, and outside institution, data; indicative of our model’s generalizability. Hence we believe that our model will be able to effectively extract nodule TI-RADS scores from unstructured and semi-structured radiology reports. We plan to deploy the graphical application powered by the Ensemble Fusion BERT developed in this project to standardise point of care thyroid ultrasounds being performed by non radiologists in the endocrine clinic.

Abstract
Community-based telehealth programs (CTPs) allow patients to regularly monitor health at community-based facilities. Evidence from community-based telehealth programs is scarce. In this paper, we assess factors of retention—patients remaining active participants—in a CTP called the Telehealth Intervention Programs for Seniors (TIPS). We analyzed 5-years of data on social, demographic, and multiple chronic conditions among participants from 17 sites (N=1878). We modeled a stratified multivariable logistic regression to test the association between self-reported demographic factors, caregiver presence, status of multiple chronic conditions, and TIPS retention status by limited English proficient (LEP) status. Overall, 59.5% of participants (mean age: 75.8yrs, median 77yrs, SD 13.43) remained active. Significantly higher odds of retention were observed among LEP females, English-speaking diabetics, and English proficient (EP) participants without a caregiver. We discuss the impact of CTPs in the community, the role of caregiving, and recommendations for how to retain successfully recruited non-English speaking participants.

Introduction
Increasing demand for healthcare in response to the needs of a growing aging population, and more recently to the rapid adoption of telemedicine due to the COVID-19 (SARS-CoV-2) pandemic, has expedited the urgency to ensure telehealth that is safe, effective, efficient, patient-centered, timely and equitable. Access to high-quality care for aging populations is increasingly complex due to the unique needs of older adults as their diversity in race/ethnicity, socioeconomics, and complex health status demonstrates. This group accounts for the largest population affected by multiple chronic conditions (MCC) or having two or more chronic diseases. While 25% of all Americans live with an MCC, this figure increases to over 60% among older adults.1 Treating MCCs in fragmented healthcare delivery systems creates higher costs overall, and results in poorer quality for older Americans. This risk is compounded for racially and ethnically diverse older adults and those who speak English less than “very well.” They are considered limited English proficient (LEP) because they are more likely to experience care delays and communication barriers since their primary language is not English. Further, as older adults, they are also facing higher rates of cognitive impairment, dementia, reduced functional status and increased emergency visits among Medicare beneficiaries.2 Evidence underscoring the benefits of aging-in-place3 for older adults who wish remain in their homes include better mobility, cognition, social status, and lower depression risk.4 In response, innovations in telehealth and telemedicine interventions have become ubiquitous.5, 6 This technology has enabled the delivery of safe and effective care for Americans who need to access care remotely or require constant monitoring.9,11 Many telehealth technologies for older adults are home-based. Despite offering many benefits, home-based telehealth programs face great challenges in adoption and uptake due in part to the usability and cost issues of telehealth device.12, 13 In recent years, community-based telehealth (CTPs) programs—offering telehealth services in community settings (e.g., congregate housing, community centers)—are gaining momentum, because 1) they are less equipment intensive, thus less cost is transferred to the patients, and 2) in-person support is available for immediate monitoring and feedback.9,14,15 However, issues persist among older Americans with complex needs that impede successful uptake related to the usability, tailoring, and feasibility make technology enabled healthcare inaccessible for many older adults and can be particularly prohibitive for low-income, diverse older adults who are LEP.16, 17 This is in addition to the already significant barriers related to accessing healthcare due to language and communication.18, 19
Given the scarce evidence on CTPs, we analyzed 5-years of data on social, demographic, and multiple chronic conditions among participants in the community-based Telehealth Intervention Program for Seniors (TIPS) to provide insights to the feasibility of CTP implementation, particularly on retention. By examining TIPS program retention in a diverse, low-income population of older adults, our study contributes to understanding the roles of language
proficiency, multiple chronic conditions status, and the role of caregivers in retaining participants in CTPs and how informatics approach can address identified challenges.

**Background**

Telehealth is essential for monitoring high-risk aging populations with chronic conditions in the community in order to ensure timely and high-quality care, reduced care utilization and hospital readmissions, and improved outcomes.\(^{20, 21}\) There are different types of telehealth programs designed to provide care to older adults. The most commonly and widely-adopted model is home-based telehealth interventions. Numerous studies have demonstrated the effectiveness of home-based telehealth.\(^{7, 8, 10, 11, 22}\) Home-based telehealth is associated with improved self-management of multiple chronic conditions (MCC) among older adults,\(^{23, 24}\) and may benefit those that experience mobility and transportation barriers most.\(^{25}\) Seminal work has focused on examining different aspects of this type of telehealth program, such as user acceptance,\(^{12, 13}\) usability,\(^{26}\) and effectiveness.\(^{10}\) However, this approach has several barriers, hindering its uptake and adoption. For example, the usability of home-based telehealth systems for the aging population is problematic as many older adults may not be able to use and navigate the system as well as their younger counterparts.\(^{27}\) Even more concerning is that current home-based telehealth technology requires installation of equipment in a user’s home, regular maintenance, and individualized healthcare services, all of which pose significant financial burden on older adults.\(^{28}\) Thus, home-based telehealth services are often not an optimal option for many older adults and less so for those with lower socioeconomic status.

To deliver remote monitoring to large-scale aging populations at a lower cost, an alternative approach—community-based telehealth programs (CTPs)—is increasingly being deployed in recent years.\(^{8, 14, 15}\) Such programs are expected to provide unprecedented opportunities for low-income, high-risk older adults to play an active role in self-management, and in turn, reducing the rates of hospital visits in older adults and the burden of health and social care services.\(^{15}\) A study assessing the benefits of a CTP in a senior-living facility described as “high-intensity” telemedicine found reductions in emergency visits and readmissions.\(^{29}\) Despite the benefits, CTPs face salient challenges and barriers in engaging users because older adults may not necessarily know the potential benefits of these interventions and lack motivation to receive health services through CTPs over time.\(^{30, 31}\) The lack of user engagement and retention with CTPs could negatively affect the effectiveness of delivering and promoting community-based healthcare self-management.

Literature evaluating home-based telehealth for LEP populations with MCC emphasized the need for language access.\(^{32, 33}\) interventions included mobile interpreting apps, and texting-based self-management interventions.\(^{34, 35}\) Our review found a lack of telehealth resources for LEP patients an issue that was highlighted early into the COVID-19 pandemic.\(^{32}\) We found no evidence evaluating CTPs for older adults with LEP. Therefore, it is critical to examine the factors affecting vulnerable user retention in CTPs. Our study will contribute to bridging this research gap. TIPS brings affordable and easier-to-access telehealth to low-income older adults who often face barriers due to age, language, literacy, and costs.

**TIPS Program Overview.** TIPS is a CTP implemented in the U.S. Northeast that provides remote patient monitoring and wrap-around social services to financially vulnerable older adults living in congregate housing or who attend local community centers. Older adults were eligible to enroll in TIPS if they were over 55 years old and registered as a Medicare and/or a Medicaid beneficiary. Older adults access this program by visiting their local community center, or their own long-term care facility that is staffed weekly by trained Telehealth Technician Assistants (TTAs). TTAs are recruited and trained by TIPS to operate the telehealth devices and technologies (e.g., blood pressure cuffs, pulse oximeters, and tablet computers for data entry) and help older adults with onsite assessment of physiological measures (e.g., blood pressure, pulse oximetry, weight, etc.). TTAs also record details about each participant’s evolving medical status (e.g., hospitalization, medication taken, fallen, and overall feeling). Such programs are responsive to the unique needs of older adults, often including social and technology support.

During the initial visit, each participant was asked to fill out an intake questionnaire, which assessed their socioeconomic status (e.g., income, living arrangement, caregiver), demographics (e.g., age, sex, primary language, ethnicity), Medicaid/Medicare or other received benefits, medical history, and multiple chronic conditions. In addition to the questionnaire, TTAs also collected a set of physiological biomarkers (heart rate, blood oxygen saturation, blood pressure, and body weight) and self-reported incidence of (1) ER admission, (2) single hospitalizations, and (3) readmissions less than 30 days following hospital discharge, in the 12 months before enrollment. The intake information and initial monitoring data formed the baseline standards for each participant.

Following initial intake, participants were instructed to visit a TIPS site at least once per week, set-up was the same at every site. At each visit, TTAs used the devices to measure the participant’s physiological biomarkers and record details about their recent medical history using a five-question survey: (1) Have you changed medications since your
last screening visit? (2) Have you changed your medication dosage since your last screening visit? (3) Have you fallen since your last screening visit? (4) Have you been hospitalized or had an ER visit since your last screening visit? (5) How are you feeling today? (response options include “very good”, “good”, “feeling OK”, “feeling a little down”, “not too well”, or “terrible”). The results of the assessment were transmitted to a secure, HIPAA-compliant data server, and then reviewed by a team of TIPS nurses. When a participant was involved in the program, their visit frequency was tracked over time. Individuals who missed more than 4 consecutive weeks of TIPS monitoring were contacted by their designated TIPS nurse regarding why they had stopped using the telehealth service. The reason for the stopped use of TIPS service for each participant was recorded, such as deceased, moved away, or preferred to not continue with the TIPS service. This data indicated whether or not a participant stayed active in the program. Studies using these interventions have demonstrated successful monitoring of older adults with heart failure and MCC. However, a lack of user engagement with such programs has suggested variable implementation of CTPs. To address this problem, we assessed factors associated with older adults staying active in TIPS.

Methods

Dataset. Our study is an observational comparison of baseline characteristics of participants retained and not retained in the TIPS program since it was deployed. Data were collected by staff on-site and transmitted asynchronously (store-and-forward) for review by a team of Registered Nurses, who review the data and contact the participant if their health data triggered an alert during their visit. We merged baseline data from TIPS program sites across New York, New Jersey, Pennsylvania, and Connecticut (N=1878). These data include all baseline data for available sites at the time of sampling (November 2014–October 2019). All analyses and co-authors’ data use agreements were approved by the Pace University IRB.

Variables. We developed a dichotomous outcome variable to represent patients who stayed active with TIPS at the time of analysis to equal “1” and those who were not active equal to “0”. Independent factors included demographics: sex, age, language, caregiver status, MCC, and Medicaid eligibility. LEP participants were identified at enrollment by their self-reported primary language. If any language other than English was selected, they were classified as LEP=“1”. To assess caregiver status, participants were asked if someone (family member or not) took care of them, either living with them or not. If someone did have a caregiver, they were classified as CG=“1”; the reference group for all of these variables was “0”. MCC and other conditions reported at baseline were coded as “1” if yes and “0” if no. MCC and other conditions were self-reported as: hospitalization before TIPS enrollment in the last 12 months, obesity, falls, fractures in addition to self-reported diagnosis of depression, early-stage dementia/Alzheimer’s disease (ADRD), congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), coronary artery disease (CAD), diabetes mellitus (type 1 or 2), hypoglycemia, liver disease, renal failure, stroke, hypertension, and hypotension. These data were collected at the intake and coded as “1” if selected to indicate yes and “0” if not. We created an additional dummy variable to account for data collection site closures to assess if this had any impact on the sample.

Analysis. We used chi-square analysis to compare group differences across select factors for model selection. We found a significant interaction between caregivers and English proficiency (p=0.0233) and thus presented all descriptive and inferential results stratified by English and non-English proficiency and whether they stayed active in the program (Table 1). Based on our findings and diagnostics, we modeled stratified multivariable logistic regressions to test the association between demographic and MCC factors and the odds of staying active in the TIPS program by language proficiency. All data management and analyses were conducted using SAS 9.4 (Cary, N.C).

Results

Overall, 59.7% of participants stayed active in the TIPS program for the study period. Retention among English speakers (62.6%) was significantly better than that of LEP respondents (47.3%, p<.0001). The average participant age was 75.8 years (median 77.0, SD 13.43), most were female (78%), and did not have a caregiver (95.3%). Also, 36.5% reported having Medicaid and 24.8% were LEP. Table 1 demonstrates comparisons by English proficiency. Over 50% of LEP participants were Medicaid recipients compared with EP (p<.0001), and LEP were significantly more likely to report having a caregiver compared with EP, 6.9% vs. 2.9% (p=0.0004). Both groups reported lacking a caregiver at over 90%.

Table 2 compares retention status across EP and LEP participants. We observed that 65 to 85-year-old participants were most likely to report staying active in TIPS compared to other age groups, independent of language. Although not significant, findings suggest a trend among female participants being more likely to stay active in the program compared with males also across both EP and LEP. Retention was higher among EP participants on Medicaid (51.1%, p=0.0048) compared with LEP Medicaid recipients (41.6%, p=0.0096). Among EP participants, retention was significantly higher when no caregiver was reported (62.1%) compared to 38.9% of EP with a caregiver (P=.0048). Conversely, LEP participants did not hold the same pattern. Although not significant, LEP participants reported similar retention with (48.3%) or without (47.3%) a caregiver. Retention of LEP participants without an MCC was higher (50.3%) compared to 39% of LEP with an MCC (p=0.0351). Chronic conditions that were significantly associated with retention status for English participants were depression, history of fracture, hypoglycemia, and hypertension (Table 2). For LEP participants we found only COPD to be significant.

Results from the stratified multivariable model are in Table 3, showing that age was associated with greater odds of retention in TIPS among both EP and LEP participants. Adjusted odds of retention were 71% (AOR 1.71; 95CI 1.12-2.58) greater for English speaking adults age 65-74 and nearly 3-fold greater (AOR 2.60, 95CI 1.21-5.60) for LEP participants in the same age group compared with the reference group (<65 years). English participants age 75-85 reported 65% greater odds (AOR 1.65; 95CI 1.11-2.45), compared with similar 3-fold greater odds for LEP participants (AOR 2.86; 95CI 1.37-5.96)

Notes: Some values may not add up to full N=1878 due to missing values and/or rounding. Hospitalized in the last 12 months prior to program participation. If cell value is n=5 or less, Fisher’s Exact Two-sided P-value is reported. MCC= sum(FallHX, ADRD, CHFHX, CorArtD, Diabetic, HypoglycemiaHx, HypertensionHx, LiverHx, ObeseHx, HypotensionHx, renalHx, StrokeHx). No MCC=0; 1 chronic conditions; MCC=2+ chronic conditions

Only LEP participants had persistent significantly greater odds of retention for adults over 85 years (AOR 2.63; 95CI 1.19-5.80). Sex was significantly associated with retention but only among LEP participants with females reporting 71% greater odds than males (AOR 1.71; 95CI 1.06-2.75). English proficient and LEP Medicaid recipients reported similar significantly lower odds of staying active (AOR 0.61 and AOR 0.60, p<0.05). Only English participants were associated with significant 3-fold greater odds of staying active if they report lacking a caregiver (AOR 2.53; 95CI 1.23-5.22).

Discussion

The TIPS program demonstrated efficacy in reducing rehospitalizations. However, retention is key to sustaining such benefits of the program. Our study provides evidence on retention in CTPs, which is lacking in the literature. Compared with available evidence on CTPs, our study population consisted of a higher proportion of participants who were LEP (1 in 4), a hard-to-reach population. Even with this vulnerable population, 47.2% participants stayed active in TIPS throughout the 5-year study period. Such long-term evidence is scarce in the literature, and other similar programs with less vulnerable population had faster rate of attrition (e.g., telehealth kiosks where 47% remained active after only 10 months). Our findings from a diverse and geographically heterogeneous sample of community-based older adults with MCC brings key implications to building knowledge on the predictive factors of retention in CTPs among vulnerable aging populations.
Our study population comprised of a diverse sample of low-income older adults with LEP and chronic conditions, many of whom classified as having MCC. We found that, regardless of their chronic condition status, EP and other social-demographic factors were predictive of greater odds of retention in TIPS. Thus, it is the predisposing factors that participants have little control over (e.g., language, income) that may be a greater contributor to retention than
any physical element. Another factor is the health care delivery systems, as structured, struggles to support self-management change in vulnerable populations due to its inability to target well. CTPs appear to fill a critical need in this respect. It is imperative for participants with MCC to experience benefits from telehealth programs like TIPS. While our findings showed that LEP participants with MCC are less likely to be retained, significantly better odds of retention were observed among English proficient participants with select chronic conditions. Consideration for tailoring the socio-technical design structure of TIPS and other CTPs to language and culturally diverse populations may be an opportunity to retain high-risk participants. For instance, given the increased use of smartphones and agents embedded in mobile phones by these vulnerable population, additional monitoring or assistive devices can be appropriated to aid any shortcomings of current technical, clinical, and social infrastructure that TIPS provides. Being able to increase retention among those who need the resources the most will be critical in maximizing the benefits TIPS can provide to its participants.

The role of caregivers as facilitators of home-based telehealth is critical. In community-based settings where the deployed telehealth system is multi-user and may be operated by support staff or a self-operated mobile unit (e.g., kiosk) we found greater retention when there was no caregiver, suggesting CTPs may support this critical role. Interestingly, our finding that participants without a caregiver reported greater odds of retention was limited to EP participants. LEP participants had inverse odds, though not significant, suggesting, they were not seeking a caregiver proxy. Rather, the significantly higher odds of LEP females remaining active in the program suggests, they are the caregivers. Accordingly, TIPS may serve as a great supportive mechanism for older adults who do not have caregivers, which consist the majority of Americans who are older adults. Furthermore, TIPS can be a supportive mechanism for LEP older adults who may have played multiple social roles in the household as caregiver, head of household, or women who have not had much support. TIPS recruited more LEP participants than most programs, but retained fewer LEP participants, demonstrating recruitment success but retention barriers. Previous studies suggest existing barriers to healthcare utilization among older LEP adults include health literacy and technology access (they don’t have the smartphones). These barriers also apply to CTPs, LEP participants struggle to engage in technology-based healthcare to the same extent of their non-LEP peers. There is a lack of evidence on the efficacy and feasibility of CTP participants with LEP. Studies on the acceptance of telehealth systems show usability as one of the main barriers to successful adoption. Specific to LEP populations are the lack of comprehensive usability and seamless integration into care delivery since language access is needed at every interaction, thus making accessibility a higher priority. Some studies show navigators help mitigate some of these barriers similar to the role that TIPS on-site technical support. On top of existing usability issues, the needs of LEP clients must be addressed to ensure their participation.

Pew Internet Research has shown older adults are increasingly using mobile phones and smartphones. Furthermore, due to the COVID pandemic, older adults are increasingly adopting mobile and computing devices. This rapidly changing technological adoption pattern encourages potential technological solutions that may ameliorate language barriers. Emerging studies show older adults’ increased use of conversational or voice-based agents, which have become prevalent in everyday mobile devices, due to their ability to generate more natural user interaction than existing user interfaces. These more accessible mobile applications specifically designed for low health and technological literacy and technological support for the TIPS staff to aid translation may generate solutions for the programs that lack resources around language interpretation and translation. Limitations of our study exist, starting with the larger proportion of female (N=1046) versus male participants (N=279). This gender difference, however, is not uncommon—the literature shows that older women are more likely than men to use technology and services. Though there were no significant differences by gender across language or attrition, future work should strive for a balanced sample. Further, MCCs and hospitalization history were self-reported and may not be fully accurate. But there is sufficient evidence of good concordance between self-reported data and medical record review. Finally, retention is measured as a binary outcome, more detail such as time in program could improve understanding of individual behaviors.

Conclusion
The rapid deployment of telemedicine interventions and the changing social and technological environment due to the COVID-19 pandemic brings urgency to fulfilling the needs of all populations without leaving behind the populations that can most benefit from technological innovations. Leveraging technology and community engagement can contribute to community resilience, especially in the face of a public health emergency. By supporting social interactions, community connectivity, and strong system resilience, the probability of successful aging-in-place is more likely. Our study occurred in the areas hardest hit by the initial wave of COVID-19 cases. Our study brings demonstrated viable solution to engaging older adults, while discovering critical challenges that the informatics community can address to support all populations.

Abstract While remarkable advances have been made in Computed Tomography (CT), most of the existing efforts focus on imaging enhancement while reducing radiation dose. How to harmonize CT image data captured using different scanners is vital in cross-center large-scale radiomics studies but remains the boundary to explore. Furthermore, the lack of paired training image problem makes it computationally challenging to adopt existing deep learning models. We propose a novel deep learning approach called CVH-CT for harmonizing CT images captured using scanners from different vendors. The generator of CVH-CT uses a self-attention mechanism to learn the scanner-related information. We also propose a VGG feature based domain loss to effectively extract texture properties from unpaired image data to learn the scanner based texture distributions. The experimental results show that CVH-CT is clearly better than the baselines because of the use of the proposed domain loss, and CVH-CT can effectively reduce the scanner-related variability in terms of radiomic features.

1 Introduction

Computed Tomography (CT) is one of the most commonly used imaging modalities for patient diagnostics due to its ability to capture detailed anatomical features1. For years, Canon (former Toshiba), Siemens, General Electric (GE), and Philips have been supplying high-quality CT scanners worldwide. Owing to increasing competition frequent innovations regarding slice count, dose optimization, reconstruction methods, etc. are taking place in the market. Each medical imaging vendor gradually develops its unique techniques2 to advance CT imaging. The divergence among CT imaging techniques, however, introduces image feature variations in terms of radiomic patterns2,3, which greatly hinder the progress of cross-vendor data sharing, ambiguity in large-scale data analysis, and automated diagnostics4.

To address the radiomic feature discrepancy problem, one of the computational approaches is to normalize the radiomic features of CT images captured with different protocols. However, since the concepts of radiomic features are not well defined5, an image feature normalization tool that works for a set of radiomic features may not work for the others. Alternatively, we can harmonize CT image data directly while preserving their anatomic details3,6. From the harmonized images, radiomics analysts can extract their desired radiomic features for further analysis without worrying about the feature discrepancy problem. Mathematically, let x be a CT image acquired using a scanner, \( \hat{x} \) be its corresponding image captured with a different scanner, the image harmonization framework aims to compose a synthetic image \( x' \) from \( x \), such that \( x' \) follows the feature distributions of \( \hat{x} \) rather than \( x \).

The CT image harmonization problem can be viewed either within scanner or between scanners. Recent progress on this topic has been focused on the former one. Choe et al7 developed a Convolutional Neural Network (CNN)-based approach for CT image standardization. The model learns the residual representation of the target images, and then a residual image is combined with its source image to generate a synthesized image. The model, since it trains a CNN from scratch, requires large training data. Liang et al8 proposed a cGAN-based9 CT image standardization model named GANai. An alternative training strategy was developed to effectively learn the data distribution. GANai achieved better performance comparing with cGAN and the traditional histogram matching approach10. However, GANai focuses on the relatively easier image patch synthesis problem rather than the whole DICOM image synthesis problem. Selim et al6 proposed a GAN-based CT image standardization model named STAN-CT. In STAN-CT, a loss function was developed to consider both the latent space loss and the feature space loss. While the former is adopted for the generator to establish a one-to-one mapping from standard images to synthesized images, the latter allows the discriminator to critic the texture features of both standard and synthesized images. Similar to GANai, STAN-CT was applied at image patches and only a few texture features were used as the evaluation criteria. Another GAN-based CT
The generators $A_2B$ and $B_2A$ are both CNN networks with a similar structure. The discriminator $D$ is a fully convolutional network classifier for determining the source of the synthesized images. A VGG texture feature-based domain loss is used to train the model with unpaired data. Domain loss is calculated as a mean square error between the gram matrix representation of $I_A$ and $I_B$.

Image standardization model named RadiomicGAN\textsuperscript{11} took the advantage of transfer learning and proposed a dynamic window-based training approach to adopt the learned information from the RGB image domain into the CT image domain. The results were evaluated on a wide range of radiomics features.

However, all these models require paired training data, greatly limiting the application scope to harmonizing images captured with the same type of scanners.

The cross-vendor CT image harmonization remains a critical bottleneck for inter-institutional data harmonization. This is mainly because it is difficult to obtain paired imagery data\textsuperscript{12}. For example, a patient is scanned using a GE scanner, it is less likely that the patient will be scanned using a Siemens scanner in close time. In this paper, we present a novel deep learning model, called CVH-CT (cross-vendor harmonization of CT images), for cross-vendor CT image harmonization (see Figure 1). CVH-CT relaxes the need for paired training data. Using unpaired training data, CVH-CT can synthesize images from vendor A to vendor B and vice versa. CVH-CT integrates a self-attention layer named CBAM (Convolutional Block Attention Map)\textsuperscript{13} to systematically learn the global features that appear in the images due to the use of different vendors. CVH-CT borrows the CycleGAN\textsuperscript{14} loss and improves it with the feature-based domain loss to determine the feature gap between the synthesized images and the target images in the target domain. Overall, CVH-CT has the following advantages:

1. CVH-CT effectively learns the feature distributions between two different CT image domains without paired training data.
2. The self-attention block, CBAM, with the convolutional layers helps the network to capture the scanner’s relevant global distribution.
3. The domain loss can calculate the feature gap between unpaired data which assists the network to learn the target domain distribution.
4. Experimental results show CVH-CT is better than the state-of-the-art CT image harmonization methods.

## 2 Background

**CT Scanner.** CT is a widely used clinical imaging modality for patient diagnostics. CT scanner vendors in the market, including Canon, Siemens, GE, and Philips, have developed unique reconstruction algorithms to improve image quality while reducing the dosage\textsuperscript{2}. The CT image radiomic features discrepancy problem due to the use of scanners with different imaging techniques poses a gap between CT imaging and radiomics studies\textsuperscript{3,3}. 
Radiomic Feature. Image features, commonly known as the radiomic features, are critical for radiomics study, e.g. tumor characterization\textsuperscript{15}. Mathematical and statistical models are used to extract these features from images. Radiomic features reflect the cellular and genetic levels phenotypic patterns that are hidden from the naked eye\textsuperscript{16,15}. Thus, there is a great potential to capture tumor heterogeneity and phenotypic details with radiomic features. However, the effectiveness of radiomic features, especially for large-scale cross-institute studies, is greatly reduced due to the non-standard practice of medical image acquisition\textsuperscript{17}, since radiomic features are dependent on both inter and intra-scanner protocol settings\textsuperscript{18,17}.

Image synthesis. Image synthesis is a common practice for artificial data generation which mimics the real data distribution\textsuperscript{19}. An image synthesis algorithm may require no input or a random noise for data synthesis but this type of algorithm has less control on the synthesized data\textsuperscript{20}. Medical data synthesis requires high quality with valid clinical meaning. So not all the available image synthesis models may not be appropriate for the medical domain. Recent progress on deep learning for image-to-image transformation provides better control on the synthesized data which makes a suitable choice to adopt it in the medical domain\textsuperscript{21}.

Generative Adversarial Networks (GAN), which are often used for data and image synthesis\textsuperscript{19}, normally consist of a generator $G$ and a discriminator $D$. The generator that could be a Convolutional Neural Network (CNN) is responsible for generating fake data from noise, and the discriminator tries to identify whether its input is drawn from the real or fake data. Among all the GAN models, cGAN is capable of synthesizing new images based on a prior distribution\textsuperscript{22}. The conventional GAN-based image-to-image translation model training requires paired training data that limits its scope where paired data is unavailable. A variation of GAN named CycleGAN\textsuperscript{14} is designed by combining two GAN models to synthesized images for unpaired data.

3 Methods

CVH-CT is designed to harmonize the scanner-related variability by generating synthesized CT images without the need for paired cross-vendor training data. Built on top of the CycleGAN framework, CVH-CT incorporates consecutive convolutional and self-attention layers to learn the global features of entire CT images efficiently. CVH-CT also introduces a new VGG\textsuperscript{23} feature-based domain loss function, which can be directly calculated using unpaired images.

CVH-CT Architecture

Based on the cycle generative adversarial network method called CycleGAN, CVH-CT consists of two generative adversarial networks (GANs). Each GAN has its generator $G$ and discriminator $D$ but with the same structure. A GAN tries to map the data distribution from data domain $A$ to domain $B$. The two generators are $G_{A\rightarrow B}: A \rightarrow B$ and $G_{B\rightarrow A}: B \rightarrow A$. The discriminator $D_A$ is responsible to distinguish between the data being real or fake in terms of domain $A$ and the same job is done by $D_B$ for domain $B$. In Figure 1, given training datasets from two domains, e.g. one set of CT images captured using scanner A and another set captured using scanner B, an initial mapping of $G_{A\rightarrow B}$ is learned to generate synthesized of domain B based on the input image from A. The mapping of $G_{B\rightarrow A}$ is learned to generate synthesized domain A’s image using the input image from B. Discriminator $D_A$ tries to determine whether the input image is from domain $A$ or not and the same for discriminator $D_B$.

CVH-CT Generator. The generator of CVH-CT, as shown in Figure 2, is a convolutional neural network with dedicated convolutional-attention layers. Specifically, each convolutional layer followed by an activation function is used to extract features from the previous layer and store it in a feature map. The convolutional layer dimension is kept consistent throughout the network. For every two convolutional layers (except the last three layers), a self-attention mapping is constructed to capture key global features from the corresponding convolutional layers. These self-attention layers are designed to learn the global features from the spatial dimension and the inter-channel dimension.

Convolutional Block Attention Map (CBAM). In complementary to the convolutional filters focused on extracting local features, self-attention layers are added into CVH-CT to capture the common features in each channel of the network. Such network structure change allows CVH-CT to capture domain-relevant features in the cross-vendor CT image harmonization problem. Figure 2 illustrates the architecture of CVH-CT where each self-attention layer called Convolutional Block Attention Map (CBAM)\textsuperscript{13} consists of the channel-wise attention and the spatial attention.

1101
Figure 2: The architecture of CVH-CT generator and discriminator. The generator uses a series of convolutional layers followed by a Convolutional Block Attention Map (CBAM). The convolutional layers are responsible for fetching the local details while the CBAM is responsible for fetching the global details within the feature map coming from its previous convolutional layers.

Channel-wise Attention Map: The channel-wise attention map is the first phase of CBAM that establishes an inter-channel relationship within a feature map. Max-pooling and avg-pooling operations are used to extract features from the spatial dimensions. Both feature maps are passed through a Multilayer Perceptron neural network (MLP). The output features are concatenated, and an element-wise product operation is used to produce the channel attention map.

Spatial Attention Map: The spatial attention map works on top of the output from the channel-wise attention map. Avg-pooling and max-pooling are used along with the channel axis. The average and maximum feature values pool out the impotent feature. Convolution is done on the concatenated feature of the average and max-pooling feature. After softmax, the output is element-wise multiplied with the input feature map. The output feature map is passed to the next layer for further process.

CVH-CT Loss

Conventional CycleGAN is trained using a comprehensive loss function including adversarial loss, cycle consistency loss, and identity loss. In CVH-CT, we introduce a new loss function called “domain loss” to compare key texture features between unpaired synthesized and target domain images.

Domain Loss. It is a widely used practice to extract style and content features using a pre-trained VGG network. In the cross-vendor CT image harmonization task, a synthesized image and an unpaired target image may have different anatomic structures but similar scanner-relevant texture features (aka. style). We adopted the style-related features from the trained VGG network, which are traditionally the layers closer to the fully connected layers in VGG. The domain loss is calculated as a Mean Square Error (MSE) of the gram-matrix representation of those layers. The domain loss is defined as:

$$ L_{fA} = \frac{1}{m} \sum_{i=1}^{m} (GRAM(G_{A2B}(a_i)) - GRAM(b_i))^2 $$  

$$ L_{fB} = \frac{1}{m} \sum_{i=1}^{m} (GRAM(G_{B2A}(b_i)) - GRAM(a_i))^2 $$

$$ L_f = L_{fA} + L_{fB} $$

where $GRAM(\cdot)$ is the gram-matrix calculated by multiply the feature maps by itself as described in Gatys et al. A and B are two image domains, and m is the batch size.
Adversarial loss. We apply the adversarial loss to both generators, where each generator synthesizes images of its target domain, while its corresponding discriminator tries to distinguish its input images from the target domain distribution or not. In model training, the generator aims to minimize the adversarial loss while its corresponding discriminator tries to maximize it. Note the discriminators if CVH-CT are trained only with $L$ distribution or not. In model training, the generator aims to minimize the adversarial loss while its corresponding discriminator tries to distinguish its input images are from the target domain Adversarial loss.

We apply the adversarial loss to both generators, where each generator synthesizes images of its target domain, while its corresponding discriminator tries to distinguish its input images are from the target domain.

$$L_{adv}(G_{A2B}, D_{B}, A) = \frac{1}{m} \sum_{i=1}^{m} (1 - D_{B}(G_{A2B}(a_i)))^2$$  \hspace{1cm} (4)

$$L_{adv}(G_{B2A}, D_{A}, B) = \frac{1}{m} \sum_{i=1}^{m} (1 - D_{A}(G_{B2A}(b_i)))^2$$  \hspace{1cm} (5)

where $m$ is the batch size, $a \in A$ is the input image of domain $A$ and $b \in B$ is the input image from domain $B$.

Cycle Consistency Loss. We apply the adversarial loss to both generators, where each generator synthesizes images of its target domain, while its corresponding discriminator tries to distinguish its input images are from the target domain distribution or not. In model training, the generator aims to minimize the adversarial loss while its corresponding discriminator tries to maximize it. Note the discriminators if CVH-CT is trained only with $L$.

$$L_{cycle}(G_{A2B}, G_{B2A}, A, B) = \frac{1}{m} \sum_{i=1}^{m} ||G_{B2A}(G_{A2B}(a_i)) - a_i|| + ||G_{A2B}(G_{B2A}(b_i)) - b_i||$$  \hspace{1cm} (6)

Identity Loss. The identity loss is introduced to preserve the key details of the input and target domains. It is calculated by proving the target domain data as input of the generator and calculating the L1 loss between input and synthesized images.

$$L_{Idt}(G_{A2B}, G_{B2A}, A, B) = \frac{1}{m} \sum_{i=1}^{m} ||G_{A2B}(b_i) - b_i|| + ||G_{B2A}(a_i) - a_i||$$  \hspace{1cm} (7)

Finally, the total loss of the CVH-CT generator $L(G)$ is defined as:

$$L(G) = L_{adv}(D) + \lambda_1 L_{cycle} + \lambda_2 L_{Idt} + \lambda_3 L_f$$  \hspace{1cm} (8)

where $\lambda_1 \in [0, 1]$, $\lambda_2 \in [0, 1]$ and $\lambda_3 \in [0, 1]$ are weight factors.

4 Experimental Results

Dataset

A multipurpose lungman chest phantom was scanned using the Siemens CT Somatom Force scanner and General Electric (GE) Revolution EVO scanner machine to obtain the training and testing data. The phantom has synthetic nodules in its lung which makes it an accurate life-size anatomical model of a human torso. Note that the phantom does not contain lung parenchyma, so the space within the vascular structure is filled with air. Using the human chest phantom with several synthetic lung nodules, in total 11,070 image slices were obtained from a GE scanner. In total 9,156 image slices were obtained using a Siemens scanner where 7,290 image slices are from the chest phantom and 1,866 are from lung cancer patients. All the image slices are 512 × 512 with 16-bit pixel encoding. The image acquisition parameters and the data description are in Table 1. Images in the training dataset are randomly paired. To evaluate the performance of CVH-CT and baseline models, we prepared a slice-by-slice paired dataset using phantom scans. Using the GE and Siemens scanners, in total 250 image pairs were generated with five different KVPs and a fixed (5 mm) slice thickness.

Also, we tested the performance of CVH-CT on CT images collected from the same scanner but with two different image reconstruction kernels using patient scans. The model was trained with a total of 9,580 CT image slices from lung cancer patients using four different slice thicknesses (0.5, 1, 1.5, 3mm) using the Siemens CT Somatom Force scanner. To enable model performance evaluation, we reconstructed two images from the same scan using reconstruction kernels Bl64 and Br40 respectively. Bl64 is the reconstruction kernel often used for lung screening, and Br40 is used for regular screening.

Model Implementation

The generator of CVH-CT consists of seven convolutional layers and three CBAM blocks. Each convolutional layers have 64 filters with kernel size $4 \times 4$ and stride=1. The discriminator is a fully connected convolutional neural network with seven hidden layer. The convolutional layers used $4 \times 4$ filters. LeakyRelu is adopted as the activation function in all the hidden layers. The last layer of the generators uses $Tanh$ activation and discriminators use $Sigmoid$ activation. The model uses $80 \times 80$ soft-tissue image patches from the training dataset to train the model and the testing is done using the full CT slice that is $512 \times 512$. The synthesisization is done with the Hounsfield Unit (HU) ranging from $-1000$ to $900$. Random weights are used during the network initialization phase. Maximum training epochs are set to 50 with the learning rate being 0.0001 with momentum 0.5. The batch size is set to 32.

CVH-CT is implemented in PyTorch and runs on a Linux computer server with eight Nvidia GTX 1080 GPU cards. It takes about 4 hours to train the model from scratch. Once the model is trained, it takes about two seconds to harmonize a CT image slice. (Source code: https://github.com/A VAILABLE-SOON)

Evaluation Metric

Model performance was evaluated systematically at the whole image level and with randomly selected regions of interest (ROIs) from the soft tissues. For each CT image or ROI, quantitative radiomic features are extracted from six different feature classes using Pyradiomics. These feature classes and the number of features are, First Order Statistics (18), Gray Level Co-occurrence Matrix (GLCM, 24), Gray Level Run Length Matrix (GLRLM, 16), Gray Level Size Zone Matrix (GLSZM, 16), Neigbouring Gray Tone Difference Matrix (NGTDM, 5) and Gray Level Dependence Matrix (GLDM, 14). The six feature classes contain a total of 93 features.

We evaluated the CT image harmonization models by the radiomic features reproducibility analysis and the visual quality of the synthesized images. The radiomic feature reproducibility is analyzed by Concordance Correlation Coefficient (CCC) score and the visual quality of the synthesized images are determined by Peak Signal-to-Noise Ratio (PSNR), Structural SIMilarity (SSIM), and Normalized Cross Correlation (NCC).

Concordance Correlation Coefficient (CCC, see Eq. 9) was employed to measure the level of reproducibility of radiomic features. Mathematically, CCC represents the correlation between the input and the target image features in the six feature classes:

$$CCC = \frac{2\rho_{s,t}\sigma_s\sigma_t}{\sigma_s^2\sigma_t^2 + (\mu_s - \mu_t)^2}$$

where $\mu_s$ and $\sigma_s$ (or $\mu_t$ and $\sigma_t$) are the mean and standard deviation of the radiomic features belong to the same feature class in a synthesized (or target) image respectively, and $\rho_{s,t}$ is the Pearson correlation coefficient between $s$ and $t$. CCC ranges from -1 to 1 and is the higher the better.

Peak Signal-to-Noise Ratio (PSNR, see Eq. 10), which is a widely used metric for measuring the relative perceptual quality in image and video comparison. PSNR is defined as a logged ratio of the peak signal and the mean-square-error between the synthesized and the target images and is the higher the better.

$$PSNR = 10 \cdot \log_{10} \frac{MAX(X)^2}{\frac{1}{mn} \sum_{i=0}^{n} \sum_{j=0}^{m} (x_{ij} - x'_{ij})^2}$$

where $X$ and $X'$ are target and synthesized images with $m \times n$ dimension respectively. All the feature values are normalized to $[0, 1]$ range.

Structural SIMilarity (SSIM, see Eq. 11) is defined as a co-relation between the synthesized and the standard images with values ranges from -1 to 1, and the value 1 indicates perfect structural similarity.

\[
SSIM = \frac{(2\mu_s\mu_t + c_1)(2\sigma_s\sigma_t + c_2)}{\mu_s^2 + \mu_t^2 + c_1(\sigma_s^2 + \sigma_t^2 + c_2)}
\]  

where \(\mu_s\) and \(\sigma_s\) (or \(\mu_t\) and \(\sigma_t\)) are the mean and standard deviation of the synthesized (or target) image respectively, and \(\sigma_{st}\) is the co-variance of \(s\) and \(t\). \(c_1\) and \(c_2\) are two constant. The SSIM values ranges between -1 to 1, and the value 1 indicates prefect structural similarity.

Normalized Cross Correlation (NCC, see Eq. 12), which is the correlation between a synthesized image and its corresponding target image and is defined as:

\[
NCC = \frac{\sum_{i=0}^{m} \sum_{j=0}^{n} x_{ij}x'_{ij}}{\sqrt{\sum_{i=0}^{m} \sum_{j=0}^{n} x_{ij}^2} \sqrt{\sum_{i=0}^{m} \sum_{j=0}^{n} x'_{ij}^2}}
\]

where \(X\) and \(X'\) are the target and synthesized image features respectively. All the values are normalized to [0, 1].

Performance Evaluation

We compared CVH-CT with the conventional CycleGAN and two CVH-CT variations. CVH-CT¹ is constructed with CycleGAN with the proposed domain loss \(L_f\). CVH-CT² is constructed with CycleGAN with the proposed CBAM layers. We evaluated all the models in two settings, i.e. transform a GE image into a synthesized image with the Siemens domain, and transform a Siemens image into a synthesized image with the GE domain. Note the source image of one domain is the target image of another domain. Table 2 shows the effectiveness of CT image harmonization in soft-tissue ROIs. The CCC scores of synthesized and actual images are reported for six different

Figure 3: Case study of model performance comparison. Heat maps of the residual images obtained by comparing two target images with the corresponding synthesized images under both GE-to-Siemens and Siemens-to-GE conversions. The input column includes images need to be harmonized and the rest of the columns are for the results of the respective models. Overall, CVH-CT has the lowest residues. Values close to 0 (blue) in heat map indicate high similarity between target and synthesized images, while values close to 1 (red) indicate high dissimilarity.

Feature classes. The row “Input” indicates the CCC scores of the source image in the six feature classes, which serve as the baseline. The rest CCC scores indicate the performance of all the compared models regarding the improvement of feature reproducibility. In both conversions, CVH-CT achieves the best score in five feature classes. All the values in the column “First order” is close to 1.0 indicating that anatomic features are well preserved with all the models. The CCC scores of CVH-CT are significantly higher than that of CycleGAN on the texture feature classes. Table 4 shows the PSNR, SSIM, and NCC scores for image quality assessment. Overall, CVH-CT effectively improved the visual quality in the synthesized images according to the three metrics.

We further tested CVH-CT using unpaired image data collected from the same scanner using two reconstruction kernels, namely Bl64 and Br40. The CCC score for Br40-to-Bl64 conversion is 0.87 ± 0.12 and the score for Bl64-to-Br40 conversion is 0.86 ± 0.10, indicating that CVH-CT works well not only on cross-vendor image harmonization but also on cross-protocol image harmonization.

Figure 3 shows the results of two sample images obtained from CycleGAN, CVH-CT¹, CVH-CT², and CVH-CT.
The source images of GE-to-Siemens conversion are the target images for Siemens-to-GE conversion and vice versa. The residual images at the second, fourth, sixth, and eighth rows were calculated as a numerical difference between a synthesized image and its corresponding target image. Values close to 0 (blue) indicate high similarity between them, while values close to 1 (red) indicate high dissimilarity between them. Overall, CVH-CT performed clearly better than CycleGAN. The residual image of CVH-CT indicates that its synthesized images are very close to the corresponding target images. For example, in the first row, the outer side of the lung has a high mismatch in all the synthesized images except for the image from the proposed CVH-CT model.

Figure 4 shows the effectiveness of the proposed domain loss in CVH-CT. In this case study, we synthesized an image in the GE domain using a Siemens image with different anatomic features (i.e. unpaired images). The visualization of images in different training epochs indicates that CVH-CT was efficiently trained to learn the textures from the GE domain. Also, these synthesized images at different epochs were not disturbed by the target image structure indicating the proposed domain loss can learn texture details while ignoring the structural information. The domain loss values are visualized in the right-bottom corner of the figure.

5 Conclusions

Data discrepancy in CT images due to the use of scanners with different imaging techniques adds an extra burden to radiologists and also creates a gap in large-scale cross-center radiomic studies. To facilitate large-scale medical image studies and to address the long-existing cross-center CT image data integration problem, we propose CVH-CT, a novel tool for CT image data harmonization. In CVH-CT, both the CBAM layers and the domain loss are introduced for efficient model training. CVH-CT can harmonize images without the need for paired training data. The experimental results demonstrate that CVH-CT is significantly better than the existing tools on CT image harmonization.

Comparing Deep Learning and Conventional Machine Learning Models for Predicting Mental Illness from History of Present Illness Notations

Ingroj Shrestha, Padmini Srinivasan, Ph.D.
University of Iowa, Iowa City, Iowa, United States

ABSTRACT
Mental illness, a serious problem across the globe, requires multi-pronged solutions including effective computational models to predict illness. Mental illness diagnosis is complicated by the pronounced sharing of symptoms and mutual pre-dispositions. Set in this context we offer a systematic comparison of seven deep learning and two conventional machine learning models for predicting mental illness from the history of present illness free-text descriptions in patient records. The models tested include a new architecture CB-MH which ranks best for F1 (0.62) while another attention model is best for F2 (0.71). We also explore model decisions using Integrated Gradients interpretability method which we use to identify key influential features. Overall, the majority of true positives have key features appearing in meaningful contexts. False negatives are most challenging with most key features appearing in unclear contexts. False positives are mostly true positives in actuality as supported by a small-scale clinician-based user judgement study.

INTRODUCTION
Mental illness is the leading cause of disability globally – one in five adults in the U.S. lives with it[28]. Even prior to the COVID-19 pandemic mental illness and suicidal ideation were increasing among adults[32]. The same report shows that the number of people seeking help due to moderate or severe anxiety and depression has shown an alarming increase. These trends emphasize the importance of multi-pronged strategies to subdue the upsurge in mental health challenges: prediction models able to assist in effective diagnosis of mental illness is a key component.

The national drive towards Electronic Health Records (EHR) has resulted in vast collections of multi modal, structured and semi-structured patient records that compile information related to various encounters and activities with patients. These are naturally seen as resources that may be used to identify patients having specific diseases or disorders including those related to mental health. While EHR are generally encoded with disease codes from systems such as ICD-9/10/CM etc., there are well recognized limitations when these codes are used for secondary purposes such as phenotype or cohort identification. For example, these codes are known to be incomplete and error-prone[16, 31]. This has generated active research in building models that rely more on the free-text portions of patient EHRs, as for instance to predict disease states and prognosis. Thus we see papers and reviews on machine learning methods, both conventional and more modern deep learning (DL) for building prediction models from free-text EHR data[30, 31].

Despite the excitement over the development of DL models in health care applications[32], the emphasis on mental illness diagnosis from free-text portions of the clinical record has been minimal. In contrast, there has been active research with traditional machine learning models[2]. A 2020 review[28] of DL in mental health identifies under five papers exploring the free-text portions of EHR. These were directed at different goals including symptom severity[22] and cohort definition[23]. The one paper directly about mental illness prediction from free-text is by Tran et al[23]. They explore CNN and RNNs using the history of present illness portions of clinical notes for predicting 11 mental health conditions. The limitation is that they use a small dataset of only 1000 notes. Thus, it is still unknown as to how well deep learning models will perform on the task of predicting mental health conditions using free-text portions of EHR and consequently it is also unknown as to which DL models are best suited for this problem.

The problem of predicting mental illness is particularly challenging as unlike typical chronic conditions laboratory tests to aid in diagnosis are not generally available[25]. Instead there is reliance on patient observation, self reports, responses to questionnaires etc. These impressions are generally summarized in the patient notes. Another challenge is that the shared underlying biology is pronounced with mental disease. For example, people with depression share symptoms with those having generalized anxiety disorder such as irritability and sleep problems[17, 18]. Moreover, multiple problems may co-exist with one pre-disposing another[13]. Any predictive model will have to make fine distinctions between classes in this multi-label, multi-class setting.

1109
Set in this context, our goal is to rigorously compare deep learning (DL) methods in their ability to predict mental illnesses from free-text clinical notes. We also include conventional machine learning algorithms in our comparison. We systematically compare nine models representing CNNs, LSTMs, different mechanisms to include attention components (exploring both self and soft attention mechanisms), transformer based models as well as conventional SVMs and Logistic Regression. We also propose a DL model Convolution BiLSTM Multi-Headed attention that we call CB-MH. This architecture includes a multi-head attention mechanism. We compare the models using a large collection of 150,085 psychiatry clinical notes spanning 10 years (history of present illness portions). We make comparisons using both F1 and F2 measures. We then go deeper into one best DL model to get a better understanding of its predictions. For this we utilize an interpretability approach using the Integrated Gradients methodology which allows us to identify key features, with weights designating their relative importance in model decisions. We use these key features to examine reasons for true positive decisions as well as reasons for errors (both false positives and false negatives). We close with a small scale judgement study involving two clinicians who provide further insights on the nature of a sample of erroneous model decisions.

Next under Materials and Methods we describe our dataset, the DL and traditional ML models we compare. Next is the Results section followed by a section analyzing decisions made by a select DL model for one disease. Discussion, Conclusions and future work sections follow.

**MATERIALS AND METHODS**

**Dataset**

We used a 10-year span (2008-2017) of de-identified patient visit data from the psychiatry outpatient clinic of a leading midwestern hospital. There are 203,466 clinical visit records corresponding to 15,986 distinct patients. Each record has a de-identified patient id, visit date, notes on history of present illness (average length 219 words), and diagnoses in the form of ICD9 codes. After removing duplicates and records without a mental health diagnosis, there are 150,085 records for 14,916 patients. Domain experts grouped low frequency ICD labels resulting in a final set of 8 codes/diagnoses for our prediction goals. Table 1 describes our data.

Besides performing experiments on the Full set of 150,085 records we also experimented on a (Sample) of 15,009 records (10% of Full) to see if results scale well. Unlike most prior work, we explore this question while considering prediction confidence level. The smaller set is obtained using stratified sampling to maintain the same distribution of diagnosis as in the Full set (Table 1) within a 1% difference. The data were split into training (65%), validation (15%), and testing (20%). All records of a patient were either in training, validation, or testing.

**Deep Learning Models Tested**

**BERT:** This is a bidirectional language model based on the transformer model and is trained on two tasks masked language modeling (MLM) and next sentence prediction (NSP). MLM helps achieve bidirectionality and NSP learns sentence relationships during training. BERT is trained on a large corpus — the English Wikipedia and BooksCorpus and fine tuned for several NLP downstream tasks. We used pretrained uncased version of BERT base model modifying the last layer for our prediction task and fine tuning it.

**LSTM:** This is the standard sequence-to-sequence model (an extension of RNN) involving an input gate, forget gate, output gate, and a cell state to handle short term memory. The gates control the flow of input information (i.e., what information to remember or forget) and help to better handle context (in contrast with RNN). Equations representing these gates are as in Lipton et al. At an abstract level, we represent the final learned representation of the text as $\overrightarrow{h_t} = LST\overrightarrow{M}(x)$, where $x$ is the input clinical note, $\overrightarrow{h_t} \in R^{bh}$. where the hyperparameter $h_{\alpha}$ represents the size of

hidden layer.

**BiLSTM:** Here two LSTMs are combined, one that processes the text in the forward direction and the other in the backward direction. Both the LSTMs are of the same dimensions. Representing text \( x \) processed in the reverse direction as: \( \hat{h}_t = \overrightarrow{\text{LSTM}}(x) \), the final representation \( (H) \) is as in Eq.1 where \( H \in R^{2h_n} \).

\[ H = [\overrightarrow{h}_t, \overleftarrow{h}_t] \quad (1) \]

Based on insights from He et al.\(^6\) and preliminary experimentation with the validation data, we found it effective to add a global max pooling layer followed by a dense layer with ReLU activation before the final output layer.

**CNN:** This is a standard CNN with convolutional filters and max pooling followed by a dense layer with a non-linear activation function ReLU\(^9\).

**CNN-BiLSTM:** The objective here is to take advantage of the CNN convolutional layer and BiLSTM hidden representations. Thus we built this model by adding a BiLSTM on top of the CNN.

**CB-Atn:** This is our first model exploring attention. Here we add to the top of the CNN-BiLSTM architecture a soft attention layer\(^1\). We use \( H \) from (Eq.1) to obtain word level attention weights \( (a) \) using Eq.2b. These activation weights indicate the relative importance of different portions of the input text. The final vector \( (f) \) representation weighted by attention uses Eq.2c where \( W \in R^{c_v \times 2h_n}, b \in R^{c_v} \), and \( v \in R^{c_v} \) is a learned context vector.

\[
\begin{align*}
  u &= \tanh (WH + b) \\
  a &= \frac{\exp (u^T v)}{\sum_T \exp (u^T v)} \\
  f &= \sum_T aH
\end{align*}
\]

**CB-MH:** Inspired by work with the transformer model\(^2^4\) we propose a new architecture with multi-head self-attention mechanism instead of the single head soft attention. A single head will get different distributions each time it is run. Our insight is that a multi-head architecture will reduce this variation in distributions, thus giving attention to similar phrases. Thus, we capture attention multiple \( (r) \) times with different weight matrices \( W^Q_i, W^K_i, W^V_i \) for \( i = \{1, 2, ..., r\} \) with a final concatenation of attention using Eq.3a. Like CB-Atn this model builds off CNN-BiLSTM.

\[
\begin{align*}
  MultiHead(Q, K, V) &= \text{Concat} (\text{head}_1, ..., \text{head}_r) W^0 \\
  \text{head}_i &= \text{Attention}(QW_i^Q, KW_i^K, VW_i^V) \\
  \text{Attention}(Q, K, V) &= \text{softmax} \left( \frac{QK^T}{\sqrt{d_k}} \right) V
\end{align*}
\]

Here \( W^0 \in R^{d_v \times 2^h_n}, W_i^Q, W_i^K, W_i^V \in R^{2^h_n \times d_k} \) are learned parameters, and \( d_k = d_v \), where \( d_v \) represents the hidden size per head. The configuration for hidden size and the number of attention heads is the same as in BERT\(_{\text{BASE}}^4\). In Eq.3c the attention function maps a set of queries \( (Q) \), key-value pairs \( (K-V) \) to an output. In our case, we set the values of \( Q, K, \) and \( V \) as the output of BiLSTM layer (Eq.1), i.e. \( \text{MultiHead} (H, H, H) \). Our code for CB-MH is available at [https://github.com/IngrojShrestha/CB-MH](https://github.com/IngrojShrestha/CB-MH).

All models were configured with optimal hyperparameter settings using validation data. Table2 lists the key parameters explored and the selected values.
Table 2: Parameters for deep learning models (tuning range for hidden layer: [64, 128, 256], embedding dim.: [200, 400], dropout: [0.5, 0.6, 0.7, 0.8], global output threshold: [0.2, 0.4, 0.5, 0.6, 0.8], kernel size: [3, 4, 5, (3, 4, 5), (2, 3, 4, 5)]. dropout is used in penultimate layer.

**General settings for DL models:** The input texts had stopwords removed and were stemmed. We use pre-padding and pre-truncation to handle variable sequence length. Input text tokens were represented by 400 dimension pre-trained embedding vectors using word2vec\(\text{[23]}\) trained on PubMed abstracts from PubMed Baseline 2018\(\text{[29]}\). The final output layer (of size \(L\) equal to the number of classes) uses a sigmoid function to output the probability of prediction for each label \(P(\cdot)\). All DL models learn the optimal parameters by minimizing the binary-cross entropy loss in Eq. 4. We use the Adam optimizer with a learning rate of 0.001 and Keras for implementation using one NVIDIA Tesla P100 PCIE (16GB) GPU.

\[
\left\{-\frac{1}{L} \sum_{i=1}^{L} y_i \log P(y_i = 1) + (1 - y_i) \log (1 - P(y_i = 1))\right\}
\]

(4)

**Traditional Machine Learning Models Tested**

We test (1) Logistic Regression and (2) SVM with L2 regularization. Each note is represented by a TF-IDF weighted word unigram vector after stopword removal. For LR no stemming is optimal while for the SVM stemming (Porter’s stemmer\(\text{[26]}\)) is optimal. We create one SVM classifier/LR regressor for each class using scikit-learn\(\text{[20]}\).

**Performance Measures**

We report micro-averaged recall (R), precision (P), F1 and F2 scores. F2 (recall twice as important as precision) is important in medicine to minimize risk of missing a positive, i.e., of making Type II errors. Micro-averaging is appropriate as each visit is considered equally important.

**MODEL COMPARISON RESULTS**

Table 3 presents the results. We use bootstrapping shift test\(\text{[25]}\) to estimate 95% confidence intervals for comparing models. Specifically, we sample the test set with replacement 10K times; for each sample we calculate both F1 and F2 per model and we then generate 95% confidence intervals over these 10K bootstraps for each model and measure.

We see that F1 and F2 scores are significantly higher in the *Full* dataset compared to in *Sample* with only four exceptions of 18 comparisons (e.g., exception: F2 scores for our model CB-MH are statistically equivalent in both datasets). 18 comparisons refers to 9 models * 2 scores (F1 and F2). For some cases on moving from *Sample* to *Full* (a) F1 improved but F2 worsens (b) F1 improvements are significant but F2 improvements are marginal. When we move from *Sample* to *Full*, precision (P) improved but recall (R) decreased for some models. Moreover, the magnitude of change in precision was relatively large compared to that for recall in the 2 cases (out of 9) where F2 drops while F1 increases. Most importantly, confidence intervals for *Full* are tighter than for *Sample* and the DL models better distinguishable. For instance, in *Sample*, CB-MH and BiLSTM do not have significantly different scores, whereas in *Full* they do. This is consistent with expectations as DL models are more stable given more data. Thus, in our remaining analyses we focus on the *Full* dataset results.
With one exception (LSTM in F1), all DL models are significantly better than SVM and LR in both F1 and F2. The smallest statistically significant improvements are 3.6% in F1 (CNN) and 12.2% in F2 (LSTM), the highest 12.7% in F1 (CB-MH) and 44.9% in F2 (CB-Atn).

We find that F2 scores (minimizing Type II errors) are systematically larger than F1 scores for the DL models. But for SVM and LR, F1 scores are better than F2, these appear to favor precision over recall. But as noted earlier these models do not do as well as the DL models.

The attention models perform the best. **CB-MH** is the best for F1 (0.62 (95% CI : [0.613, 0.618])). As described earlier this involves a multi-head attention (12 heads) architecture. For F2 the best is CB-Atn of 0.71 (95% CI : [0.705, 0.710]). This uses a soft attention component. While our CB-MH performance is close (0.68 F2), there is a small difference of 0.02 in their confidence intervals. The use of multi-head attention seems to provide an advantage in making more precise predictions with a penalty in recall which brings down F2. BiLSTM and CNN-BiLSTM are second best on both F1 and F2 and LSTM is the weakest. The unidirectional sequence based model (LSTM) is not better than the non-sequential CNN. On the other hand, bidirectionality helps make BiLSTM better than CNN. Also, BERT trained on Wikipedia and Book-Corpus is likely limited for biomedicine.

</tbody>
</table>

Table 4 provides class level results (ignoring Other class) four **CB-MH** with rows ordered by decreasing data size. With one strong exception (Psychotic disorders), we see higher F1 with larger class size. The pattern is less consistent for F2 due to differences in the relative success with recall and precision. E.g., recall is favoured in Unipolar Depression and Cluster B personality and precision in Bipolar disorders. Exploring influential factors for these patterns in recall over precision (beyond dataset size variations) is left to future work. For completeness, we report macro-averages across classes and for the best traditional machine learning approach (LR). The percentage improvement of our proposed model over the LR approach is 18.8% in macro F1 and 47.5% in macro F2; these percentage improvements are in fact larger than micro average improvements reported earlier (12.7% F1, 38.8% F2, Table 3).
ANALYSIS OF CORRECT AND ERRONEOUS MODEL PREDICTIONS

We analyze model predictions using Integrated Gradients (IG) an interpretability or explainability technique. We analyze both correct decisions (focusing on true positives (TP)) as well as erroneous decisions, both false positive (FP) and false negative (FN) decisions (see Error Analysis section). We focus our analysis on decisions made by the CB-Atn model which had the highest F2 scores and the class unipolar depression. Our CB-MH model is an equally viable model for analysis since it leads in F1. However, we chose to analyze the model with lower Type II errors. First we present an overview of the IG based analysis approach and then present our observations.

Integrated Gradients (IG) estimates the extent to which each word feature contributes to model predictions. This is estimated based on the gradients of the model with respect to the input. At a high level the method operates as follows. We are given the embedding vector representation ($e$) for the input text, the baseline zero embedding vector ($e'$), and $F(.)$ the function in the model that gives the output vector. The interpolated method computes a series of $m$ vectors (here $m = 100$) between $e$ and $e'$. Then gradients for each interpolated vector are computed; the gradient for an input feature is the partial derivative of $F(.)$ with respect to that feature ($e_i$). The final integrated gradient score for a word feature ($IG_i$) is then the average of its $m$ gradients multiplied by $(e_i - e_i')$. This calculation is as in Sundararajan et al. and is shown in Eq. 5.

$$IG_i = (e_i - e_i') \sum_{k=1}^{m} \frac{\partial F(e' + \frac{k}{m} (e - e'))}{\partial e_i} \frac{1}{m}$$

IG scores are normalized $(-\infty, +\infty)$ to $[0, 1]$ with negative values mapped to $[0, 0.5]$ and positives to $(0.5, 1]$. A feature with a positive value indicates that its presence increases the likelihood of of the model predicting a label. Similarly, a negative value indicates that the feature’s presence in the note reduces the likelihood of the same event. Scores close to 0.5 signal neutral features.

Analysis strategy

Given a note of interest we first use IG to identify key features used by the CB-Atn model to make its predictions. Key feature(s) is/are the word(s) with the highest IG score. We limit features to relevant UMLS semantic types: Mental or Behavioral Dysfunction, Sign or Symptom, Disease or Syndrome, Mental Process, and Pharmacologic Substance. Our code for semantic filtering is available at [https://github.com/IngrojShrestha/CB-MH](https://github.com/IngrojShrestha/CB-MH). We analyze a note if it has a key feature with IG score $\geq 0.51$, i.e., it has some positive influence on the prediction. The two authors then manually categorized a surrounding context of $k$ ($=15$) words into: (1) positive: context indicates depression present, (2) negative: context indicates depression absent, or (3) unclear: context insufficient to analyze. There was strong agreement between the two sets of judgements (kappa=0.81; 89.9% agreement).

Analysis of True Positives

There were 113 TP notes to analyse. The majority (82%) appear in positive contexts indicating sound reasons for these correct positive decisions. We see such examples in Table 5. Notably, in the last example the patient has depression that is improving making this a correct prediction. While depression appears as a key feature in some notes it is crucial to note that a simple keyword search strategy using ‘depression’ on our Full dataset yields very poor results (F1: 0.47, F2: 0.41). The remaining 18% of TP key features appear in unclear/uninterpretable contexts. Thus the majority of the true positive decisions made by the model are sensible and justifiable.

</tr>
</tbody>
</table>

Analysis of False Positive and False Negative Errors

False Positives: Key features occur in two types of contexts

The 34 FP notes analyzed were about evenly split between positive for depression contexts and unclear contexts. In the first example in Table 6, the patient is under antidepressants, which indicates that model prediction is correct. The next two examples indicate that depression continues from the past into the present. In the last example, while the patient is improving treatment for depression is clearly stated. The interpretations for these FP decisions (and we found several similar ones) point to likely errors of omission in ICD annotations.

Table 6: False positive examples (key feature is in bold)

<table>
<thead>
<tr>
<th>Key Feature</th>
<th>Context</th>
</tr>

</tr>
<tr>
<td>insomnia</td>
<td>some overall improvement review of depressive symptoms shows that she has some initial and intermittent insomnia and fatigue particularly in the early morning she feels she should resume her previous morning</td>
</tr>
</tbody>
</table>

False negatives: Key features are mostly in unclear contexts

The vast majority (84%) of the 74 FNs analyzed fall into unclear contexts making this the most challenging class of model errors for analysis. In example 1 in Table 6, the patient note has: “...Trazodone causes severe daytime sedation so he avoids it... .... He agrees to reduce Remeron to 7.5 ...” The model fails to connect Remeron and Trazadone with unipolar depression, possibly due to insufficient training data. Instead, it views thoughts as the key feature but its context is not specific enough to predict unipolar depression; instead Bipolar Disorders is predicted. In the (psychosis) example the model clearly made an error. In example three, the context for anxiety indicates the absence of depression (i.e., negative context). This could be why the model does not predict unipolar depression. Examining the full note we do not find any indication of a patient having depression. Similarly, in the last example (paranoia) there is no evidence in the rest of the note. Thus in a few cases the IG interpretation shows that evidence for a label is missing, pointing to possible errors of commission in ICD labeling.

Error Analysis with Clinical Expertise

Next we present a small user study to determine if the model’s FNs and FPs decisions are due to annotation errors.

Sample selection: We first ranked the FP and FN notes by IG score given to a key feature. To explain, the top ranking
Table 7: False negative examples (key feature is in bold)

<table>
<thead>
<tr>

</tr>
<tr>
<td>paranoia</td>
<td>no current depressive sx does not believe he currently has an anxiety problem no hallucinations paranoia no history of mania past psychiatric history</td>
</tr>
</tbody>
</table>

Manual annotation: Two clinicians independently annotated each note. They were given the full history of present illness and asked to decide if an ICD code pertaining to depression should or should not be assigned. They were also allowed to use a ‘not sure’ category. They agreed in 18/25 cases (kappa = 0.59; 85.7% agreement). Four notes had at least one judge mark ‘not sure’ while they disagreed on three notes. Gauged against the 18 decisions where the judges agreed, our model’s FP and FN decisions were correct in 78% (14/18). To explain, we marked an FP (FN) decision as correctly declared positive (negative) if both judges indicated that the note should (should not) be annotated with a depression ICD code. Interestingly, all FP decisions were declared correct (12/12) while a third (2/6) FN decisions were correct. These results are encouraging especially for the FP decisions.

DISCUSSION

Our proposed model, \( CB-MH \), is top ranked in F1 (0.62) while \( CB-Atn \) is best in F2 (0.71). The differences between their confidence intervals is slight (0.02 at most). Both models use attention. In the case of our model the run time for both training and testing with the Full set is approximately 122 minutes. We find that while scores are generally higher in the Full set compared to the Sample, notably confidence intervals are tighter with the larger set. Traditional machine learning algorithms do not fair as well as DL models. They seem less well equipped to capitalize on the semantics underlying diagnoses as well as DL models. They seem less well equipped to capitalize on the semantics underlying diagnoses as well as DL models. DL models are good at reducing Type II errors achieving higher F2 scores compared to F1 scores. As pointed in a recent review of DL models operating off clinical texts, it is important to continue comparing DL with traditional methods. While our DL models fared well, in 11% of the studies they surveyed DL algorithms performed worse than traditional machine learning algorithms.

Setting aside differences across papers, our best scores are lower than recent DL results for heart failure (F1: 0.9), COPD (F1: 0.9), and kidney diseases (F1: 0.92). Our LSTM (F1:0.54) also fared lower than an LSTM for cardiovascular disease (F1:0.61). These differences underline the greater challenge in predicting mental illness with its fine distinctions between disease classes. Our results also point to room for improvement and the need for research on stronger decision models for this challenging problem setting.

A high majority (82%) of true positive model decisions for depression analyzed involve key features that appear in meaningful contexts. This points to model success in this regard. Interestingly, about half of the FPs analyzed involve features in contexts indicating disease presence - suggesting possible errors of omission in ICD labels. Our follow up small scale study using clinician judges lend further support to this suggestion. All of the model’s FPs reviewed by the judges using the notes where declared to be true positives. The FN group was the most challenging: 84% of analyzed notes had key features that were in unclear contexts. For some notes, the model was clearly incorrect, possibly there were weaknesses in the training data. In still others, evidence supporting a positive annotation for depression was not in the note. In this context, the clinician judges found a third of the model's FN decisions to be true negatives. Overall, agreement between judges was moderate (clinician judgements) to strong (author judgements). This suggests - in general - that the task of looking for evidence supporting depression diagnosis, either in a text window of +/-15 words or in the whole note is more straightforward than nuanced.
Our error analysis, especially with the false positives indicate a possibility for the future. Perhaps there is the potential for combining model prediction from free-text with interpretability based error analysis as a pathway towards strengthening, i.e., selectively correcting ICD annotations of clinical records. We will explore this in future research.

CONCLUSION

We compared seven deep learning and two traditional machine learning algorithms on the multi-class, multi-label problem of predicting mental illness from free-text notes. The tested models included one that we proposed CB-MH, a multi-head, soft-attention model. This model achieved the highest F1 score and a close to highest F2 score. Error analysis was conducted using Information Gradient methodology to identify features which contributed most to model decisions. We showed through clinician judgements that FPs with highest IG scoring features were actually TPs; similarly a third of the FNs were true negatives. We show a potential way forward for using DL models with error analysis through IG as a mechanism to correct ICD annotation errors in clinical datasets.

LIMITATIONS AND FUTURE WORK

We have not explored resources such as BioBERT. Though built for applications related to genes and diseases these may prove useful. Given the manual effort involved we focus on extracting explanations for a single disease. Our next goal is to scale this up by automating the process of identifying explanations from IG scores of features and their contexts. We analyzed micro averaging results alone (Table 3) primarily due to space restrictions. With micro averaging larger classes are likely to dominate. However, Table 4 does provide some results with macro averaging.

ACKNOWLEDGEMENTS

The authors thank the two clinicians Dr. L. Durairaj and Dr. A. Aggarwal for their participation as judges in the user study.

BlockIoT: Blockchain-based Health Data Integration using IoT Devices

Manan Shukla¹, Jianjing Lin, PhD¹, Oshani Seneviratne, PhD¹
¹Rensselaer Polytechnic Institute, Troy, NY, USA

Abstract

The development and adoption of Electronic Health Records (EHR) and health monitoring Internet of Things (IoT) Devices have enabled digitization of patient records and has also substantially transformed the healthcare delivery system in aspects such as remote patient monitoring, healthcare decision making, and medical research. However, data tends to be fragmented among health infrastructures, and prevents interoperability of medical data at the point of care. In order to address this gap, we introduce BlockIoT that uses blockchain technology to transfer previously inaccessible and centralized data from medical devices to EHR systems, which provides greater insight to providers who can, in turn, provide better outcomes for patients. This notion of interoperability of medical device data is possible through an Application Programming Interface (API), which serves as a versatile endpoint for all incoming medical device data, a distributed file system that ensures data resilience, and knowledge templates that analyze, identify, and represent medical device data to providers. Our participatory design survey on BlockIoT demonstrates that BlockIoT is a suitable system to supplement physicians’ clinical practice and increases efficiency in most healthcare specialties, including cardiology, pulmonology, endocrinology, and primary care.

Introduction

In the last several decades, the explosion of information technology has profoundly changed how information is stored, exchanged, managed, and analyzed in medicine. For instance, the invention of EHRs has enabled digitization of patient records and has substantially transformed the healthcare delivery system. At the same time, the emergence of IoT health devices has also been increasingly applied in remote patient monitoring, healthcare decision making, and medical research by offering a variety of physiological data (such as heart rate, EKG, blood sugar levels) of the patient [1]. The advancement of these technologies has created the potential to improve the quality and efficiency in the healthcare industry. However, clinical data is still primarily stored and managed in a fragmented manner, which creates friction in information exchange at the point of care and also hinders large-scale health-data research empowered by technology such as artificial intelligence/machine learning (AI/ML). This paper focuses on the integration between EHRs and health-monitoring IoT devices in a decentralized environment, in the hope of offering a potential solution to this challenge.

As of 2020, almost every patient’s health information has been stored in some EHR system, and an increasing number of patients carry medical IoT devices, especially those with chronic diseases. However, we believe that the true value of medical devices has not been realized, given the minimal application of physiological data in clinical practices. Such a limited application could arise from various reasons, including conflicting incentives from different parties, imperfect regulations, technology barriers, etc. Our paper aims to provide a potential solution in the technical aspect of this issue. The foremost important issue is lack of interoperability between medical devices and clinical data infrastructures, such as the EHR system, where providers mainly store and retrieve patient health information. As a result, medical device data is not accessible by most providers when it could have been helpful to reach a proper clinical decision. Moreover, data security has always been a significant concern. For instance, storing data in a centralized system has been criticized to expose sensitive data to cyber-attacks. According to the Healthcare Data Breach report, millions of patient medical records are compromised every month [2]. Concerns on data security and patient privacy make the transmission of health information even more cumbersome and costly, which further impedes the improvement of healthcare decision making and the advancement of medical research.

To assuage these concerns, we propose an innovative information transfer system combining a blockchain-based technology and an API that enables interoperability between IoT medical devices and EHR systems, titled BlockIoT. First, BlockIoT serves as a method that allows medical devices to quickly and easily interface with the EHRs. It removes a significant amount of overhead (in the form of labor/development costs necessary to modify existing medical device protocols) necessary to transfer data between different parties that use individual proprietary systems to manage
data. The proposed system will allow individual medical device data to be securely transferred to providers without changing any firmware on medical devices or forcing companies to modify existing protocols when creating medical devices. As a result, it simplifies the required infrastructures for data transmission and reduces the number of middlemen involved, which could potentially improve cost efficiency in this process. Another advantage of BlockIoT is the ability to present providers with essential data points by communicating and analyzing medical device data. For instance, providers or insurance companies can use algorithms and visual diagrams to quickly understand medical data and determine whether the patient’s health is within normal limits or requires medical attention. This allows for quicker healthcare interventions, which prevents unnecessary and costly visits (such as to the emergency room) and allows patients’ symptoms to be resolved at a much faster pace than in the current healthcare setting. Notably, the proposed system can be combined with emerging technology such as AI/ML to improve the quality and efficiency of healthcare delivery. For example, it can be connected to an automatic alert system facilitated by AI technology to generate messages to providers about unexpected abnormal symptoms or to remind patients to comply with medication. Studies have shown that simple reminders or alerts in the form of text messages or emails can change patients’ behavior and improve their health as a result [3][4][5]. However, due to constraints in time and resources, such interventions from providers are often not readily available and thus, patients have to undertake most of the responsibility to stay compliant and follow the proper treatment regimen, which is particularly challenging for elderly patients with multiple complicated comorbidities.

We assess the proposed system by conducting structured interviews with healthcare practitioners from various backgrounds. During the interview, we first introduced BlockIoT and then presented a mockup of a sample EHR system integrated with BlockIoT. We also provided a History of Present Illness (HPI) description of a sample patient, who suffers from multiple complications and carries different types of medical devices. Then we asked providers opinions on how to treat the sample patient in the presence and absence of the device data. We also asked for suggestions on what additional information is desired and how the presentation of information can be improved. The majority of respondents viewed medical device data as enabling a more complete and objective picture of patients’ health. Moreover, the system can improve providers’ understanding of patients’ health and facilitate communication with patients. Adopting such a system can streamline the healthcare delivery workflow as long as the system is user-friendly and information can be presented clearly and succinctly. Our clinician evaluators, in general, acknowledge the value of the system, especially if the associated devices are also easy to use for patients.

Related Work

There have been several attempts at bridging blockchain, EHR, and wearable health IoT devices. However, our literature review indicated that the success of these systems had been limited. This section illustrates some of the comparable related works and how BlockIoT transcends the capabilities offered by them.

A system for remotely monitoring patients in a Health Insurance Portability and Accountability Act (HIPAA) compliant manner is introduced in [6][7]. However, the system does not focus on specific methods or protocols a device can use to communicate with the blockchain, forces device manufacturers to change device specifications to conform to the system’s requirements, no method is described that enables medical devices to integrate into the system, or in regards to representing this data to a physician. A data transfer system between a physician and patient through the use of a blockchain system for the transfer of labs and medical charts (rather than medical device data) is described in [8]. However, unlike in our system, this transfer of data is only one-sided and does not allow any analysis of the data present, which subjects the blockchain integration to be simply another form of a database. The integration of IoT devices to mobile applications is discussed in [9]. The framework manages medical devices but is very shallow in terms of its data transfer and storage. Primarily, representing data in a mobile application that is only available to a patient severely limits the potential use of the data itself. Secondly, because the system is centralized rather than decentralized, a significant risk is present in which any breach of that system can result in the release of significant amounts of medical data. Finally, there is no method present at all that can analyze or encrypt incoming data. An EHR system that can connect various IoT devices is introduced in [10]. However, the method it uses to achieve this has severe limitations. Data is primarily stored in a centralized rather than a decentralized system, which results in a significant risk in which any breach of that system can result in the release of significant amounts of medical data. Secondly, while data can be analyzed, the system can be integrated with only specific medical devices and support a
minimal scope of incoming data.

On improving EHR security, a system that enhances the security of current blockchains without the use of any specific keys is described in [11]. However, they do not provide practical methods to input or output data from the system. Instead, it forces a physician to manually input data into the system itself. Using blockchain to secure medical device data and prevent any malware or breaches from occurring is introduced in [12]. However, enforcement of this security comes with significant limitations as well. Primarily, no method is present to communicate medical data to another party, preventing physicians access to patient data. Secondly, similar to other papers above, the system forces manufacturers to create an entirely new device to satisfy the system’s needs, which prevents any commercial device to use the system.

On data sharing beyond the clinical settings, a secure method to transfer data between a researcher, patient, and physician through the use of blockchain is investigated in [13]. However, the paper does have some limitations. Primarily, no method or protocol exists for medical devices to send data in real-time to the system. Instead, the system leaves this data to the medical device company or the patients to do on their own. This process significantly discourages the transfer of medical device data from the patient to the relevant physician, and the data itself is unable to be analyzed in real-time, which prevents any life-threatening alerts from reaching the patient.

Methodology

The BlockIoT system is developed with four main functional goals. (1) Receiving real-time raw data from various commercial but standards-compliant medical devices; (2) converting raw data-points into well-defined and structured information, which are stored in a decentralized system; (3) analyzing raw data-points through smart contracts for potential patient or physician alerts; and (4) releasing this data to various EHR systems to represent medical data in a concise and easy-to-read fashion. These four aspects serve as a basis for the implemented work to increase patient data interoperability between medical devices and EHR systems. We first introduce the system’s architecture and the various parties involved and detail specific operations that highlight interoperability.

System Architecture

The BlockIoT system is constructed as a combination of an API and various smart contracts that connect existing EHR systems to several medical devices (Figure 1). It is primarily characterized as a decentralized system to store encrypted patient medical device data received from the API, which contains endpoints that receive data published by a patient’s medical IoT device. We define a medical IoT device to be an equipment that serves to collect and transmit patient health data from the patient’s location (such as the patient’s home) to a specific destination (such as commercial servers of the medical device company) using IoT. For example, a medical device can be a wearable heart-rate monitor that can transmit real-time heart rate to a specific destination over WiFi.

Figure 1: High-level Overview of the Data Streams Integrated into the BlockIoT System

Before describing the system’s implementation, some definitions are introduced first to establish the role of each component in the system.
**BlockIoT API** The API component is created to serve as a receiving endpoint for all incoming medical device data. Because of the immense number of medical devices found in the market today, the API was created with flexibility in mind. As a result, multiple communication protocols such as HTTP(S), MQ Telemetry Transport (MQTT) [14], and Constrained Application Protocol (CoAP) [15] are implemented in the API to ensure maximum possible coverage of all medical devices present in the market.

**Decentralized Storage** A decentralized network was chosen (rather than a centralized system) to be the most optimal solution to ensure security, immutability, and efficiency when storing the patient data. We implemented the storage for BlockIoT using the InterPlanetary File System (IPFS) along with the InterPlanetary Naming System (IPNS), in which each patient is connected through a peer-id that is generated based on their biometrics (first name, last name, and date of birth). IPFS was the primary choice of the BlockIoT system due to its ease of use and its ability to make data resilient over time. However, because the IPFS hashes change as the content of the file changes, IPNS is used to ensure that the address of patient content is the same regardless of the patient data change.

**System Features** The system is divided into two primary sections, including a medical device uploading data to the decentralized storage system, and an EHR requesting data regarding a certain patient.

**Security** Compared to more popular and widespread centralized systems, a blockchain network architecture is likely to be more secure due to the location of data storage. Because data is stored between trusted peers rather than in a central location, the risk of patient data being leaked in wholesale from a central location is very minimal. Patient data is stored through asymmetric key encryption, in which keys to the data belonging only to two parties, i.e., the physician’s EHR for a specific patient and the BlockIoT system, prevents an unauthorized user from accessing patient information. At the same time, patient data is only available for a specific amount of time before data access expires. This is achieved through smart contracts, which provide an IPNS link to the physician once the EHR system makes a request, and a transaction is created on the blockchain. After a certain period that is denoted on the contract, this link will expire, and another request must be made for extended access.

**Immutability** One of the main concerning aspects of centralized servers is that it is relatively easy to mutate incoming data, which can compromise the stored medical device data. The ledger in the underlying blockchain in the BlockIoT system solves this problem, as the data added to the distributed ledger is permanently stored, and any modification of the given data is discouraged, which ensures data integrity throughout BlockIoT.

**Storage** In medical devices, the amount of data collected about a patient can be generated as fast as once per second. This rate extended to a larger population of 10,000 patients can reach up to millions of different data points per minute, which is enough to overwhelm most, if not all, centralized servers over time. This issue can be alleviated through a blockchain, which is server-less and can distribute the storage capacity necessary for all of these data points throughout its users. Through this system, enormous amounts of data can be stored without significant risk of a crash.

**Template-driven Data Harmonization** Templates are methods that are used to analyze and identify incoming data. Because each medical device sends values with different keys, templates are essential in determining what type of data is transmitted from the device. Secondly, based on the device’s identifiers, one can verify the device based on its output itself. Each type of device will have its own template. For example, a heart rate sensor will have a template that will contain all types of information transmitted by the heart rate monitor (such as beats per minute and SpO2). The upper limit and lower limit values are also present to recognize whether a specific incoming value is within or outside a normal limit, leading to alerting the physician if the patient’s condition is life-threatening. These templates are essential in BlockIoT because not only are they used as a template for data storage, but they can also serve as labeled anonymous data that can serve as training data for AI/ML algorithms for that specific physiology.

While it is possible to send over raw medical device data to an EHR system, the data sent to the EHR system are not useful to the physician as is. It is better to facilitate the physician by providing them with vital statistics or charts. These summarized outputs enabled through smart contracts can quickly allow a physician to review the patient’s health metrics and decide further treatment as necessary. To facilitate this process, based on templates created for each type of data, physician-accessible graphs are generated and are exported to the EHR system. AI/ML algorithms are used to further determine trend lines and pinpoint metrics of interest. These algorithms can be trained to generate greater insight with real-time data, which may be further useful for a physician.
Making BlockIoT FHIR-Proof

As interoperability is a highly desired feature in BlockIoT and because we want to reach as many medical devices as possible, we designed BlockIoT to be compliant with existing standard EHR protocols that are widely used today. By being able to replicate and accommodate to specific standards that are used by a majority of the systems that are used in the healthcare industry, such as HTTP, one can state with a certain level of confidence that the proposed system will be able to function in a real-world scenario. However, we took an additional effort to make the BlockIoT system primarily compliant with the Fast Healthcare Interoperability of Resources (FHIR) Standard [16], a system of requirements and guidelines on EHR system development created by the standards organization HL7. We closely examined the HL7 FHIR documentation [16] and leveraged the concepts related to medical devices and observations to the BlockIoT system.

Current data in the BlockIoT system is stored in the IPFS system in a folder with various JSON files (depending on the number of medical devices that a patient has) containing patient data ordered by a timestamp. In this case, the file itself will serve as a patient resource designed to be interchangeably used between the BlockIoT system and the EHR system. Each resource contains a logical ID assigned upon the creation of the file. The resource is created as a JSON representation with various properties that describe the patient’s biometrics, the template used to identify the data, and the medical device data the patient has. A resource may also be an image that contains an interpretation of the data, such as a graph or specific data points a physician can examine before seeing the patient. The image resource is only created when an HTTP request is created to ensure that data is the most recent and relevant as possible.

Communication with a standardized EHR system is done through a RESTful API, which consists of various verbs used to transmit and receive resources (as defined above) from one system to another. Following this API protocol will ensure that transmittance is reliable and the incoming data is usable by a standard EHR system. The current system can conform to existing API requests properly as the routes present in the current system are identical to the routes described in the FHIR documentation. As a result, because the architecture of the resources and the syntax of the API conforms to the FHIR documentation, one can ensure with some confidence that the BlockIoT system will successfully communicate with an existing FHIR-based EHR system.

Blockchain and Smart Contracts

To implement smart contracts, and store transactions in a decentralized fashion, a blockchain system is implemented. In such an architecture, the nodes are the servers run by major third parties participating in this system, such as an EHR system at a hospital, manufacturer, and researchers who will employ smart contracts to send or receive patient data. Each type of node has a different level or type of access to data. EHR systems can only request data about a specific patient, for example. A smart contract will then be placed that allows physician access to the patient’s data representation (in the form of an IPNS link) for a 24 hour time period. After this time access is complete, the link will become non-existent, and another request would have to be made.

Smart contracts will then be used to analyze patient data and compare data with specific templates. For example, the “adherence” smart contract will be programmed to examine data and check for timestamp discrepancies, and therefore determine whether the patient has missed a dose of medication. Such smart contracts can also be used for more complex data types, such as EKG monitoring, where external or industry-standard algorithms can be used to examine EKG waves, and detect whether a heart arrhythmia is present. Through the use of smart contracts, passive data transmission can lead to more proactive interventions. Based on physician and patient preferences (which would be present in the patient’s configuration file), the smart contract can then send alerts to the relevant party if the algorithm detects an abnormality. For example, a physician can choose to ignore sharp increases in a patient’s blood sugar level if the patient had just had a meal. If this option is selected by the physician, the smart contract would first detect an increase in sugar levels, text the patient if he/she had just had a meal, and the patient’s response to determine whether an alert is necessary to send to the physician. Both physicians and patients can also choose when and how to receive alerts as well.

BlockIoT In Action

The BlockIoT model of data collection was evaluated with synthetic patient health data to test for practicality and usability. The data used for the system simulation was generated through Synthea [17], which is a patient population generator commonly used to produce synthetic data based on distributions learned from real patient data. We tested BlockIoT against 1000 generated patients, which is typical of the number of patients associated with a physi-
cian’s practice. These patient records contained different types of data, such as systolic/diastolic blood pressure, heart rate, body height/weight to represent basic vital signs, and more sophisticated lab results such as hemoglobin levels, leukocyte/erythrocyte counts.

First, the synthetically generated patients were used to determine whether uploading and downloading from IPFS is reliable, and a decentralized system can be used as a method to store medical device data. Out of the 1000 patients simulated, all 1000 patients were successfully securely uploaded to IPFS, and medical data was reliably stored. There was no missing data present, and no packet losses occurred when uploading data. Next, the BlockIoT model was evaluated with multiple types of medical data, as described above. Templates for each type of data were created, and the system was checked to see if any errors with data handling occurred. Out of the 8 different types of data tested (blood pressure, heart rate, blood oxygen, sugar levels, EKG, compliance, spirometry, and cell counts), the system handled all 8 types of data appropriately, in which, the data points that were not within normal limits were recognized and represented adequately in the physician user interface. Secondly, each data point was properly stored by timestamp, and the system also captured trends over time. Finally, the BlockIoT system was evaluated for the ability to receive a significant amount of incoming data at once. Because medical devices tend to send information extremely rapidly (in terms of seconds), the system must handle incoming requests quickly and efficiently to ensure that all data can be uploaded in real-time. 10,000 requests were to the system at a rate of 0.5 seconds for each request. The system was able to process each request within 5-6 seconds and handle all the incoming requests without delay.

**Participatory Design Survey**

Fourteen healthcare providers (thirteen physicians and one nurse practitioner) were invited to review the BlockIoT System in order to understand the need and impact of medical devices in a clinical setting, and determine whether there is potential in patient outcome improvement that can be attributed to integrating a system such as BlockIoT in their clinical practice. While we acknowledge that the sample size is not large enough to make a statistically significant conclusion about BlockIoT’s effectiveness, this evaluation aims to determine whether such a system has the potential to be feasible and useful in a participatory design setting for clinical data collection and usage scenarios. The providers were recruited through professional and personal relations of the researchers. However, a particular focus was put on inviting physicians from different specialties. As a result, the total sample of physicians consisted of a cardiologist, a gastroenterologist, a dermatologist, a geriatrician, an emergency physician, a surgeon, an anesthesiologist, a pulmonologist/allergy/sleep medicine physician, internal medicine specialist, and multiple primary care physicians. During the recruiting process, no prior information about the project was provided to the participants, including the concept, demonstration, or questions regarding BlockIoT. We followed this procedure to ensure authenticity during the interviews.

The recruited providers were given an option to either complete a form, or attend a virtual interview if they had time. The providers were not offered any remuneration for their answers. We conducted interviews through WebEx, and with permission from the providers, we recorded the sessions and later transcribed the discussions for analysis. For the forms, a Google Form (available at [http://bit.ly/blockiot-evaluation](http://bit.ly/blockiot-evaluation)) was used with a recorded demonstration of BlockIoT, descriptions and questions.

During the survey (for both survey types), each provider was shown a presentation describing the BlockIoT system. Afterward, the physician was shown a mockup of a sample EHR system with BlockIoT implemented. The mockup was designed to seem like an EHR system, which the physician would be most likely familiar with and therefore will easily visualize the integration. Each provider was also provided with a HPI of a sample patient. Table 1 summarizes the patient’s health status.

The sample patient described in the HPI was designed to have multiple complications, such as obstructive sleep apnea, asthma, high blood pressure, obesity, and diabetes. This detailed patient profile was compiled to accommodate each specialist who, in this case, will be treating that aspect of the patient (for example, a cardiologist will treat the patient’s blood pressure related issues). Secondly, different diseases tend to be associated with different types of medical devices. For example, a smart blood sugar monitor’s purpose and method of function are different from a smart blood pressure cuff. As a result, by understanding these different devices’ uses by different specialists, one can tailor the data representation through the specialty. Furthermore, the HPI was generated to be very realistic to a typical patient these

providers would see in their clinical practice. While the patient is complicated, each diagnosis is associated with the other potentially co-morbid conditions. For example, increased risk of obesity is associated with high blood pressure, diabetes, asthma, and obstructive sleep apnea, which is further corroborated because typically, patients who have diabetes are more likely to develop cardiovascular disease. As a result, the other four diagnoses were also included in the HPI. Both correlations above were used to create the HPI of the sample patient. The provider was then shown 2-4 graphs representing sample medical device data (such as blood pressure readings, blood sugar levels, and compliance rates). The graphs shown to the provider depended on their specialty. For example, a pulmonologist would be shown a graph with the patient’s albuterol use and medication compliance in the last 30-60 days, and their blood pressure chart (Figure 2).

Figure 2: Synthetic Patient Charts from BlockIoT Shown to Evaluators

During each presentation, the provider was asked what difference was present between what is shown in the HPI and what the medical device data provides based on the information presented in the charts. We asked these questions to determine whether any significant impact is visible between the additional medical device data and whether this additional data can potentially change the provider’s medical decision. Secondly, the provider was also asked if the graph’s representation could be improved (such as changing the time axis or changing the type of graph present). This feedback can be used in future work, where the type, amount of data, or the time at which data arrives can help drive how the medical device information is represented to the provider. Moreover, each provider was asked about their overall review of the system and potential foreseeable drawbacks. At the end of the survey, for providers who were virtually interviewed, implications of the system in insurance claims, malpractice, medical data transfer from providers to providers, and potential impacts on the clinical workflow (in terms of efficiency) were also discussed.

We analyze the response data using a qualitative approach. In general, the providers’ responses were positive. All of the providers found the proposed system useful, with 87% of providers reporting that they would be willing to use the summary views as well as the patient/physician interventions throughout the patient care (the others were more inclined to just use the summary views of the medical device data). When asked whether the data coming from the BlockIoT system can change or influence the way the provider treats a patient, all the providers responded in agreement. Out of the providers asked about the efficiency impact of BlockIoT, all the providers expected the system
to streamline the workflow in the long run. Most of the providers stated that there are different levels of trust in the patient supplied information, and they use a variety of techniques to ascertain the information supplied to them by the patients during the visit. All the providers agreed that having longitudinal physiological data is better for the practice and makes them more efficient in the diagnosis process leading to better patient outcomes. However, at the moment, access to means for obtaining such data is minimal or non-existent. Physician 4 mentioned that they institute a log for patients with chronic illnesses; however, they admitted the quality of the data in these logs is only “about 50%”, which is not sufficient enough to make an accurate health suggestion. BlockIoT would be a trustworthy mechanism in which such data could be collected in a minimally intrusive way for the patients. Physicians 12 and 13 confirmed that having access to long-term blood pressure data for example, could help make them determine if a higher reading at the clinic is due to the “white coat hypertension” phenomena [13], especially if the readings taken at home as available through BlockIoT appear to be lower.

Confirming the main focus of BlockIoT, the need for more data-driven analyses in clinical practices was best summarized by Physician 3.

“The only way we know whether the patient has high blood pressure is whether the patient takes a one-time blood pressure reading a day at home in the morning, and that is only when we really ask to do it. Even then, they will only do it for some of the time, not all the time. Or when they come to the doctor’s office every 2 to 3 months. A blood pressure reading can change every second, which means that we are missing millions of data points right now!”

However, access to this device data is also variable, i.e., no standardized method exists currently. As best stated by Physician 1 when asked about retrieving data from various medical devices:

“It totally depends on the device; blood sugar monitors give you readouts, pacemakers need to be interrogated for data, blood pressure cuffs need to be brought to the office.”

Physician 2 also raised their concerns about the lack of integration of many of the devices patients use.

“For devices like the Apple Watch and Fitbit, there is no official way to get those reports. It’s essentially the patient showing you, like ‘this is what my Apple Watch said’ or ‘this is how much sleep I’ve been getting.’ For FDA-approved devices by Medtronic, Boston Scientific, those types of companies, the office will receive data from the companies, and it’s sort of like an additional provider level. But for other consumer devices, there is no specific support.”

To our question on AI-driven patient-centric notifications endorsed by the provider, all of our evaluators expressed enthusiasm. In particular, physician 2 said;

“It makes the patient-physician interaction more dynamic and more trustworthy, and the patient’s getting more involved with their care, and they’re more likely to be compliant with diet or lifestyle change or medication compliance if they know that they’re doctors following up with them.”

Physician 4 also mentioned that there would be some positive behavior change aspect when the patient knows that their data is being collected.

“It has to be easy for the patient because the patient knows ‘hey, somebody’s watching me. I can’t cheat. I can’t do it.’ This can make a huge difference.”

A specific interest the providers had was to not simply look at the analyses provided through the AI algorithms in their workflows but to also pinpoint certain aspects of the data between different time-frames, to look at anomalies presented in the data analysis closely, and interrogate the data. To this end, physician 2 said;

“We talked about having the ability to zoom in on certain times of day for certain parameters. I think that would be helpful, but it’s all going to come down to how easily I can access this information.”

However, some of the providers touched on the regulatory aspects of such a data-sharing ecosystem. In particular, physician 3 said;

“You have to make sure that when there’s a ton of data, there is always the patient’s approval or consent that is needed so that there is not an automatic transfer from my office to the hospital. You really have to have consent. In some countries, you will find it a bit tedious in terms of getting consent, while in other
health systems, it is going to be easy.”

The consensus on using the data supplied by BlockIoT for insurance claims, in authorizing tests, and in malpractice lawsuits had mixed reactions from the providers. Most of their concerns were centered around the fact that the current medical landscape is extremely complex, and any technological changes will have to be supplemented by regulatory interventions, and those changes will take some time to take effect.

**Conclusion**

Within the last decade, the rise of EHRs and medical devices has revolutionized the healthcare industry by altering how to capture and manage health information. Based on our participatory design survey, however, it appears that the information from an EHR is not nearly enough to result in an optimal clinical decision. For instance, there is no concrete method of determining or verifying how a patient’s health has evolved within a few months before a medical visit, as pointed out by most of our evaluators. Instead, most physicians determine diagnosis or set up treatment plans based on a snapshot of symptomatic information captured during the patient encounter or the patient’s subjective description, which presents a need to access more granular and real-time patient health information. As stated by all our evaluators whose specialty involves the usage of medical devices, data from these devices can be instrumental in determining compliance, detecting problems with patients whose disease has an asymptomatic nature (such as cardiac-related problems), or figuring out the change in patients’ health since the last visit. In traditional EHR systems, the accessibility to patients’ daily health data at a granular level is still extremely limited due to centralized and proprietary medical devices that cannot share patient data with third parties. In our survey, more than half of the evaluated physicians are unable to retrieve medical device data in their current clinical practice. Among those with limited access, they have to either ask patients to physically bring in the data or obtain the data via specific ties with the device companies.

To address these challenges, we propose and implement a universal, secure, decentralized bridge between patient-facing medical devices and physician-facing EHR systems, called **BlockIoT**. It is designed to provide real-time medical device data to physicians, who are usually constrained by their busy schedules, in an easy-to-understand manner so that they can use this data to provide higher-quality and more-efficient care. As per the evaluation, BlockIoT has shown potential in improving quality of care, patient-physician interaction, office visit efficiency, and overall more informed physicians’ decision-making. BlockIoT may also help physicians rule out certain diseases by offering additional data that underlie patients’ health to reduce time and costs that would have been spent on determining the diagnosis. Moreover, BlockIoT may also contribute to other aspects, such as justifying reimbursements or reducing malpractice suits due to its ability to provide objective and concrete patient data. A key advantage of BlockIoT is offering physicians an integrated look into data streams—that capture information from closely monitoring patient daily life and are traditionally unavailable to them—in a relatively easy and reliable way. Data from such an integrated system are more likely to form a complete and accurate health profile of patients, which could help improve the ML algorithm that is currently mostly based on biased, truncated or even distorted data. The data supplied to the EHR systems by BlockIoT contains more specific health information that could come from a variety of patients and can potentially be incorporated into a training algorithm without excessive efforts via the proposed system. The findings may assist physicians in making more viable treatment plans for the underrepresented population and even help reduce health disparity between groups. We believe that the proposed system, combined with the emerging technology like AI/ML, could have more far-reaching impacts. As pointed out by our physician evaluators, closely tracking patients’ health evolvement and offering timely interventions and reminders could be extremely valuable but is currently very challenging given the already-heavy workload. An automatic alert system facilitated by BlockIoT and supported by AI/ML technology could be transformative, let alone the potential feature of constantly-updated parameters thanks to the improving predictability of the training algorithm after incorporating the data from medical device.

The current version of BlockIoT, however, is far from perfect. Based on the providers’ interviews, the user interface and accessibility were the primary focus when asked about the potential drawbacks of the system. The consensus was that the system has the potential to be very useful to them in their clinical practice, as long as the data is easy to use and versatile enough to fit the specialist’s needs. A consent system is also necessary to ensure that patients can consent to what data should be shared with the physician and how long access should be present. After the system undergoes all possible upgrades, the system’s value needs to be further justified using a larger sample with sufficient statistical
power. Also, there remain significant challenges to persuade stakeholders to participate in the system due to varying incentives. While the proposed system is not a panacea for the issues plaguing the healthcare industry, we believe that our system establishes a building block for future research and enables a step forward in addressing all the challenges faced by healthcare providers in their clinical practice, ultimately leading to better patient outcomes.

Abstract:

Pediatric sepsis imposes a significant burden of morbidity and mortality among children. While the speedy application of existing supportive care measures can substantially improve outcomes, further improvements in delivering that care require tools that go beyond recognizing sepsis and towards predicting its development. Machine learning techniques have great potential as predictive tools, but their application to pediatric sepsis has been stymied by several factors, particularly the relative rarity of its occurrence. We propose an alternate approach which focuses on predicting the provision of resuscitative care, rather than sepsis diagnoses or criteria themselves. Using three years of Emergency Department data from a large academic medical center, we developed a boosted tree model that predicts resuscitation within 6 hours of triage, and significantly outperforms existing rule-based sepsis alerts.

Introduction:

Estimates suggest that pediatric sepsis is responsible for approximately 75,000 hospitalizations and 10,000 deaths annually in the United States(1). While no specific treatment for sepsis exists, rapid volume repletion with intravenous fluids and the prompt administration of broad-spectrum antibiotics have been shown to decrease morbidity and mortality(2–5).

Current consensus guidelines emphasize that treatment should begin within one hour, and such rapid intervention requires rapid recognition, leading to a great deal of interest in systems to improve the accuracy, reliability and speed of sepsis diagnoses(6–13). The current guidelines suggest the use of a formalized screening tool to identify patients who meet sepsis criteria, as well as the use of a “bundle” of interventions to be performed should a positive screen occur(14). While these systems can be deployed as manual tools, they are well suited to integration into the electronic health record, and many institutions have done just this. But though useful and effective, this “screening” based approach has several intrinsic limitations.

The first is that current definitions of “sepsis” in pediatrics are extremely broad, particularly because pediatric definitions include the distinction between sepsis and “severe sepsis”, which has been abandoned in the adult criteria. In children, sepsis is defined as the presence of the “systemic inflammatory response syndrome” (“SIRS”) in the setting of known or suspected infection. SIRS itself is defined as a constellation of age adjusted vital sign abnormalities that must include temperature abnormalities or an abnormal white blood count. A patient who meets these sepsis criteria and who has evidence of organ dysfunction is said to have severe sepsis, and one who has sepsis and hypotension despite adequate fluid resuscitation is considered to have septic shock(15).

These definitions complicate attempts to build clinically relevant screening and prediction tools. Because SIRS vital sign criteria are generously defined (outside the 10th percentile for age), the category of “sepsis” can capture large numbers of children with mild, self-limited infections who are in little danger of progression towards organ dysfunction or death. Indeed, in one study SIRS criteria were found to be present in 15% of all emergency department visits, and over 80 percent of those children were discharged home without readmission(16).

This means that tools that identify “sepsis” often lack adequate specificity, with values around 85%. This can generate dozens of false positives a day in a busy emergency room, forcing hospitals systems to either de-tune their alerts to reduce false alarms or impose a significant burden on their clinicians with the concomitant risk of alarm fatigue. Furthermore, screening approaches fail to account for the fact that sepsis is a rapidly evolving process, and only approximately 40% of patients who develop severe sepsis meet criteria at presentation(6). Tools to identify
existing sepsis are undeniably helpful, but methods for predicting which patients will go on to develop sepsis prior to actually doing so have the potential to interrupt a dangerous and self-reinforcing process before injury is done.

Several groups have already published work using machine learning techniques to predict the occurrence of severe sepsis in selected populations, with good results(16,17). But while this work is important and likely to be clinically useful, it is not without drawbacks, because models that predict which patients will develop severe sepsis after presentation to an academic medical center effectively predict those patients who do so despite treatment, and therefore such models will not identify patients for whom resuscitative therapy interrupts physiological decompensation. We propose an alternative approach in which machine learning is used to predict which patients receive resuscitative treatment aimed at preventing the development of severe sepsis rather than its ultimate occurrence.

Altering the target of our predictive efforts from severe sepsis to resuscitation has several significant advantages. As above, it allows us to capture a group of patients who have the most to gain from more timely intervention- those for whom resuscitation can interrupt progression to severe sepsis. More prosaically, because initial resuscitation is a much more common event than the development of multi-organ dysfunction due to sepsis, it greatly increases the number of events on which we can train our algorithms.

This is not a trivial advantage. Because pediatric severe sepsis is rare, assembling a large enough cohort to derive meaningful predictive models requires multiple years of data from a large institution or a combination of data from multiple sources, the latter of which can create significant data-integrity problems. Furthermore, even if a predictive tool is developed using an enormous data set, it must be validated by potential users on “native” data before it can be responsibly employed, and then continuously surveilled lest its predictions “drift” off course. For any but the largest institutions, pediatric severe sepsis is simply too rare an event for this to be possible, whereas resuscitation occurs sufficiently frequently that validation and surveillance become feasible.

Methods:

We assembled data on 26,564 pediatric emergency medicine visits at New York University Langone Medical Center between January 1, 2017 and December 31, 2019. Data were extracted from the EHR data store (EPIC, Caboodle).

These data included demographics, triage vitals, triage nurse comments, chief complaint information, as well as orders placed and medications administered within 6 hours of arrival. Additionally, entries for the patient problem list were included if they were added prior to the date of arrival to prevent contamination. No laboratory testing data was included.

Visits were excluded from analysis if they were missing critical information including a weight associated with that visit (not necessarily recorded at triage), a date of birth, or any vital sign measurement at triage (HR, Temp, RR, SBP, DBP, O2 sat). A total of 2,760 visits (10%) were excluded, the vast majority (2,490) because of absent values for both systolic and diastolic blood pressures, leaving a final data set of 23,804 visits (see Table 1).

Triage vital signs for use in the predictive models were normalized for age using median values for age, and no subsequent vital signs after triage were included in the data set. Vital signs for SIRS criteria were not transformed, but rather compared to age specific cut-offs specified by the SIRS criteria (See supplementary Table 1).

Membership in the resuscitation group was determined by the presence of order and medication administration data indicating that the child received:

1. >19 cc/kg of normal saline; AND
2. Broad spectrum parenteral antibiotics; AND
3. A blood culture,

all within 6 hours of admission to the Emergency Department.

The value of 19 cc/kg was chosen rather than 20 cc/kg because a large number of patients who were ordered to receive boluses of 20cc/kg were found to have received between 19-20cc/kg because of rounding related to common fluid bag sizes and pharmacy dispensation.

Text data, including the chief complaints, triage notes, and triage comments was tokenized and sorted based on word frequency. Words that occurred more than five times throughout the data set were reviewed, and any word related to known risk factors, including immunosuppression, malignancy, chronic disease, and the presence of indwelling lines, tracheostomies, and g/j- tubes, severe illness, or fever prior to presentation were added to a keyword list (see supplementary Table 2). The presence of any keywords meeting these criteria was recorded as a positive result for that category and each was encoded as a single separate feature (i.e. Problem list +, Chief complaint -, etc)

Models were fit on a training set composed of a random sample of 80 percent of the available data (n = 19,044) stratified to included 80 percent of the cases which met our resuscitation criteria, and then tuned using 5 fold cross validation with this data set. Final model performance was evaluated on a similarly stratified test set composed of the remaining 20 percent of the data (n= 4760), and this process was repeated 25 times to estimate confidence intervals. Several methods were employed, including standard and regularized regression (glm and elasticnet), random forests (randomForest, Rborist), gradient boosted trees (GBM and Xgboost), and generalized additive models (mgcv). All models were evaluated with the pROC and PRROC packages in R.

Results

As a baseline, we evaluated the performance of the existing SIRS criteria-based alert at triage to predict which patients would receive resuscitation. This alert performs relatively well with regard to specificity (0.909), but fired on fewer than half of the patients who received resuscitation within the next 6 hours (sensitivity 0.465). (See table 2).

We next built basic models using only the same data used by the SIRS criteria, with the addition of diastolic blood pressure and oxygen saturation levels. While this sort of sparse data is not ideal for machine learning applications, the value of using minimal data in model construction is that it allows for easy implementation in a real-world context as well as provides a “fair” comparison to the SIRS criteria, as little additional information is added. Performance improved slightly, with increases in the AUPRC to just over 0.15, with sensitivities set to match those of the SIRS criteria. (figure 1, table 3).

</tr>
</tbody>
</table>

We next attempted to increase performance by adding additional data to our training set, in order to capture several known risk factors for severe sepsis using keyword searches of the patient’s chief complaint, triage comments, and problem list (prior to the day of presentation). These additional features improved model performance substantially, with AUPRCs rising from 0.15 to just under 0.20. The best performing model (Xgboost), was able to achieve a specificity of 94.3% and a positive predictive value of 17.6% while matching the sensitivity of the SIRS criteria (figure 2, table 4).

Feature importance in the Xgboost model (figure 3) was analyzed by relative importance, showing very strong contributions from temperature, and significant contributions from chief complaint and problem list keywords, as well as most of other vital signs, although blood pressures, particularly diastolic blood pressures, had very little impact. Similar results were seen with other tree based techniques, and with regression based approaches as well.

Figure 1: Representative AUROC and AUPROC for models based on vital signs only
As an exploration of whether models built to predict resuscitation would perform well at predicting the development of severe sepsis, we assembled a list of 17 patients who were retrospectively judged (after manual chart review of administrative data) to have met criteria for severe sepsis within 6 hours of presentation to the emergency room. Of these patients, 11 met SIRS criteria at triage, and 15 were identified by our keyword trained models (a net increase of 4 patients).

Figure 3: Relative Variable importance for XGB Keyword Model
Discussion

Given the burden of morbidity and mortality caused by pediatric sepsis and the importance of speed in its treatment, there is a strong need for effective predictive risk models to allow clinicians to identify patients at high risk in order to intervene as quickly as possible. However, development of these models has been hampered by slippery definitions, the intrinsic rarity of severe sepsis, and the possible masking of cases by successful treatment. To mitigate these issues, we built models that attempt to predict resuscitative treatment rather than severe sepsis itself, and were able to significantly outperform existing alert systems, based on the SIRS criteria.

There are several weaknesses in this study, the most glaring of which is that while our ultimate goal is to predict those patients who should receive resuscitation in order to provide that information to clinicians, what we have done in this paper is predict those who will receive resuscitation. While logically flawed, we believe that this decision is defensible on several grounds. Most importantly, authoritatively answering who should receive treatment requires a randomized controlled trial of resuscitation criteria, which would be both resource intensive and ethically knotty. Additionally, while all physicians are capable of error, we believe that the pooled judgement of dozens of pediatric emergency physicians over three years provides a very close approximation of the standard of care, and therefore who should receive resuscitation.

That said, it is also true that the standard of care is necessarily imperfect, and this fact exposes another deep limitation in this approach. Because we base our predictions on clinical decisions that are already being made, we are unable to discover new risk factors or suggest a different approach where the current standard of care is systematically wrong. If we had performed this experiment in the middle ages, our models would confidently suggest bloodletting for a tertian ague. While we believe that using treatment decisions as targets can be very useful in developing tools for clinical decision support, it cannot replace more conventional definitions when trying to understand the phenomenology of sepsis itself.

The next area of difficulty is the definition of “resuscitation”. In developing our definition, we attempted to capture the first steps of resuscitative care based on national and institutional standards, but this definition remains arbitrary. This can clearly be seen from our decision to reduce our fluid requirement from 20cc/kg to 19cc/kg when inspection of the data revealed a large number of children in the 19-20cc/kg range due to rounding and commonly available fluid bag sizes. While this decision is certainly defensible, a similar argument could be made for a cutoff of 18 or 17.5 cc/kg, but ultimately any computational definition of what qualifies as resuscitation is a balance between a “strict” definition that misses instances of resuscitation, and a very “loose” one that introduces noise by capturing patients who received these treatments for reasons other than a risk of severe sepsis.

This latter effect is clearly visible in our data. During subjective validation of our results, we found numerous examples of younger children with known, but non-life-threatening infections such as cellulitis or oro-facial infections who were judged to have been “resuscitated” by virtue of receiving maintenance or “maintenance and a half” fluids throughout the first 6 hours of their ER stay.

Another notable limitation of this study is that we have only examined data from a single point in time. The decision to focus on the moment of triage is based on the desire to develop a system that provides the earliest warning possible based on the least amount of data, but it is clear that in doing so we are excluding highly valuable information, particularly that from laboratory testing and longitudinal changes in vital signs. It is not uncommon for children to present with very early sepsis, and for resuscitation to begin after the child has “declared” himself while in the emergency room. This is simply the nature of the problem, and other authors have reported only approximately 40% of patients who go on to develop severe sepsis meet criteria at presentation. Indeed, review of model errors showed that patients who are afebrile at presentation are almost certain to be missed by both machine learning and criteria-based models. Models like ours, which are designed to operate at triage, must be supplemented by additional tools that can perform continued surveillance while taking advantages of the richer data streams that accumulate as a patient’s stay progresses.
Conclusion

Despite these limitations, we believe that there are two useful conclusions to be drawn from this data. The first is not strictly related to our project of developing machine learning models for resuscitation prediction, but relevant nonetheless: the SIRS criteria, when applied at triage, do not perform particularly well at identifying children who will receive resuscitation in the near term. Indeed, a SIRS based alert system fires on fewer than half of the total patients who go on to receive resuscitation within 6 hours, while generating more than 7.5 false positives for each patient who does receive treatment. These results are generally in line with other studies that have used formal definitions of sepsis (ICD codes and manual chart review), and further underscore the contention that these SIRS criteria alone are not well suited to implementation as part of clinical decision support, which requires that the information relayed to providers be of high enough quality to meaningfully alter their treatment decisions.

The second conclusion is that training models to predict resuscitation, rather than severe sepsis, can provide a way to generate actionable decision support. While we believe that use of criteria confirmed severe sepsis as a target is flawed because it fails to account for “interrupted” cases of sepsis, the most fundamental advantage of focusing on resuscitation is simply that many more resuscitation events occur than instances of severe sepsis. By increasing the number of events, this “looser” target ameliorates one of the core problems in applying machine learning to pediatric sepsis, particularly the difficulty of fitting and validating models for very rare events.

Another important advantage of focusing on resuscitation as a predictive target is that aligns very closely with the real-world issues facing clinicians. In an emergency setting, the most immediate question is whether to begin initial resuscitation and workup, and by using this as a target, we generate a prediction that is easy to operationalize in a by linking the prediction of these models to the EHR in order to provide decision support.

But when considering the application of these models to decision support, several additional factors must be considered. While we achieved the best performance by using an ensemble of boosted trees (Xgboost), these models are relatively difficult to integrate into EHR systems, and have the further downside of limited explainability. This can both reduce clinicians’ trust in the model’s output and make it more difficult for them to identify situations where the model is inapplicable. Use of alternative model types, such as the use of explainable boosted trees and generalized additive models can provide much more comprehensible predictions, with only moderate loss of performance. As an example, a generalized additive model fit to our data provided a positive predictive value of 18% compared to Xgboost’s 20%, but can provide straightforward explanation of how each variable contributes to an individual prediction.

This is particularly important when decision support is being offered in a critical situation, as would be the case when a clinician is considering whether or not to start resuscitation out of a concern for sepsis. Very few practitioners or institutions are likely to be comfortable trusting the predictions of a mysterious algorithm when the stakes are so high, and model selection should be driven by a balance of ease of implementation, interpretability, and performance.

Regardless of the model chosen, great caution should be taken when considering the use of predictive algorithms to provide clinical decision support. While we believe that we used appropriate methods to limit the risk of overfitting, and report only test set results, it is well known that machine learning methods generally perform more poorly in the real world than on the data from which they were built, and any potential application will require thorough prospective validation before use.

Assessing the Readability of App Descriptions and Investigating its Role in the Choice of mHealth Apps: Retrospective and Prospective Analyses

Wu-Chen Su, MS1, Khyati Y. Mehta, MS1, Kirandeep Gill, MS1, Peng Yeh, MS3, Ming-Yuan Chih, PhD4, Danny T.Y. Wu, PhD, MS12
1Department of Biomedical Informatics, University of Cincinnati; 2Department of Pediatrics, University of Cincinnati, Cincinnati, OH; 3Department of Statistics, University of Kentucky; 4College of Health Sciences, University of Kentucky, Lexington, KY

Abstract

People with low health literacy are more likely to use mobile apps for health information. The choice of mHealth apps can affect health behaviors and outcomes. However, app descriptions may not be very readable to the target users, which can negatively impact app adoption and utilization. In this study, we assessed the readability of mHealth app descriptions and explored the relationship between description readability and other app metadata, as well as description writing styles. The results showed that app descriptions were at eleventh- to fifteenth-grade level, with only 6% of them meeting the readability recommendation (third- to seventh-grade level). The description readability played a vital role in predicting app installs when an app had no reviews. The content analysis showed copy-paste behaviors and identified two potential causes for low readability. More work is needed to improve the readability of app descriptions and optimize mHealth app adoption and utilization.

Introduction

Health literacy is a critical factor affecting health behaviors and decisions and further impact health outcomes1. The readability level of patient education materials (PEMs), however, may not match the health literacy of the general public2. Additionally, studies have reported that 35% of adults in the United States (US) had basic or below basic health literacy3 and 47% of European Union adult residents had limited health literacy4. To meet the needs of average Americans who read at the eighth-grade level5, the American Medical Association (AMA) and the National Library of Medicine at the National Institutes of Health (NIH/NLM) have suggested that PEMs be composed on a third to eighth-grade level, or even fifth to sixth grade level6,7. PEMs failing to meet this required reading level (RRL) may not effectively delivery health information to their readers.

With the advances of information technology, PEMs have been published online and widely accessed by lay persons. Overall, 63% of US users and 71% of European users search health information on the Internet for a variety of purposes8-10. People with low self-reported health literacy are more likely to use mobile apps and to get health information from social networking sites11. However, this population may have limited ability to read app descriptions and understand app purposes, which can negatively impact their app choices. Meanwhile, the large amount of healthcare mobile apps (“mHealth apps” hereafter) available on the markets imposes challenges to the choice of suitable apps. These mHealth apps may target multiple user groups, including students, patients, healthcare professionals, and policy-makers12,13, which adds to the challenge of app choices. Recent studies have explored the factors behind app choices and found that users from the US are more likely to download medical apps, and that price, app features, descriptions, reviews, and rating stars were the most important factors affecting app choices14,15. These factors can also be confounded with each other. For example, paid apps (price) are expected to provide better quality than free apps in most regards, and thus a less readable description may diminish the perceived value of paid apps16. While many studies have enhanced the understanding of these decision factors and their relationships, no study so far focuses on improving the readability of app descriptions to help app developers and vendors design a better app and improve app utilization.

In this study, we aimed to assess the readability of app descriptions and explore the role of readability in app choices. Readability assessment has been conducted on online health information17,18 as well as other types of health information such as electronic health records. For example, a recent retrospective study revealed that free-text directions on electronic prescriptions (information about medications) can be less readable to the patients19. This study found that 51.4% of randomly sampled directions from 966 patients have at least one quality issue, and that the pharmacy staff had to transcribe these directions to make them more readable. Similar to the issue of understanding the directions of medication, many mHealth apps may confuse their potential users if the readability of app descriptions is low.
Here we had three research questions. Firstly, what were the RRL of app descriptions and their relationships with other app metadata in the major app markets, namely the Apple App Store and Google Play Store? Also, did the app readability meet the recommended readability guideline by AMA and NIH/NLM? We hypothesized that the app readability would not meet the recommended readability level similar to many online health information. Secondly, did the app readability play any role in app choices? The literature showed multiple factors, such as number of reviews and ratings, can play a significant role in app choices. We hypothesized that users were more likely to download and/or install an app if the RRL of app description is low (i.e., a lower readability score can predict a higher number of app installs). Finally, what would be the writing styles and mechanics contributing to the higher RRL of app descriptions? What were possible reasons for app developers to write a less readable description? Had any app developers taken any actions to improve the description readability? By answering these research questions, we aimed to bridge the knowledge gap, help increase the readability of app descriptions, and further assist the lay public to choose proper mHealth apps to improve their health.

Methods

Data Collection

In order to conduct large-scale app analyses, a request was sent to the authors who created a mHealth app repository\(^1\). This mHealth app repository contained rich metadata of ‘Medical’ (ME) and ‘Health and Fitness’ (HF) apps on Apple App Store and Google Play Store, leading to four subsets of data based on the two app categories and the two vendor markets. Table 1 shows the metadata collected in each of the markets. This repository was released in four time periods, namely, the second and fourth quarters in 2015 and 2016 (Q2/2015, Q4/2015, Q2/2016 and Q4/2016). In the present study, only apps with English descriptions and published on the US market were selected. In order to identify apps with English-only descriptions in the repository, a Python library called “langdetect” was used\(^2\). The metadata of the selected mHealth apps were processed and stored in our MySQL database.

<table>

</tr>
</tbody>
</table>

Language Surface Metrics

The app description was characterized using surface metrics including average document length (ADL) and vocabulary coverage (VC) as listed in Table 2. A general English dictionary, GNU Aspell\(^3\), was used to compute the VC of app descriptions and has been used in previous studies\(^4,5\).

Readability Measures

Two readability measures were utilized to assess the descriptions of healthcare apps, including Flesch-Kincaid Grade Level (FKGL)\(^6\) and Gunning-Fog Index (GFI)\(^7\), which were chosen in the present study due to their simple calculation and easy interpretation of the scores. These readability measures are considered “classic” measures due to their general design. They have been widely used since the 1970s and recently been used to assess online PEMs. Microsoft Word has implemented FKGL to allow users to assess and report the readability level of a document\(^8\). To simplify the interpretation of RRL, an average readability score (ARS) of FKGL and GFI was used since both measures are strongly correlated\(^2,9\). Table 2 lists the definition of the readability measures.
over time. The or just copy was investigated "copy and paste" behaviors using a python library called 'FuzzyWuzzy'.

SUMMARIZED:

Lastly, a content analysis was conducted to understand the description writing styles. Of note, analyzing the concepts of the app descriptions was out of the scope of the present study. The first step in this analysis was to summarize the number of apps that each developer created in each market, assuming that a larger portion of apps were developed by a small group of app developers who created multiple apps. The second step followed the first and investigated “copy and paste” behaviors using a python library called ‘FuzzyWuzzy’. A percentage was calculated by averaging the pairwise text similarity of the app descriptions of each app developer. The rationale was that copy-paste behaviors can exist if a developer creates multiple apps and uses a template to write the descriptions or just reuse existing descriptions. In this case, the readability of app descriptions would not change dramatically over time. The last step of the content analysis was to randomly select 50 apps that had a description with readability

Data Analysis

The data analysis included three components; each corresponding one of the three research questions. In the first analysis, a retrospective analysis was conducted to describe the mHealth apps statistically and compare the RRL among the groups using the surface metrics and the readability measures listed in Table 2. Specifically, the distribution of mHealth app groups by category, vendor market, and over four time periods were summarized. The ADL-SENT, ADL-LEX, VC were applied to characterize the app descriptions. Non-parametric (Mann-Whitney U) tests were used with the significance level of 0.05 to examine if there was any significant difference among the group medians.

Specifically, a total of 240 free Google Play apps listed in the mHealth app repository were crawled for three months (mid-April to mid-July of 2019) using a Python library called ‘play-scraper’. The actual number of apps included in this analysis was determined by the alive apps, the capacity of the Python library, and the study period. The included apps, regardless of their categories (i.e., ME vs HF), were further separated into two groups based on their number of reviews. The apps without any review were put into one group while the apps with at least one review were put into the other group. Linear regression in the R statistical package was used to model the data in each group, with the number of installs as the dependent variable and key metadata as the independent variable (predictors). The selection of metadata (independent variables) were based on the literature, including but not limited to: number of reviews, number of review rating, number of screenshots, and readability scores. The coefficient of determination (R-squared value) of each mode was reported to show the proportion of variance in the dependent variable explained by the independent variables.

Finally, a content analysis was conducted to understand the description writing styles. Of note, analyzing the concepts of the app descriptions was out of the scope of the present study. The first step in this analysis was to summarize the number of apps that each developer created in each market, assuming that a larger portion of apps were developed by a small group of app developers who created multiple apps. The second step followed the first and investigated “copy and paste” behaviors using a python library called ‘FuzzyWuzzy’. A percentage was calculated by averaging the pairwise text similarity of the app descriptions of each app developer. The rationale was that copy-paste behaviors can exist if a developer creates multiple apps and uses a template to write the descriptions or just reuse existing descriptions. In this case, the readability of app descriptions would not change dramatically over time. The last step of the content analysis was to randomly select 50 apps that had a description with readability

at the eighth-grade level and above in each of the market, totaling 100 apps. These 100 app descriptions were manually reviewed by the research team to form suggestions.

Results

Descriptive Statistics and Group Comparisons

Figure 1 shows the numbers of mHealth apps based on their attributes in vendor markets (Apple App Store and Google Play Store), category (ME and HF), and published time period (Q2/15, Q4/15, Q2/16, and Q4/16). Each group for comparison was denoted using the abbreviation of the attributes. For example, Health and Fitness apps on the Apple App Store were denoted as “A_HF”. Similarly, Medical apps on Google Play Store were denoted as “G_ME”. Here bar charts instead of line charts were used to show the comparisons because of our focus on vendor market and app category.

Overall, Apple App Store has more apps than Google Play Store. The average quarterly increase rate of the numbers of apps was more than 10% between 2015 and 2016 for apps in the Apple App store. For Google Play store, there was a similar tendency, although the average increase rate is more than 45%. In both markets, HF apps contributed more to the increase than ME apps; G_HF apps outgrew A_ME apps in Q4 of 2016.

![Figure 1. Distribution of the selected mHealth Apps.](image)

Table 3 shows the summary of surface metrics. Apps on the Google Play Store had more sentences and lexicons in their descriptions than those on the Apple App Store. However, there is no statistical difference of the average document length (ADL-LEX and ADL-SENT) among the app categories between the markets. The app descriptions were around 200 words in 10 sentences. The VC is high (>90%) in both markets, meaning the app descriptions were written in common vocabularies most of time rather than rare terms.

*LEX: average number of lexicons per document. SENT: average number of sentences per document.

bstd: standard deviation.
Figure 2 shows that the ARS for these four groups of apps was between eleventh- and fifteenth-grade level. They were far beyond the recommended readability levels from AMA and NIH/NLM. The RRLs of app descriptions on the Apple App Store are statistically lower than these on the Google Play Store combining the categories and the time periods (Mann-Whitney U test, p < .01). Further, the descriptions of ME apps had higher RRL than HF apps in both markets (Mann-Whitney U test, p < .01). Additionally, only around 6% of apps on average on both markets met the readability recommendation, where more HF apps met the readability recommendation than ME apps (Figure 3).

![Figure 2. Average readability scores (ARS) for different groups and time periods.](image1)

![Figure 3. Percentage of Apps meeting recommended readability guideline (third- to seventh-grade level).](image2)

Next, the relationships between the RRL and the two metadata (i.e., price and content rating) were examined to understand the potential impact of description readability on app users. The analysis indicated that the paid apps did not have a lower RRL than the free apps. Meanwhile, suitable content may not always be readable to the targeted app users, which may have a negative impact on app choices and utilization. Specifically, apps with ‘4+’ content rating on the Apple App Store and ‘Everyone’ content rating in the Google Play Store were selected for analysis. As shown in Table 4, these apps categorized for any age group required their users with at least eleventh-grade level literacy to read the descriptions.

* Medical apps on the Apple App Store with ‘4+’ content rating in the second quarter of 2015 had a mean readability score (ARS) of 14.06 with a standard deviation of 6.14.

### Model Readability and App Installs on Google Play Store

When we tracked apps prospectively, the total number of apps dropped from 240 (collected in the mHealth app repository) in mid-April to 218 (alive in the app stores when crawling) in mid-July. The modeling results (Table 5) show that the free Google Play apps with no review had three significant independent variables (p < .01) to predict the number of installs. These significant independent variables (predictors) include the number of user ratings (β = 60.08), the number of screenshots (β = -6.93), and the average readability score (ARS, β = -4.62), with an intercept of 140.64. However, the effect size of this model was weak (R-squared=0.203). On the other hand, the free Google play apps with at least one review had six predictors significant (p < .01), including the number of user ratings (β =
39.52), the average user rating ($\beta = -1308.85$), the number of screenshots ($\beta = -142.35$), the average rating of top 4 most helpful reviews showing on the landing page ($\beta = 1517.23$), the average rating of top 10 most useful reviews ($\beta = -9544.52$), and the average rating of top 10 most recent reviews ($\beta = 8511.05$, with an intercept of 10114.91. The effect size of this model was moderate (R-squared=0.5332). The number of user ratings and screenshots were significant in both groups with and without a review, which speaks to the universal importance of these variables. When there was no review at all, the average readability score of the app descriptions seemed to play a significant role in predicting the number of installs of an app. The negative coefficient supported our hypothesis: the lower a RRL (ARS) is, the more the number of app installs would be. On the other hand, when there was at least one review, the predictors were dominated by the review ratings.

**Content Analysis**

Figure 4 shows the numbers of active app developers in each group over the four time periods. There were more app developers in the Apple market than in the Google market. Similar to the trend of app increase rate shown in Figure 1, the app developers grew steady in the Apple market while the developers grew two to three times faster in the Google market. In both markets, an app developer created two apps on average. Moreover, more than half of the apps were created by a small group of developers who had two or more apps. For example, for the Health and Fitness apps on the Apple App Store, 53% of the apps were created by 11% of the app developers with two or more apps, while 47% of the apps were created by 89% of the app developers with only one app.

**Figure 4. Distribution of active app developers**
The content analysis continued to investigate potential copy and paste behaviors since many apps were created by a small group of developers. The copy-paste behaviors were confirmed by the high (more than 50%) text similarity of the app descriptions for developers who created at least two apps in both markets. In addition, the analysis of app descriptions changes from time to time indicated that ME apps had a large variance of changes in both markets. Furthermore, only 13.86% of apps had a description change that led to a lower RRL. In other words, most description changes resulted in the same or even a higher RRL.

After reviewing the selected 100 apps which had a readability level of eighth grade or above (higher than the recommended level), two common factors contributing to the low readability of app descriptions were identified. 1) Lack of Writing Standard. Unlike online health education materials, there is no standard way to write app descriptions on either market. Therefore, the writing styles had high variations and app descriptions may contain repetitive content and unnecessary information. For example, an app description may contain a ‘To-Do list’ (Table 6 left, App 1) with different subjects or the change history of the app. In these cases, many difficult words (words with many syllables) were included, thus increasing the complexity of reading. App descriptions can be revised in a more succinct and organized way to improve the readability, which may favor the readability measure in improving the sentence length and the syllable count. 2) Search Optimization. Similar to many existing web search engines, the app stores have their own mechanism to retrieve relevant apps for users given a query. The search mechanism may consider app title, description, user ratings, and other metadata, and help users uncover the apps they need. Therefore, there are some App Store Optimization approaches\textsuperscript{32} to boost the search results in the app stores. Obviously, some app developers would employ these strategies and incorporated many popular keywords (Table 6 right, App 2) in the descriptions, and expected that these approaches will bring more awareness and traffic to their apps. However, these approaches may also make the app descriptions less readable, or negatively impact the readability of app descriptions.

*The app descriptions were extracted from the mHealth app repository, not the most current information. Both apps were on the Google Play Store.

Discussion

In this study, we characterized the mHealth apps in both Apple App Store and Google Play Store and summarized the readability of app descriptions. Although there were more apps on Apple App Stores, the Google Play Store was fast growing, especially in the Health and Fitness category. The overall RRL of app descriptions was between eleventh- and fifteenth-grade level, which was far beyond the recommended third- to seventh-grade level. This
finding was consistent with a recent study indicating that the privacy policies of mHealth apps were not very readable (sixteenth-grade level)\(^3\). Moreover, only around 6\% apps that meet the recommended grade level highlights the need for improvement.

We also explored price and content rating and their relationships with description readability. Interestingly, paid apps did not provide better readability than free apps, and the content ratings of apps did not always match the corresponding grade levels. In other words, apps with suitable content may not be as readable to the target users as they are supposed to be and unfortunately become unsuitable. There could be other predictors. For example, expert involvement may increase the app installs\(^34\). Another key factor in the choice of apps may be the ability of a mHealth app to manage patient-generated health data given the current advances and wide adoption of smart watches and wearable devices. Developers and vendors should consider these factors carefully in app development and advertisement.

The content analysis of the less readable apps revealed that a small group of app developers created two or more apps and contributed to a significant portion of the apps. These app developers may copy and paste their app descriptions for efficiency and they have no incentive to improve the readability of app descriptions over time. The high RRL of app descriptions may be contributed by the lack of writing standard and the desire for search optimization, which is a similar pattern identified in a previous study analyzing cardiological apps in the Apple App Store in German\(^35\). More research is needed to demonstrate the best practice of writing app descriptions, balancing between readability, retrievability, and efficiency.

This study had several strengths. Based on our knowledge, this is the first study conducting both retrospective and prospective analyses with a focus on the readability of mHealth app descriptions in both Apple and Google market. Moreover, this study adopted multiple methods. Not only did it conduct statistical summary and group comparisons, but also it developed a model to predict user behaviors as well as reviewed app descriptions to understand potential causes for low readability. This study also had a few limitations. First, we only analyzed ‘Health and Fitness’ and ‘Medical’ categories based on the data obtained from the previous study\(^9\), acknowledging that there could be other related (or new) categories that we missed. Second, different app markets have different developer groups, description writing guidelines, and management policies, which affect our analysis results. Moreover, since we only focused on Apple Apple Store and Google Play Store, and the results may not be generalizable to other app markets (e.g. Amazon Kindle Store). Third, the study did not consider that fact that users install apps but delete them afterwards due to the lack of usefulness. Also, the study did not conduct a thorough content analysis to understand how the readability of app descriptions may impact the end users. Next, the modeling of app installs and their metadata only showed weak to moderate effect size and can be improved. In addition, the classic readability measures used in the present study have known limitations. For example, a word with multiple syllables may not be difficult and some short words can be very difficult to read and understand. Last but not least, the readability of app descriptions was not validated by app users. Future research can conduct user studies to validate the readability scores as well as understand user’s perspectives on less readable app descriptions.

**Conclusion**

We assessed the readability of mHealth app descriptions and demonstrated its potential role in mHealth app choices. This study serves as the first attempt to address this issue and enabled future studies to develop solutions to improve the readability of app description and further help lay persons select suitable mHealth apps for their health needs.

**Acknowledgements**

We thank Dr. Welong Xu and Dr. Yin Liu for their willingness to share the mHealth app repository. We also thank Mr. Karthikeyan Meganathan at the University of Cincinnati College of Medicine for his assistance on the statistical analysis and Ms. Anunita Nattam for her efforts in proofreading the manuscript.

ABSTRACT

Predictors from the structured data in the electronic health record (EHR) have previously been used for case-identification in substance misuse. We aim to examine the added benefit from census-tract data, a proxy for socioeconomic status, to improve identification. A cohort of 186,611 hospitalizations was derived between 2007 and 2017. Reference labels included alcohol misuse only, opioid misuse only, and both alcohol and opioid misuse. Baseline models were created using 24 EHR variables, and enhanced models were created with the addition of 48 census-tract variables from the United States American Community Survey. The absolute net reclassification index (NRI) was applied to measure the benefit in adding census-tract variables to baseline models. The baseline models already had good calibration and discrimination. Adding census-tract variables provided negligible improvement to sensitivity and specificity and NRI was less than 1\% across substance groups. Our results show the census-tract added minimal value to prediction models.

INTRODUCTION

Substance misuse is a common cause of hospitalization and death in the United States. The most common type of primary and secondary substance-related diagnosis among inpatient hospitalizations is alcohol-related disorders, and it ranks second in 7-day readmission rates\textsuperscript{1}. Additionally, rates of opioid-related deaths have continued to increase, particularly with the advent of synthetic opioids. Approximately 70\% of drug overdose deaths in 2018 involved opioids\textsuperscript{2}. Both alcohol and opioid misuse are complex behavioral conditions that encompass a variety of co-existing conditions and social determinants of health.

Both alcohol and opioid misuse have been shown to be associated with social and behavioral determinants of health, such as poverty level\textsuperscript{3}, education level\textsuperscript{4}, and employment status\textsuperscript{5}. Furthermore, substance use outcomes appear to be clustered by geographic area\textsuperscript{6}. One community study using geographical information software suggests its benefit in characterizing drug use in neighborhoods\textsuperscript{7}. This suggests that environmental influences may play a role in substance use. Measures of census-level socioeconomic status (SES) indicators function as proxies for individual-level SES information, help fill a gap in electronic health record (EHR) data\textsuperscript{8}, and improve the accuracy for identifying cases of substance misuse in patients. The SES indicators provide additional value beyond individual risk factors in predicting health risk and examining health outcomes\textsuperscript{9,10}. Few studies have linked EHR data with census-level data for substance misuse, so their effectiveness is less apparent for prediction.

In this study, we used the publicly available United States American Community Survey data summarized to census-tract to represent SES for patients. We linked the census-tract variables to geo-coded patient addresses in the EHR at a tertiary care health system to examine the added benefit in the census-tract data to existing structured EHR data. We aim to study the added benefit of the census-tract data for the prediction of alcohol misuse, opioid misuse, and both alcohol and opioid misuse. We hypothesize that census-tract data will improve the net reclassification of cases for each type of substance misuse over EHR data alone.
METHODS

Patient Setting
Loyola University Medical Center (LUMC) is a 559-bed hospital and tertiary academic center, including a burn and Level 1 trauma center serving Chicago and its western suburbs. LUMC has maintained Epic (Epic Systems Corporation, Verona, Wisconsin) as its EHR vendor since 2003 and includes a Microsoft SQL server-based clinical data warehouse (CDW) that has been available for research since 2007. The study was performed at an encounter level. The study population is composed of all adult (≥18 years of age) inpatient encounters between January 1, 2007 and September 30, 2017. Exclusion criteria were the following: (1) outpatient encounters and (2) encounters where census-tract data could not be matched to patient address.

Reference labels for substance misuse
Misuse included patients with opioid use disorder, taking an illicit opioid or non-prescribed opioid, alcohol use disorder, and excessive alcohol consumption as defined by National Institute on Alcohol Abuse and Alcoholism. Two methods were used to identify cases. First, a combination of International Classification of Diseases (ICD)-9 and –10 codes for opioid misuse and alcohol misuse were adopted from the Healthcare Cost and Utilization Project (HCUP) ICD codes for opioid abuse, opioid dependence, opioid poisoning, alcohol dependence, and alcohol abuse. A total of 20 ICD codes were used for opioid misuse and 22 ICD codes for alcohol misuse. Second, computable phenotypes that used natural language processing were applied to the clinical notes of the EHR for both alcohol and opioid misuse. The computable phenotypes for opioid misuse and alcohol misuse had previously been trained and validated at LUMC and they both had an area under the receiver operating characteristic curve (AUROC) of greater than 0.9011-13. All the data (ICD codes and clinical notes) used to build the reference labels were independent from the variables that were used as features in the models below.

Candidate Variables from the EHR
Variables for analyses from the EHR were extracted from the following domains: (1) demographics including insurance status; (2) comorbidities organized by Elixhauser disease classification categories and present on admission (excluding the codes used in the reference labels)14; (3) Elixhauser readmission score and Elixhauser mortality score; (4) inpatient pain score from the admission nursing flowsheets; (5) ICD codes for chronic pain present on admission; (6) laboratory testing with blood alcohol concentration (BAC) in mg/dL. A total of 24 EHR variables were examined. Median imputation for integer variables and mode imputation for nominal variables were applied to integer values with missing data except for BAC which was categorized as not tested.

Candidate Variables from Census Tract Data
The United States (US) Census Tract socioeconomic (SES) data were used as a proxy for individual-level social and behavioral determinants of health. The ‘censusapi’ R package was used as a wrapper for the US Census Bureau’s Application Program Interfaces (API)15. The Census APIs were used to match the addresses to corresponding geocodes for all patients in our analytic cohort16. The data were extracted from the American Community Survey 5-year Data between 2013 and 201717. Forty-eight census-tract variables for analyses were extracted from the following domains: (1) demographics; (2) highest education level; (3) marital status; (4) household composition; (5) insurance status; (6) employment status; (7) first language; (8) veteran status; (9) percent of households below poverty level.

Statistical analysis: Association of EHR and census-tract variables with substance misuse
Individual EHR and census-tract variables were examined across groups by substance use type (alcohol misuse only, opioid misuse only, alcohol and opioid misuse, and no misuse) (Tables 1 and 2). The variables were entered into a generalized linear mixed effects model with Poisson distribution and included random intercepts to account for within-patient correlation due to multiple inpatient encounters over time. A total of 72 candidate variables were examined representing both the structured EHR variables and census-tract variables. Results from all substance use models were reported using prevalence ratios with 95% confidence intervals (CI).

Predictive Analytics
The dataset was split into 70% (n=130,628) for training and 30% (n=55,983) for testing. Variable selection was performed using the least absolute shrinkage and selection operator (LASSO) in a GLM and hyperparameter tuning to find the largest value of $\lambda$ that is within one standard error of the minimum was performed on the training set using 10-fold cross-validation. First, baseline EHR models were derived to select features from the candidate EHR variables for predicting each type of substance misuse (alcohol misuse vs. no misuse; opioid misuse vs. no misuse; both types
vs. no misuse). Second, the census-tract variables were added to the list of candidate variables and variable selection with LASSO was performed. The Area Under the Receiver Operating Characteristics (AUROC) was calculated for each model, and the AUROC between the baseline and enhanced models were compared using a bootstrap test for two correlated ROC curves with 100 permutations. The following formula was used: $D=(\text{baseline AUROC} - \text{enhanced AUROC})/s$ where $s$ is the standard deviation of the bootstrap differences and $D$ is compared to the normal distribution. In addition to examining discrimination with AUROC, we also examined calibration with the calibration slope and intercept with their 95% CIs.

The absolute Net Reclassification Index (NRI) was applied to examine the benefit in adding census-tract variables to EHR data across multiple thresholds on the AUROC. The thresholds examined were the following: (1) Youden’s J index (maximizing accuracy and minimizing error); (2) the highest sensitivity/recall threshold when specificity was set to 75%, and (3) the highest specificity threshold when sensitivity/recall was set to 75%. The highest absolute NRI from these possible thresholds was reported in the results. The absolute NRI represents the absolute number of patients correctly reclassified by the enhanced model over the EHR-only model. It was used to determine if the enhanced model performed better than the EHR-only model. The net reclassification was calculated by subtracting the incorrect reclassification of the enhanced model and the correct reclassification enhanced model. An incorrect reclassification is when the baseline model accurately classified the case, but the enhanced model incorrectly reclassifies the case. Similarly, a correct reclassification is when the baseline incorrectly classified the case, but the nested model correctly reclassifies the case. The absolute NRI can be calculated by the following equation:

$$\text{Absolute NRI} = \frac{\text{misuse net reclassification} + \text{no misuse net reclassification}}{\text{total encounters}} \times 100$$

In addition, classification plots were built to better visualize discrimination and compare AUROCs. Classification plots also overcome the problem of comparing model performance conditional on specific thresholds by showing all true positive (sensitivity) and false positive rates (specificity) by risk thresholds. Figure 1 shows sensitivity/recall and specificity conditional on all risk thresholds.

The analysis was performed using RStudio Version 1.1.463 (RStudio Team, Boston, MA). All results from the prediction models are reported on the test dataset. The Institutional Review Board of Loyola University Chicago approved this study.

RESULTS

Patient Characteristics

The census tract variables for SES could not be linked in 16.2% (n=37,254) of patient encounters due to missing or incorrect address information in the EMR. The final cohort analyzed was composed of 186,611 adult hospitalizations. There were 13,263 (7.1%) positive cases of alcohol misuse, 4,484 (2.4%) positive cases of opioid misuse, and 2,896 (1.6%) cases of concurrent alcohol and opioid misuse. The association of different patient characteristics derived from the EHR data is listed in Table 1. The Elixhauser comorbidity most strongly associated with alcohol misuse was liver disease at 3.26 (95% CI, 3.07-3.46), followed by psychosis at 2.30 (95% CI, 2.14-2.47). Psychosis was the most strongly associated with opioid misuse and combined alcohol-opioid substance use groups with a prevalence ratio of 2.66 (95% CI, 2.40-2.95) and 2.50 (95% CI, 2.13-2.94), respectively. Discharge to a psychiatric facility was strongly associated with all categories of substance use (p<0.01 for all substance use types). Detectable BAC levels of <80 mg/dL and >80 mg/dL (above legal limit) had the strongest association for alcohol misuse with prevalence ratios of 9.25 (95% CI, 6.30-11.29) and 8.43 (95% CI, 8.55-10.01), respectively.

Variables from major domains of the census-tract variables from the 2013-2017 American Community Survey are listed in Table 2. Higher levels of per capita income, median household earnings, and median income were associated with lower prevalence of each substance use type (p<0.01 for all comparisons). Similarly, greater levels of poverty were associated with higher rates of substance misuse (p<0.01 for all comparisons). Further, lower levels of high school education and increases in food stamp usage had a positive association with all substance use types (p<0.01 for all comparisons).

Alcohol-Only Model

The EHR variables selected by LASSO to create the baseline model were BAC, sex, insurance status, all the Elixhauser comorbidities, pain level, and Elixhauser readmission and mortality indices. The 23-variable model had an AUROC of 0.879 (95% CI, 0.874-0.885). The calibration slope and intercept were 1.11 (95% CI, 1.08-1.13) and 0.22 (95% CI, 0.17-0.28), respectively.

The additional SES variables selected by LASSO for the enhanced model for alcohol misuse were the following from the patient’s census-tract: (1) proportion divorced; (2) proportion veterans; (3) proportion without a high school degree; (4) proportion college graduate; (5) proportion with household size of two; (6) proportion homeowner; (7) proportion not in labor force; and (8) proportion 25-64 years old. Only one Elixhauser comorbidity was removed from the baseline model. The 32-variable model had a small improvement with an AUROC of 0.880 (95% CI: 0.875-0.886), and a p-value <0.01 for comparison between the baseline and nested models. A similar calibration slope and intercept were found at 1.10 (95% CI, 1.08-1.13) and 0.21 (95% CI, 0.15-0.27), respectively. The threshold that provided the maximal benefit for reclassification had an absolute NRI of 0.39% (Table 3). Figure 1a represents the classification plots and shows negligible gains across risk thresholds for sensitivity and specificity.

Opioid-Only Model

The EHR variables selected by LASSO to create the baseline model were BAC, age, race and ethnicity, sex, insurance status, congestive heart failure, neurological disorders, pulmonary disorders, uncomplicated diabetes, complicated diabetes, renal disorders, liver disorders, HIV, metastasis, tumor, rheumatic disorders, obesity, weight loss, anemia, psychosis, depression, and Elixhauser readmission and mortality indices. The 23-variable model had an AUROC of 0.857 (95% CI, 0.847-0.866). The calibration slope and intercept were 1.14 (95% CI, 1.10-1.17) and 0.42 (95% CI, 0.33-0.52), respectively.
The additional SES variables selected by LASSO for the enhanced model for opioid misuse were the following from the patient’s census tract: (1) proportion black; (2) proportion white, (3) per capita income; (4) proportion food stamps, and (5) median earnings. For the enhanced opioid misuse model, the 28-variable model had an AUROC of 0.857 (95% CI, 0.848-0.866) and no improvement in the AUROC was found over the baseline model (p=0.65). The enhanced opioid misuse model and relatively no change in the calibration slope and intercept of 1.14 (95% CI, 1.1-1.17) and 0.44 (95% CI, 0.35-0.54), respectively. The threshold that provided the maximal benefit in reclassification had an absolute NRI of 0.04% (Table 3). Figure 1b represents the classification plots with no appreciable change visualized across risk thresholds for sensitivity and specificity.

**Alcohol and Opioid Model**

The EHR variables selected by LASSO to create the baseline model were BAC, age, sex, all the Elixhauser comorbidities, pain level, and Elixhauser readmission and mortality indices. For the baseline alcohol and opioid misuse model, a 23-variable model was derived with an AUROC of 0.952 (95% CI, 0.945-0.960). The baseline model had a calibration slope and intercept of 1.14 (95% CI, 1.10-1.19) and 0.54 (95% CI, 0.40-0.67), respectively.

The additional SES variables selected by LASSO to create the enhanced model were the following from the patient’s census tract: (1) proportion married; (2) proportion white; (3) proportion household size of two; (4) proportion disabled; (4) median earning. For the enhanced alcohol and opioid misuse model, a 29-variable model was derived with an AUROC of 0.953 (0.946-0.960) and no improvement in the AUROC was found over the baseline model (p=0.21). The model had minimal change in the calibration slope and intercept at 1.14 (95% CI, 1.10-1.19) and 0.53 (95% CI, 0.40-0.66), respectively. None of the thresholds examined provided any benefit in reclassification with the best absolute NRI at -0.13% (Table 3). Figure 1c represents the classification plots with no improvements visualized across risk thresholds for sensitivity and specificity.

DISCUSSION

Prior studies have shown that using readily available data in the EHR may be useful in the identification of individuals with substance misuse. Because substance misuse is strongly associated with SES, we added census-tract variables, a proxy for SES data, to the EHR-only model. Our results show that including census-tract variables into the prediction model using a LASSO approach resulted in several census-tract variables being added to the model but only with small gains in AUROC for the alcohol misuse model. For the most part, there were little to no gains to the AUROC, absolute NRI, and across risk thresholds for sensitivity/recall and specificity. Our results indicate that the enhanced model did not contribute much predictive value, but our models from EHR-only data already had baseline AUROCs above 0.84 so there may have been limited capacity for performance gains from baseline. Overall, our models had good discrimination and calibration, but we show little benefit in the added complexity of linking SES data for computable phenotypes in substance misuse. Other computable phenotypes with risk factors in SES may still benefit from the addition of census-tract variables but they are likely on a case-by-case basis.
Our univariable analysis demonstrates that patient’s lower SES status is strongly associated with substance misuse, especially across census-tract data for income, employment, education level, and housing. These data are consistent with individual-level data and consistent with the strong association for substance misuse in patients with Medicaid and uninsured status. From the 72 patient-level and census-tract variables and structured data variables available to our health system, we derived models to predict each substance use type. In addition to the commonly described risk factors in demographics and comorbidities, additional factors such as comorbidities and arriving with a detectable BAC were common to all models. We also found similar characteristics in the patients identified with substance misuse to other urban cohort studies, supporting the reliability in our choice of predictors. Co-substance use, hepatitis, HIV, chronic pain, and mental health conditions are commonly reported risk factors and predictors of substance misuse. For the alcohol misuse model, the Elixhauser codes for neurologic disease include delirium and encephalopathy which are commonly encountered in patients with acute intoxication.

Measures of census-level SES indicators function as proxies for individual-level socioeconomic information and help fill a gap in EHR data. The SES indicators provide additional value beyond individual factors in predicting health risk and examining health outcomes. Few studies have linked EHR data with census-level data for substance misuse so their effectiveness is less apparent for health analyses. The selection operator in our LASSO model did pick approximately a half dozen of the census-tract variables to predict the different types of substance misuse. Across the models, the variables reflected race/ethnicity of the neighborhood, earnings and income status, and disabilities. Health systems are increasingly more accountable for the health of the communities they serve, so these additional data sources may better inform strategies for community outreach and care.

In the end, our baseline models were already well calibrated and started with high performance for discrimination with AUROCs above 0.84. This may explain why our absolute NRI metrics and classification plots across multiple thresholds did not show improvement with the addition of the census-tract variables. This may be viewed as a limitation to our study and should be further explored across other computable phenotypes that are affected by SES. The utility of census-tract variables is focused on patients with substance misuse, so their value may differ in applications to other prediction models. Prior studies have focused on the additive NRI instead of absolute NRI, but it does not consider the prevalence of the cases and non-cases in the cohort and may be misleading. Our study used absolute NRI to account for the low prevalence of cases and represent the total proportion reclassified correctly. The absolute NRI of <1% for all the models indicates little value gained in reclassifications for the added complexity of linking EHR data to the American Community Survey data.

There are several other limitations in our study. First, we assumed that there is little variability in census data between years. The census data used for the modeling were the 5-year average between 2013 and 2017; however, our patient cohort included patients between 2007 and 2017. Additionally, we used the patients’ last known address which may not be representative of the patients’ geographic location during the time of the hospitalization. We did not have accurate addresses on approximately 15% of patients which also included patients experiencing homelessness, which is a major predictor for substance misuse. Because the census-tract variables were derived from the patients’ addresses, the neighborhood characteristics serve only as a proxy for the individual-level characteristics. The result of this study may suggest that the patient’s neighborhood improves the model rather than the patient’s SES. Lastly, this was a single-center study, and an external validation study is needed to determine the generalizability of our results and other model architectures may prove useful.

CONCLUSION

Substance misuse is a behavioral condition that has been shown to be highly associated with SES. However, in this study, we showed that leveraging the publicly available census-tract data, a proxy for SES data, does not improve the substance misuse prediction models. Our results suggest that the census-tract data does not add significant value to our substance misuse computable phenotypes but more work is needed to examine their value across other EHR-level prediction models.

Abstract

The COVID-19 pandemic challenged how healthcare systems provided care in socially distanced formats. We hypothesized that the COVID-19 era changes in clinical care delivery models contributed to increased Electronic Health Record (EHR) related work. To evaluate the changes in time and volume metrics of EHR usage, we segregated EHR audit log metric data into PreCOVID2019 March/April/May, initial COVID2020 March/April/May, and late COVID2021 March/April/May for 1262 physician providers. We discovered significant and pragmatically meaningful increases in total average time providers spent in the EHR in minutes mean(SD) PreCOVID2019=1958(1576), MidCOVID2020=1709(1473), LateCOVID2021=2007(1563). Differences in total time in the EHR were significant Pre-mid:p-value=<0.001, but not Pre-Late:p=0.439. Total number of messages received across all specialties increased significantly mean(SD) PreCOVID=459(389), MidCOVID=400(362), LateCOVID 521(423) Pre-Mid p-value=<0.001 and Pre-Late p-value=<0.001. We additionally found changes in total time to differ significantly across select specialties. Based on these findings we recommend further assessment of physician workload and how new factors such as telehealth are contributing to EHR usage.

Introduction

The COVID-19 pandemic has stressed the US healthcare system from increased hospital capacity to new rapidly evolving formats for clinical care delivery. To adapt to these changes, healthcare systems have switched quickly from primarily in-person visits to telemedicine visits(1). The Centers for Medicare & Medicaid Services (CMS) led the way in payment for telehealth services, which led to widespread adoption of telehealth services by other payers (2). The rapid transition from predominantly in-person to telehealth services has led to reports of increases in EHR usage time for clinicians. Moving forward, as healthcare systems are adopting these telehealth practices, it will be important to obtain best practices to identify how telehealth will exist in a post-covid era.

The initial transition to telehealth and COVID related reduction in in-person care resulted in overall fewer patient encounters. We explored evidence for increased provider workload through an analysis of EHR usage metadata comparing pre-covid (Mar, Apr, May 2019), mid-covid (Mar, Apr, May 2020), and late-covid (Mar, Apr, May 2021) time periods. EHR usage metrics do not comprehensively report on total provider work volume, they do accurately reflect the time and interaction providers have with the EHR. In a 2017 study published in the Annals of Family Medicine, the American Medical Association found that primary care physicians spend nearly 6 hours interacting with the EHR during and after clinic hours(3). Time in the EHR both total and afterhours can be significant and varied across provider sex (4). This study aims to evaluate our hypothesis that, in the wake of COVID-19 pandemic, clinician EHR time and clinical activities has increased.

Methods:

Cohort selection:

The selected cohort represented physician providers with ambulatory care time from all specialties and with EHR usage metrics in our Epic Signal report. There are a variety of clinician types in the Signal Report, but for this review we only focused on physician providers. Providers were excluded if they had no metric data for any of the selected time periods. A total of 1262 providers were clinically active with metric data for all three time frames.

Pre/Mid/Late COVID-19 Analysis Cohorts:

To evaluate changes in EHR usage we specifically split the selected cohort into pre-COVID, mid-COVID, and late-COVID groupings using mean values of EHR usage metrics across providers in general and by specialty. To account for seasonal variations of illness that can contribute to differences in clinical volume, the same three-month period of March/April/May for 2019, 2020 and 2021 were compared.

Signal Database:

The Epic Signal report summarized provider EHR usage metrics based upon user action log data. The Signal report divides provider activities in the EHR by seven categories: time in system, clinical review, note writing, ordering, in basket, in schedule and other. We identified a subset of metrics for our study (Table 1) derived in similar fashion as previously reported including calculated metrics of total messages, proportion of received messages completed, total
after hours time, and proportion of time after hours. We selected elements from each of these for inclusion in our study (Table 1).

1\[
\text{These metrics are not directly reported in the signal database, but were calculated using signal metrics as defined above and previously described.}
\]

**Primary Outcome Assessment:** Our primary outcome measures included evaluation of provider work volume and time spent in the EHR. Work volume metrics were identified as to be the total number of appointments providers had per month and the number of messages received per month. Time metrics included total time spent in EHR clinical review, orders, in basket, and notes per month. Additionally, we looked at a total summative time spent in the EHR and time spent in the EHR after hours (outside of scheduled hours and on unscheduled days). To understand population level impact of COVID19 on EHR use, we averaged physician signal data over three month intervals (Table 1).

**Secondary Outcome Assessment:** We also looked at in-basket and provider efficiency metrics as secondary outcomes. In basket metrics included total number of messages completed by providers, total received messages, and calculated percentage of received messages that were completed. Efficiency metrics included average progress note length and percentage of appointments closed the same day. We assessed the cross specialty (specifically focusing on family medicine, endocrinology, pediatrics, psychiatry, and ophthalmology) absolute change in each of the aforementioned primary and secondary metrics (Table 1).

**Data Analysis:** Data analysis was conducted in R, an open-source data science software. Data was analyzed for basic descriptive statistics, basic counts, mean, and standard deviations for our data. Statistical significance was ascertained
utilizing unmatched two-way t-testing for differences in whole group pre, mid, and late data measures. Cross differences in terms of absolute in EHR usage metrics between the pre-mid and pre-late period were evaluated using one-way ANOVA.

_This study was approved by the Duke IRB Review Committee._

**Results:**

There were 1262 physician providers included in our analysis. These providers represented 66 specialties with the top 3 representative specialties being family medicine (n=149), internal medicine (n=94), and pediatrics (n=80). Additional specialty counts are included in Table 2.

_Full Analysis (Table 3):_

**Measures of work volume:** We evaluated two measures of work volume: total number of appointments and total number of messages received in the measurement period averaged over a month. The total average number of appointments per provider per month dropped significantly from Pre-COVID (mean(SD)=134(123)) to Mid-COVID (mean(SD)=93(86)), (Pre-mid p=<0.001) but volumes rebounded by comparison to Late-COVID (mean(SD)=130(117) values; (Pre-late p=0.404). The total number of messages received per provider per month initially dropped significantly (Pre-Covid(mean(SD)=459(380)) to Mid-Covid(mean(SD)=402(362)) (Pre-mid p-value=<0.001). Contrary to the relative return to Pre-COVID appointment volumes, the number of messages received significantly increased for the Late-COVID time period(mean(SD)=521(423); Pre-late p=<0.001).

_Time Spent in EHR:_ We collected data on provider time spent in the EHR for four activities (clinical review, in basket, orders, and in notes). There was a consistent trend demonstrating an initial decrease of provider total time spent in each EHR activity (refer to Table 3). This trend was followed by increases in time spent in EHR activities. These increases were significant in the case of time spent in clinical review, orders, and schedule (refer to Table 3). Total time spent in the system per provider per month, was significant for an initial drop in total time for the pre-mid reporting periods (Pre-COVID (mean(SD)=1958(1576)) Mid-COVID (1709(1473)) Pre-mid p-value=<0.001. With a return to baseline for total time spent in the EHR in the Late-COVID (2007(1563)) group. with no significant difference at the average provider level, Pre-late p-value=0.439).

_In-Basket Work:_ We evaluated several measures of in-basket specific provider work (completed message volume, average time spent on a message, average time between message receipt and message completion). Providers had an initial decrease, followed by subsequent increase in their total completed message volume (Pre-COVID (mean(SD)=416.69(360.96)) Mid-COVID (366.34(356.5)) Late-COVID (496.16(433.22)); Pre-mid p-value=<0.001, Pre-late p-value=<0.001), with an initial dip, but subsequent normalization of their efficiency in terms of seconds per completed message (Pre-COVID (mean(SD)=39.12(31.88) Mid-COVID mean(SD)=51.72(64.63) Post-COVID mean(SD)=40.56(34.92); Pre-mid p-value=<0.001, Pre-post p-value=0.283). Despite the increased volume, provider
response time had not significantly changed (Pre-COVID (mean(SD)=9.21(29.37) Mid-COVID mean(SD)=9.02(28.97) Post-COVID mean(SD)=9.46(36.78); Pre-mid p-value=0.868, Pre-post p-value=0.851).

**Efficiency and Complexity:** As a final measure of efficiency and complexity we evaluated provider documentation practices (for progress notes) and the percentage of provider encounter closures on the same day as the appointment. Providers had an initial significant decrease in progress note lengths, followed by subsequent significant increases in note lengths (Pre-COVID (mean(SD)=6912.48(3990.56)) Mid-COVID (6306.94(4127.15)) Late-COVID (7323.3(4262.38)); Pre-mid p-value=<0.001, Pre-late p-value=0.015) with no significant change in encounters closed the same day (Pre-COVID (mean(SD)=0.62(0.31)) Mid-COVID (0.63(0.32)) Late-COVID (0.62(0.33)); Pre-mid p-value=0.429, Pre-late p-value=0.967).

**Table 3:** Evaluated mean (standard deviation) values for measures pre COVID (pre), shortly after COVID (mid), and nearly 1 year after COVID onset (late)

**Specialty Analysis (Table 4):**

**Efficiency:** Our specialty sub-analysis revealed that many of the metrics differed by specialty. Average progress note length significantly differed across specialties both in the pre-mid and pre-late analysis (Pre-mid p-value=<0.001, Pr-
late p-value=<0.001), specialties also differed with respect to the total appointments closed the same day within our pre-mid analysis, but not for the pre-late analysis (Pre-mid p-value=0.008, Pre-late p-value=0.51).

**Work Volume:** Total appointments significantly differed by specialty in our pre-mid and pre-late analysis (Pre-mid p-value=<0.001, Pre-late p-value=<0.001). Total received messages, on the other hand differed for only the pre-mid analysis (Pre-mid p-value=<0.001, Pre-late p-value=0.087).

**Messages:** The proportion of completed messages did not differ by specialty in the pre-mid analysis, but did differ in the pre-late analysis (Pre-mid p-value=0.572, Pre-late p-value=0.043), total completed messages, on the other hand only differed across specialties for our pre-mid analysis (Pre-mid p-value=<0.001, Pre-late p-value=0.149), whereas total in-basket time differed only in our pre-late analysis (Pre-mid p-value=0.055, Pre-late p-value=<0.001).

**Time:** Specialties significantly differed by total time in orders (Pre-mid p-value=0.003, Pre-late p-value=0.05), total time in schedule (Pre-mid p-value=0.022, Pre-late p-value=0.002), and total time in notes (Pre-mid p-value=<0.001, Pre-late p-value=0.01), and proportion of time outside scheduled hours (Pre-mid p-value=0.002, Pre-late p-value=<0.001) for both the pre-mid and pre-late analysis. However, total time in system only significantly differed between specialties for our pre-mid analysis (Pre-mid p-value=<0.001, Pre-late p-value=0.068).

Figure 1. Total time in system, Messages Received, Total Afterhours Time for specialties pre, mid, and late COVID. (title to include total time in system per month)

Discussion:

We present one of the first assessments of the impact of the COVID-19 pandemic on changes in clinical activity as measured by provider EHR usage metrics. Our findings revealed an initial reduction in EHR related usage by time and volume metrics after COVID-19 lockdowns and overall decrease in clinical encounters. These reductions in EHR usage were not uniform across all specialties, with some specialties having significant increases in time and volume metrics. More than one year into the pandemic and with a loosening of COVID-19 restrictions, most EHR usage metrics have returned to baseline with the exception of increases for total messages received.

We found an initial decrease in provider volume during the months of March to May for total appointments and total time in the system. While these changes corresponded with reductions in EHR usage, the reductions were disproportionately modest. We hypothesize multiple factors accounted for these non-concordant changes. First, is the rise of telehealth. At our institution, telehealth encounters are initiated by the provider within the EHR. These encounters occur directly in the EHR with the patient as opposed to previous in-person formats where the provider usage of the EHR was utilized as needed. It may be that with providers initiating telehealth encounters within the EHR; they are more apt to chart during the clinical encounter. Telehealth encounters being in the EHR led to more overall time of use with the encounter. The specialty with the highest utilization of telehealth is our Department of Psychiatry. We observed our psychiatrists with an increase of 317 minutes of average total time spent in the system per month comparing pre to late covid. The implementation of telehealth and compensatory increase in EHR time may need further policy and oversight.

An additional instance where there is a potential for increasing time in the EHR is with our endocrinologists who manage diabetes and making changes remotely while reviewing labs in the EHR, especially the time in system per day (Pre(mean(SD)= 2435.28(1799.19), Mid(mean(SD)=2547.88(1927.34), Late(mean(SD)=3231.08(1960.24)). This may be reflective of the fact that many of the endocrinologists are managing chronic diseases, such as diabetes and thyroid disease that need persistent lab work. This poses a unique disease process that potentially contributed to the EHR usage of our endocrinologists. Surgical subspecialties such as ophthalmology were greatly impacted by the change in COVID-19 era practice changes. They initially saw a decrease in appointments per day PreMid(mean(SD)=2...
113.77(109.83) and total time in system (PreMid(mean(SD)=−766.23(629.15)). This is likely reflected in the nature of the subspecialty requiring in-person care.

Nevertheless, if these were the sole factors contributing to the reduction in time, then we would not also see an increase in the total time providers spent in the EHR outside scheduled hours. Rather, we believe that additional factors are at play. The change to predominantly asynchronous patient-provider interactions had significant changes in provider EHR usage. Shortly after the pandemic providers saw a 20.3% increase in the number of received patient messages, possibly partially accounting for those stable patients who opted to forego clinical visits. Interestingly, the short-term impact of COVID-19 on provider EHR usage was not uniform across specialties.

While most specialties saw a significant decrease in EHR total time usage shortly after initiating COVID-19 public health mandates, psychiatry saw a relatively small decrease in total time in the system. As the department rapidly transitioned to telehealth care they did not see a decline in total appointment volume partially due to a relative decrease in no show volumes. Emerging evidence demonstrating a significant impact of the COVID-19 pandemic on patient mental health(1), we hypothesize both the patients increased desire for mental health services as well as improved accessibility of services through telemedicine encounters. The psychiatry department has been able to uniquely transition the majority of their ambulatory care encounters to telemedicine formats that allow for providers to provide off site care. While this served to reduce contact risk, many have reported technology challenges for both the patients and the providers with the transition.

Consistent with reports in popular culture, providers working from home are finding themselves managing clinical work in what for some is possibly a more distracted environment(5). This too may have impacted provider EHR usage time.

Of notable concern were the increases in total messages received in our Late-COVID cohort nearly one year after the start of the pandemic along with the relative normalization back for EHR time metrics corresponding to resumption to more in person encounters. The reasons for many of these changes are likely explained by increased patient acceptance of asynchronous messaging in place of in person appointments along with mild compensatory increases in appointment volumes making up for previously deferred in person appointments.

Providers have not gone back to the pre-COVID status quo, in terms of clinical encounters or EHR usage. Our results suggest trends towards increased volume of work by evidence of increasing number of messages along with a similar volume of clinical encounters. Certainly, there has been increasing evidence demonstrating increased provider burnout during the pandemic(6). While provider EHR usage represents a sliver of the factors influencing that burden, it is one that requires addressing. If not addressed, implications of provider burnout could mean worsening patient care(7), decreased provider productivity(6), and increased organizational turnover(8).

While some may look at our data and take hope in our providers improved calculated efficiency metrics (with providers closing encounters in a timelier manner), we urge caution when evaluating these factors. If evaluated from the perspective of the Yerkes-Dodson law (which suggests bell-curve relationship between arousal-stress- and performance) it may be that our providers are at the cusp beyond which their performance would deteriorate. Furthermore, this heightened work-burden is likely to not be sustainable and we anticipate declining performance over time if such burden is to persist. With this ever-changing landscape there is an opportunity for policy to improve the implementation and reimbursement of these visits. There have been new evaluation and management (E/M) codes pertaining to time coverage, however clinicians are also using the EHR on unscheduled days. There is also a potential for improvement in automated transcription systems to have an impact on documentation.

**Limitations:** There are several limitations to our study. Firstly, our analysis is reflective of a single academic health system. Although we are unable to provide evidence for other health systems, this represents a large dataset of over 1200 providers from 66 specialties. Our state and institution did not experience an overwhelming surge in COVID19 patient volumes during the three-month time periods for 2020 or 2021. Consequently, our results are more reflective of our state and local pandemic public health constraints. Our institution constrained in person encounters and did not permit elective surgical procedures initially. Additionally, there may be variation in how healthcare systems responded to the arrival of COVID19 in regard to limited resources and COVID patient volumes.

Another limitation of this data is lack of granularity of visit type, specifically differentiation of telehealth encounters. Given the relative rapidity of significant use of these technology platforms, not having this in the Signal data is not
surprising. Future Signal data at the encounter type level would allow for greater exploration into the effect of telehealth on provider EHR usage data.

We must also consider the fact that the time spent in the EHR is not comprehensive of total clinical care. Provider time in front of their patients and interacting with them and other members of the clinical team is not captured in these metrics fully. The Signal EHR metric reports also only represents ambulatory EHR usage, inpatient encounters, where more COVID patients receive care is not represented fully.

This study did not provide a direct measurement of the impact of increased EHR metrics on our providers or our patients in terms of health-related outcomes. Further investigation is needed to see how increased EHR time may impact physicians or patient outcomes. We instead showed evidence from our usage data that there has been an increase in patient-initiated messages and time in the EHR.

Conclusion: We have demonstrated that there is an increasing trend in EHR usage. Further investigation is needed in how EHR usage has changed for other provider types and specialties. Both specialty and different provider characteristics may contribute uniquely in how the EHR is used and how they responded to the pandemic. Specialties that rely predominantly on telehealth, like the Psychiatry department at our institution, are more likely to have increased EHR usage. Further investigation is needed in how telehealth specifically impacts EHR usage, provider wellbeing, and quality of care is needed. This increase in EHR usage may also reflect a decrease in no-shows, increased provider efficiency, or related to patient convenience. The healthcare system will need to continue to adapt to new challenges to better serve its patients.

Abstract

Mental health is an increasing concern in adolescents. Mental health disorders can affect academic performance, affect the cultivation of healthy relationships, and even lead to suicide. Healthy lifestyle can improve mental health, though there are gaps in the research, partly resulted from the lack of detailed longitudinal datasets on lifestyle and mental health. To inform and engage students in the research on adolescent lifestyle and mood, the George Washington University and the T.C. Williams High School in Alexandria, Virginia teamed up in a citizen science project. Students generated questions, collected data on themselves, analyzed the data, and produced research reports relating to their mental health and lifestyle. Student feedbacks suggest that the students find the project to be generally interesting and some students (46%) reported that the participation in the project may influence their college and career plans. The anonymized dataset resulted from the project provides another contribution to science.

Introduction

There has been a rise in mental health issues in adolescents[1]. Adolescents are a unique population, going through changes in the way they think, feel, and interact with others. It is a normal part of development for teens to experience a wide range of emotions. Some teens, however, go on to have mental disorders. According to a US Department of Health and Human Services report, one in six adolescents (2.3 million/year) has had a severe mental health disorder at some point in their life[2]. Mental health disorders among adolescents can affect academic performance, affect the cultivation of healthy relationships, and even lead to suicide[3]. Particularly of concern is that rates of major depressive episodes increased by 52% between 2005 and 2017 among adolescents aged 12 to 17[1]. According to a 2019 publication, from the mid-2000s to 2017, there has been a sharp rise in the rates of suicidal thoughts, plans, and attempts.

At the same time, many adolescents do not adhere to a healthy lifestyle. Sedentary behavior continues to be a challenge, with less than 24% of children 6 to 17 years of age getting the recommended 60 minutes of physical activity daily[4]. In addition, most youth do not meet the recommended healthy eating habits[5]. Physical activity and nutrition deficits correlate with the increasing number of health issues in adolescents, including mood and weight problems. Between 1999-2000 and 2015-2016, United States obesity rates in youth increased from 13.9% to 18.5%[6]. There are many risks resulting from obesity, including high blood pressure, elevated cholesterol, breathing problems, and musculoskeletal pain. Obesity is also linked to lower self-reported quality of life, social problems, and even anxiety and depression[7].

However, gaps remain in the research on the interaction between adolescents’ lifestyle and mental health. One big challenge is the availability of a detailed, longitudinal dataset on lifestyle and mental health. For those datasets that do exist, the populations are often based in other countries, including England, Canada, and France, and the data tended to be collected from cross-sectional studies[8-12]. In addition, existing datasets still lack nuanced data to study the complex relationship between lifestyle and mood. One example is Add Health, the largest longitudinal study on adolescent health that began in 1995 and has undergone five waves of data collection, the most recent in 2016[13].

1169
While this comprehensive data set is impressive, there were 2-8-year intervals between waves of data collection, and adolescence is a period of rapid changes.

Another challenge, perhaps more social or cultural, is to engage adolescents in the enhancement and management of their health through research. Recruitment of subjects for clinical research is often not easy due to several factors: There may not be any immediate benefit from participation. Today's adolescents often have a packed schedule. Asking adolescents to track their lifestyle and mood closely over a period of time confers some burden and inconvenience.

Citizen science in the classroom is a new approach that has the potential to benefit students and to further understanding. The rise of “citizen science” offers an alternative to the traditional paradigm that separates researchers from the subjects they study. In citizen science studies, scientific work is undertaken by members of the general public, often in collaboration with or under the direction of professional scientists and scientific institutions[14-16]. In our citizen science project, students serve as both the study subjects and researchers, both as data source and as data analyst. They formulate research questions of interest to themselves and observe the impact in their own life. Collecting this data and building a resultant, anonymized dataset provides another contribution to science.

Specifically, to inform and engage students in the research on adolescent lifestyle and mood, the George Washington University (GW) School of Medicine and Health Sciences Biomedical Informatics Center and T.C. Williams High School in Alexandria City Public Schools (ACPS) Virginia teamed up in a citizen science project. Since the fall of 2016, GW and ACPS have collaborated on various projects. This collaboration has evolved into a Governor’s Health Sciences Academy and sophisticated in-class research projects. During the 2018-2019 school year, the students' research project took on a citizen science approach, developing the research questions to ask, and serving as subjects of the study. Based on input from the teacher and students, healthy lifestyle and mood were selected as the focus.

Background

The T.C. Williams High School is located in Alexandria City, where the median household income is $93,370, and 43% of households contain a married couple[17]. T.C. Williams High School is the largest high school in Northern Virginia, with 3,959 students between two campuses. The demographics of T.C. Williams HS is very diverse: Hispanic (40.8%), African American (28.2%), and White (24.1%)[18].

Mental health and obesity are prevalent health issues in Alexandria City. Between Spring 2018 and Summer 2019, the Alexandria Health Department conducted a Community Health Assessment, gaining insight from local data and community input regarding various health issues. One in five adults (21%) reported poor mental health lasting more than five days, and 22% of adults reported being obese, with community members reporting mental health and obesity as two of the top five health-related issues in Alexandria City[19]. These assessment results are consistent with national findings and support the need for further research on adolescent lifestyle choices and their relationship to mood. Moreover, compared to the national average of 49%, only 31% of Alexandria High School students reported regular exercise.

Methods

Students in the Biotechnology course at T.C. Williams High School, assisted by T.C. Williams and GW's faculty, identified pressing health issues, conducted literature research, created research questions and hypotheses, and performed data analysis submitted a poster presentation for the course.

IRB approval was requested and approved by the GW. Consent forms were sent to all parents, requesting permission for their son or daughter to participate. Additionally, students were given the option to opt-out of the data collection part of the study. A total of 3 students did not participate in the data collection but participated in other parts of the study. The remaining 18 female (64.3%) and 10 male (35.7%) students were provided an external study ID for data collection. All students were between the age of 16 and 17.

Students organized themselves into groups of two to five students in which they were to complete their research. At the beginning of the project, students were provided information on what data would be collected, allowing each group to determine a research focus. Once a group had chosen a focus, they worked closely with GW staff and ACPS library staff to carry out the research.

Students conducted literature reviews using T.C. Williams High School’s library resources with school librarians' guidance. Library resources utilized included databases, such as Science in Context and PubMed, Google Scholar, and books. After completing a search for relevant journal articles, students were instructed on how to complete a journal article review and create an American Psychological Association (APA) citation.
In addition to journal reviews, Children’s National Medical Center experts were invited to meet with the students. Two public health and policy professionals, as well as a medical doctor, spoke to the students about brain development and the current understanding of the effects of nutrition, sleep, and activity level on adolescents’ mood.

The GW staff taught a short lesson on how to develop a hypothesis and research questions. This lesson included examples of research questions, the importance of conducting a literature review before creating a research question, and the difference between null and alternative hypotheses.

To introduce the concept of research questions, students were shown a sample case study and asked to formulate two related questions. Students then categorized these questions into background and foreground questions. Once they had an understanding of the types of research questions, student groups were tasked with brainstorming potential research questions related to the study. Students were asked to follow a 5-step process to create their own research question for the project, which required them to think about the topic of interest, ideas and issues they would want to explore, problems within that topic of choice, questions they have based on their literature reviews and the context in which the study would be conducted.

Data collection was conducted between December 2018 - January 2019. Study participants completed a one-time questionnaire, daily mood tracker for thirty days, and fitness trackers to track their daily steps, physical activity, and sleep.

They were first instructed to complete, on paper, the background questionnaire. The background questionnaire was designed using previously tested and validated survey questions. It contained a series of questions regarding how students spend their time outside of school, including what activities they engaged in and how much time per week was spent on each activity. Additionally, at the students' request, the questionnaire included time spent on electronics (for personal and educational use) per day. The questionnaire was administered during the biotechnology class via paper format.

Consented students were then provided with Garmin Vivofit 3[20] fitness trackers and instructed on proper usage, including how and when to wear them. Students were asked to wear the tracker beginning December 14, 2018, through January 14, 2019, and only remove it when they were in the water, competing in activities that restricted its use, and when it was charging. It was recommended to students that they charge their device on Sunday and Wednesday evenings. At the end of the data collection period, students returned their trackers so that data (both sleep and number of steps) could be compiled.

In addition to collecting activity level and sleep data, students were given access to the Daily Nutrition and Mood Tracker, a questionnaire administered using SurveyLegend, a web-based service. Students were instructed to set an alarm to serve as a reminder to take the survey each evening before they went to bed. The daily nutrition and mood survey was completed each evening beginning Saturday, December 15, 2018, and ending Monday, January 14, 2019 (inclusive), for a total of 31 days.

The daily nutrition and mood tracker, created specifically for this study, served as a tool for students to log the food consumed at each of their meals (breakfast, lunch, dinner, and snacks) and indicate when each meal was consumed, exclusive of snacks. Additionally, students were asked to track their mood for three separate times of the day: morning (before 12 pm), afternoon (12-4 pm), and evening (after 4 pm). A numerical rating scale was used where one star indicates a poor mood and 5 stars, an excellent mood. Students were also asked to answer questions regarding the previous nights’ sleep, as well as indicate how many glasses of water they consumed each day.

Students worked closely with GW staff to organize the data in a format that would be useful to their research questions. The first step in data analysis was to have students describe the data through visuals. Next, students conducted a univariate analysis to determine any patterns in the data. This was done using Google Sheets on student Chromebooks. Students learned how to sort and filter data, count rows, and create simple graphs and charts.

Following this study, students were asked to complete an evaluation of the impact of the citizen science project and the collaboration with George Washington University. Students were asked whether they found the following topics interesting or boring: data, biomedical informatics, research, collaborating with GW and creating graphs. Information was submitted on what the students enjoyed most and least and whether this project played a role in their college and/or career plans.

Results

Student Characteristics
Besides the basic demographic information, students reported how many Advanced Placement (AP) and/or Dual Enrollment (DE) classes they were taking during the 2018-2019 school year, as well as indicate their involvement in various activities. Additionally, students reported how much time they spent per day on their phones, watching TV, and on their computers. A summary of these results can be found in Table 1 below.

**Question Formulation**

The student groups generated a total of 7 research questions (Table 2). Due to an unexpected technical difficulty in downloading the fitness data in time for student analysis, one group revised their fitness question to focus on nutrition.

Outcomes of Citizen Science Project

As a culminating task, students created posters to present at the annual Leveraging Big Data Student Showcase at T.C. Williams High School. Students were required to include the following elements on their posters: Background, Purpose, Methods, Results, Discussion, and Future Work. Attendees at the showcase included ACPS and GW Staff, parents, community members, and T.C. Williams HS teachers and students.

One of the greatest benefits of the collaboration was the opportunity for students to extend their learning outside the classroom. During the summer of 2019, five current and former T.C. Williams High School students completed an internship at the GW Biomedical Informatics Center. During this internship, students organized the current study data and collected and cleaned additional data from Health Sciences Academy students during a summer bridge program. In a final step, one of the students completed a data analysis, wrote an extended abstract, and submitted the abstract to the American Medical Informatics Association (AMIA) High School Scholars Symposium.

Evaluation

Twenty-eight students completed the evaluation survey and, of these, 13 students (46.4%) stated that this project may have played a role in their future college and career plans. Additionally, students were asked to report their interest level on various topics on a scale of 1 (boring) to 5 (interesting). All topics reached an average rating of greater than 3.5, suggesting that the students found the topics to be more interesting rather than boring. Table 4 includes the descriptive statistics of these interest levels.

</tbody>
</table>

It is clear from this feedback, that students enjoyed working on various aspects of this project. While students enjoyed the experience, they did provide meaningful and constructive feedback. A few statements from the high school students, taken from the evaluation, are shown below:

“I do not have any additional feedback on the project. I think that it was a useful learning experience. However, due to the limited time and sample size of the project, I feel that it was unable to really be used as an academic study; due to many outliers that were caused by that limited amount of data.”

“I loved this project. I think we should have collected more data because analyzing the data was hard.”

“I think that before sending the survey for approval, the staff should ask students to submit extra survey questions.”
“This project would have been more interesting if we had collected data over a longer period of time.”

Discussion

The Greek ideal of a sound mind in a sound body is supported by a good amount of modern evidence. It is to be noted that there is increasing evidence that physical activity can help improve academic performance, including cognitive skills and mood[21]. Past studies have also concluded that risky lifestyle activities, including inadequate exercise and poor diet, may lead to adverse health outcomes and chronic diseases in adulthood[22-24]. We recognize that bad mood is not the same as mental health issues. At the same time, mental health disorder requires a clinical diagnosis while mood can be tracked by individual who are diagnosed with a mental health disorder as well as those who are not. Individuals with mental health problems also often have mood issues.

In this citizen science project, a group of high school students collected lifestyle and mood data on themselves. They generated research questions, analyzed data, and produced research reports on various topics, including the effects of skipped meals, winter break on mood, the relationship between protein consumption and quality of sleep, and Advanced Placement (AP) courses’ impact on sleep and mood. Five students continued their work with the GW Biomedical Informatics Center as interns collecting additional data from a cohort of 100 students enrolled in the Governor’s Health Sciences Academy during the Academy’s 2019 summer bridge program. One of these interns, a rising senior at T.C. Williams High School, used this data to prepare a manuscript for submission to the American Medical Informatics Association (AMIA) High School Scholars Symposium.

As public school budgets continue to decrease and more emphasis is placed on meeting standards, it is important for teachers and school districts to be creative about how they engage students in scientific research. For students to understand the importance of the research, they must first understand how it is relevant to their lives and communities. Because of their focus on community-driven research, citizen science projects can be an excellent tool to engage students in these efforts. However, according to Mueller, Tippins, and Bryan, many citizen-science projects do not provide citizens the opportunity to see scientists in action, nor do they involve collaborating with these scientists to create larger-scale scientific studies. Additionally, citizens do not typically ask their own questions or use the data to construct analyses[25].

This project engaged high school students and teachers with informaticians, public health students, medical professionals, and government affairs personnel. Unlike most citizen science projects, this project allowed students to work directly with professionals in the field to ask their own questions, develop project protocol, and analyze their own data.

While there may be concerns regarding student-collected data, studies have shown that youth, when advised by adults, are capable of collecting reliable data[25]. In his book, The Shame of a Nation, Jonathan Kozol claims that young people can be trusted for the quality of their data because they approach issues without previous experiences, which might give them a bias[26]. Therefore, we cannot discredit the food, sleep, and mood logs submitted by these students. We argue this data is more accurate because students have a vested interest in learning about how their choices impact their well-being.

Student responses were generally positive toward this project. However, this research was not without its limitations. First, the sample size was small; 28 students began the project, and only 25 submitted any data. In addition, only 15 students (60%) tracked data for more than 20 (out of 31) days. Second, because of technical issues (the Garmin activity trackers only keeps two weeks locally while data was not automatically uploaded to a server), Garmin activity and sleep data were excluded from this study. At the end of year evaluation, 11 (39.3%) students reported they were initially interested in working with the Garmin sleep data and 17 (60.7%) students with the Garmin activity data. Unfortunately, because of the lack of Garmin data, students were unable to research whether activity level and/or sleep play any role in an adolescent’s well-being. Third, nutrition data gathering was challenging for many reasons. Although students were asked to be detailed in their responses, not all students followed these instructions, which made it difficult to quantify the amount of food consumed. Additionally, data had to be cleaned in such a way that prevented the identification of individual students, so foods were categorized based on traditional food groups. This task was not always as straightforward as it might appear. Lastly, and most importantly, was the lack of student knowledge in techniques of data analysis. Because this project was embedded into an existing course, there was limited time to instruct students on how to properly analyze data.

Conclusions and future work

Regardless of the limitations, this project proved to be extremely successful and worthy of future work. More work will need to be done to improve data collection to ensure a more robust and reliable dataset. In order to fully investigate the factors that impact adolescent well-being, it will be important to fix technical issues with the chosen fitness trackers, improve the process for nutrition tracking, and spend more time with students on data analysis. Additionally, after reviewing existing data sets, like Add Health, it may be worthwhile to expand the baseline survey to include
questions about family, friendships, and community. These improvements and additions will allow for a better understanding of the impact of lifestyle choices and factors on adolescent mood.

In the future, we plan to expand this data set locally, within T.C. Williams High School, and then with another high school in neighboring Prince George’s County, Maryland. (Current was underway in the 2019-2020 school year but cut short by the COVID pandemic.) Beyond that, developing a more robust data collection method that will support high school student citizen science and the collection of a much larger dataset is envisioned.

A Practical Approach for Monitoring the Use of Copy-Paste in Clinical Notes

David K. Vawdrey PhD1,2, Casey Cauthorn MIE1, Diane Francis1, Kathy Hackenberg RN1, Gerald Maloney DO3, Benjamin A. Hohmuth MD, MPH1,3

1Geisinger Steele Institute for Health Innovation, Danville, PA; 2Columbia University Department of Biomedical Informatics, New York, NY; 3Geisinger Department of Medicine, Danville, PA

Abstract

The use of copy-paste in authoring clinical notes has been widely embraced by busy providers, but inappropriate copy-paste has been lambasted by critics for introducing risks related to patient safety and regulatory compliance. At an integrated academic health system with over 4,100 providers writing notes, we developed a pragmatic approach to assess the use of copy-paste. From January 1–December 31, 2020, approximately 2.3M inpatient notes and 6.6M ambulatory clinic notes were authored in our electronic health record. Of the inpatient notes, 42% used copy-paste, and 19% of overall note content was copied; in ambulatory notes, 18% used copy-paste and 12% of note content was copied. We describe an approach for including providers’ copy-paste usage statistics into the ongoing professional practice evaluation process required for hospital accreditation, thereby offering individual training opportunities related to the lack of use of copy-paste or its potential overuse.

Introduction

Given the challenges that contribute to provider burnout, including increasing documentation requirements and poor electronic health record (EHR) usability,1,2 copy-paste is a welcome function that allows clinicians to author more comprehensive notes more quickly. Recognizing the widespread use of copy-paste in EHRs and the associated patient safety and compliance risks, the Partnership for Health IT Patient Safety provided four recommendations aimed at health information technology vendors and healthcare delivery organizations: “1) Provide a mechanism to make copy and paste material easily identifiable; 2) Ensure the provenance of copy and paste material is readily available; 3) Ensure adequate staff training and education; 4) Ensure copy and paste practices are regularly monitored, measured, and assessed.” While the first two recommendations have become standard functionality in EHR systems such as Epic Hyperspace (Epic Corp., Verona WI), the others—staff training/education, and regular monitoring of copy-paste practices—are more difficult to adopt.

At Geisinger, an integrated academic health system with over 4,100 providers on the medical staff, we developed a pragmatic approach to assess the use of copy-paste in aggregate, and also provide individual training opportunities by including providers’ copy-paste usage statistics into the ongoing professional practice evaluation (OPPE) process that is required for hospital accreditation.

Background

Copy-Paste Concerns

The “note bloat” phenomenon, where clinical notes balloon in length as large amounts of nonessential information are inserted, has been decried by experts as both annoying and dangerous.3 In addition to the potential for harm that arises when notes contain inconsistent and outdated information, note bloat may result in salient information becoming buried or lost. Wrenn and colleagues found that more than half of the text in EHR progress notes originated from prior notes accounts,4 and a 2017 study by Wang and colleagues found that 82% of text in inpatient progress notes was copied or generated by a template.5

The complex payment and medicolegal environment in the U.S. is likely a primary driver of clinical note length. In a study of U.S. and non-U.S. hospitals using the same EHR, Dowling and colleagues found that ambulatory notes in the United States are 4x longer than notes written in other countries.6 Clinicians in the U.S. may use tools like copy-paste to more efficiently author notes that meet the real or perceived requirements of stakeholders from billing, compliance, and legal departments.
In 2014, the Office of the Inspector General for CMS released a report titled “CMS and Its Contractors Have Adopted Few Program Integrity Practices to Address Vulnerabilities in EHRs.” The report warned that “when doctors, nurses, or other clinicians copy-paste information but fail to update it or ensure accuracy, inaccurate information may enter the patient’s medical record and inappropriate charges may be billed to patients and third-party health care payers. Furthermore, inappropriate copy-pasting could facilitate attempts to inflate claims and duplicate or create fraudulent claims.”

The OIG report expressing concern about copy-paste did not lead to CMS standards about the practice; indeed, compliance risks related to copy-paste seem to be significantly diminished as a result of the changes CMS included in the Physician Fee Schedule Final Rule in 2020. In this Rule, CMS explains that “the physician, the PA [physician assistant], or the APRN [advanced practice registered nurse] who furnishes and bills for their professional services” is only required “to review and verify, rather than re-document, information included in the medical record” by physicians, residents, nurses, students or other members of the medical team” (emphasis added).

Notwithstanding the 2020 CMS changes related to documentation practices, liability risks exist with improper use of copy-paste. Copy-paste is an easy target for critics because of egregious “errors of commission,” where a copied block of text is repeated in a note indicating, for example, that a patient is ‘post-op day 2’ when it has been a week since the operation. Similar examples have been identified when a note describes a patient as having a different sex or age than what is recorded elsewhere in the medical record. No matter how infrequent these cases, they are memorable examples of the risk of improper use of copy-paste.

**Copy-Paste Benefits**

While concerns related to copy-paste have been widely reported for the past 15 years, the benefits of copy-paste have been less publicized. With numerous studies documenting that clinicians spend more time in the EHR than face-to-face time with patients and growing concerns about provider burnout, any tool to improve efficiency of note-writing or any policy change that reduces documentation burden is welcome. Hilliard and colleagues recently reported on EHR factors that were associated with clinician burnout. Among “efficiency” variables—such as use of a “Chart Search” function, the number of “SmartPhrases” (personalized text templates), and the use of ordering shortcuts—the only variable independently associated with decreased reporting of burnout was a clinician’s use of copy-paste.

While unchecked use of copy-paste can result in problematic note bloat, appropriate copy-paste can improve the comprehensiveness of notes and help providers avoid the invisible error of omission. For example, a conscientious provider might bring forward important clinical information using copy-paste such as “8mm adrenal mass requires errors of commission (emphasis added)." While these links could either pull information from other places in the EHR (e.g., past medical history, lab test results) or they could prepopulate blocks of text that were created by individual providers or at the system level. When reviewing notes in the EHR, the mechanism by which text was entered into the note (manually, via template, or via copy-paste) could be visualized as shown in Figure 1.

**Methods**

Geisinger is an integrated health system with 9 hospitals and over 200 ambulatory care sites located primarily in central and northeast Pennsylvania. Geisinger implemented the Epic EHR beginning in 1996. Copying of text in the EHR could be done in several ways. First, text could be selected, copied, and pasted between notes using the same commands one would use in any text editor or word processing application. The Epic EHR also provided a copy-forward function that allowed copying a prior note (e.g., from the previous day of an inpatient encounter) and modifying it as needed for the current day. For the purposes of this study, copy-paste refers to these two methods.

There are other EHR capabilities for autogenerating text that we did not evaluate in this study. For example, text could be inserted into notes automatically using links that were either built into a note template or invoked by a text command known as a “dot phrase.” These links could either pull information from other places in the EHR (e.g., past medical history, lab test results) or they could prepopulate blocks of text that were created by individual providers or at the system level. When reviewing notes in the EHR, the mechanism by which text was entered into the note (manually, via template, or via copy-paste) could be visualized as shown in Figure 1.
Figure 1. Example of how the EHR allowed the source of text in a clinical note to be identified. Based on the user’s selection, only text that has been copied into the note is highlighted; text entered manually or via template is shown in light gray.

We assessed copy-paste practices among providers authoring inpatient and ambulatory clinic notes between January 1, 2020 and December 31, 2020. Providers were grouped into departments and departments at our institution were grouped into the following Institutes: Anesthesia/Surgical Services, Cancer, Diagnostic Medicine, Heart, Medicine, Neuroscience, Orthopedics, Surgery, Women & Children’s. We measured providers’ use of copy-paste by quantifying the percentage of notes that included text content added via copy-paste. Content was considered copied if it was copy-pasted from another note, not entered using templates that populated boilerplate text or patient-specific text (e.g., medications, laboratory test results, vital signs, etc.)

We measured the average length of notes (in characters) written by providers in various clinical institutes, and we calculated “Average % Copied Content” by dividing the number of copied characters by the total characters in each note.
Integrating Copy-Paste Statistics into the Ongoing Professional Practice Evaluation Process

The Joint Commission requires hospitals to conduct Ongoing Professional Practice Evaluation (OPPE) for all practitioners who are granted privileges as part of their Medical Staff. The goal of OPPE and its companion process—Focused Professional Practice Evaluation (FPPE)—is to support early detection and response to performance issues that could negatively impact patient outcomes. To conduct effective OPPE, an objective, data-driven foundation for making re-privileging decisions is needed. At our institution, department chairs or their designees (such as vice chairs or division chiefs) had responsibility for reviewing data twice per year with each provider in their department and recommending continued/limited/denied privileges for each.

We added the following copy-paste metrics to our OPPE:

1) Total Ambulatory Notes Authored
2) % of Ambulatory Notes Containing Any Copied Content
3) Average % of Text in Ambulatory Notes That Was Copied
4) Total Inpatient Notes Authored
5) % of Inpatient Notes Containing Any Copied Content
6) Average % of Text in Inpatient Notes That Was Copied

At our institution, OPPE reports were created using the Midas Statit Physician Profile & Review tool (Conduent Care Management Inc., Tucson, AZ). Profiles (reports) were customized based on the specialty of each physician/advanced practice provider (APP). The tool helped facilitate a timely 6-month review for each provider by sending automated reminder emails, and it provided a central repository for current and historical reports, which made it easy to support audit activities such as Joint Commission surveys. The six new metrics related to copy-paste complemented an existing library of 27 inpatient and 26 ambulatory metrics used in the institution’s OPPE reports.

Results

From January 1-December 31, 2020, approximately 2.3M inpatient notes and 6.6M outpatient notes were authored in our EHR (Table 1). The notes were written by 4,103 providers. The average length of inpatient notes by character count was 5,194. Heart Institute notes were the shortest, on average, at 2,257 characters, while Medicine Institute notes were more than three times longer (6,876 characters on average). The average length of ambulatory notes was 2,869 characters. Cancer Institute notes were the longest (6,321 characters on average), and Diagnostic Medicine notes (2,084 characters) and Medicine Institute notes (2,214 characters) were the shortest.

Of the nearly 2.3M inpatient notes, 42% used copy-paste, and 19% of overall note content was copied. Of 6.6M ambulatory notes, 18% used copy-paste and 12% of note content was copied. Copy-paste use varied considerably by Institute/Specialty (ranging from 15% [Diagnostic Medicine] to 78% [Cancer] for inpatient notes and 11% [Medicine] to 59% [Cancer] for ambulatory notes).

The Institute with the highest usage of copy-paste in the inpatient setting was Cancer—of the 31,216 inpatient notes written by Cancer providers, 78% used some copy-paste, and 30% of note content was copied, on average. Cancer providers also used copy-paste frequently in the ambulatory setting (59% use, with 39% average copied content).

The Women and Children’s Institute (comprising OB/GYN, general pediatrics, and pediatric subspecialties) had the highest average % copied content (31%) for inpatient notes, but the lowest (7%) for ambulatory notes.

Within institutes, there was also considerable variation by provider in the use of copy-paste. Of the 4,103 providers who authored notes in the EHR from January-December 2020, 3,283 (80.0%) wrote at least 200 notes. Among the notes written by these 3,283 providers, use of copy-paste ranged from 0% to 100%. There were 571 providers (17.4%) who used copy-paste infrequently, in less than 5% of the notes they authored. On the other extreme, 333 providers (10.1%) used copy-paste in more than 75% of the notes they authored.

The large majority of providers who wrote at least 200 notes—2,406 of 3,283 (73.2%)—authored notes that included less than 25% total copied content (by character count). However, there were 88 providers for whom >50% of the content of their notes was inserted via copy-paste, and 8 providers for whom >75% of the content of their notes was inserted via copy-paste.
Table 1. Use of copy-paste by clinical institute. Nurse practitioners and physician assistants were not classified by clinical institute and are listed separately. CY=Calendar Year.

Figure 2 shows the inclusion of copy-paste metrics into our software tool for creating OPPE reports. The specific example in Figure 1 shows % Copied Content for Ambulatory notes. Use of copy-paste is shown over time. While we did not set targets for the six copy-paste metrics, the OPPE tool provided benchmarking information by comparing the provider’s use with that of his/her peers.

Figure 2. Example of how an individual provider’s use of copy-paste is included in the ongoing professional practice evaluation (OPPE; Conduent Care Management Inc., Tucson, AZ). The OPPE document containing this information is reviewed by the clinician’s supervisor (e.g., division chief) and discussed with the clinician every six months.

Discussion
Our analysis is one of the largest assessments of copy-paste utilization in the EHR, representing almost 9 million inpatient and ambulatory notes written by 4,103 physicians, APRNs, and PAs over one year across a broad clinical enterprise. Wang and colleagues analyzed 23,630 notes written by 460 clinicians in the inpatient medicine care setting at an urban academic medical center. They found that 46% of note context was copied, a much higher number than the 16% in our inpatient medicine notes. Wang also reported that direct care hospitalists wrote shorter notes (5,006 total characters) than medical students (7,053) and residents (6,720). We did not break out our note-writing data by
attending physician, resident physician, medical student, etc., but the average length of our inpatient medicine notes (6,876 characters) was on the high end of what Wang et al. reported.

In 2008, O’Donnell and colleagues surveyed 253 physicians who wrote inpatient notes electronically, finding that 90% reported using copy-paste, and 70% used it almost always or most of the time when writing daily progress notes. The vast majority of our providers used copy-paste at least occasionally, but only 42% of inpatient notes and 18% of ambulatory notes contained copied text. This difference is likely due to the improvements in EHR documentation capabilities, including templated text, that have been adopted since O’Donnell and colleagues’ survey in 2008.

**Use of Copy-Paste is a Poor Metric for Note Quality**

We were very careful in designing our OPPE reports to avoid framing copy-paste usage statistics as metrics for assessing provider competence or for inferring a connection to note quality. As Stetson and colleagues have argued, assessing quality of clinical documentation requires manual review. It’s possible, and probably common, for a short note to be “better” than a long note, and for a note that employed considerable copy-paste to be superior to a note where copy-paste was not used. Developing methods for assessing note quality is an important area for further research.

While we strongly caution against using targets associated with copy-paste behavior to evaluate clinician performance, we believe that identifying outliers (i.e., providers who seldom or never use copy-paste, and providers who use copy-paste far more often than their colleagues) may provide organizational leaders with targeted opportunities for further investigation. We believe that the OPPE process is an idea setting for such exploration and related conversations to take place. For example, if a provider rarely uses copy-paste, there may be an opportunity to educate her about the efficiency gains—and potential improvement in wellbeing—associated with appropriate use of the tool. Similarly, if a provider uses copy-paste far more extensively than his peers, a deeper dive may be warranted to assess whether the provider’s notes show evidence of misuse of the function.

**Appropriate Use of Copy-paste Can Reduce Documentation Burden**

The results of our study provide useful context for ongoing discussions among clinicians, informaticians, policymakers, and others about how to optimize the clinical documentation processes. In 2011, AMIA convened a policy meeting envisioning the future state of clinical data capture and documentation. The meeting produced a valuable set of guiding principles, including the admonition that “clinical data capture and documentation should be efficient and usable while enhancing the healthcare organization's and the care team's overall efficiency, effectiveness and productivity.” In January and February 2021, AMIA, the National Library of Medicine, Columbia University and Vanderbilt University hosted “25 By 5: Symposium to Reduce Documentation Burden on U.S. Clinicians by 75% by 2025,” with the stated objective to establish strategies and approaches to reduce the documentation burden on U.S. clinicians to 25% of the current level by 2025.

Holmgren and colleagues recently reported that the median U.S. clinician spends 90.2 minutes actively using the EHR per day—over 30 minutes more than non-U.S. clinicians. They concluded that U.S. clinicians’ greater EHR burden may be associated with nontechnical factors such as policies related to clinical documentation that may adversely impact clinician wellness. Promoting the appropriate and effective use of copy-paste and other EHR documentation support tools may help mitigate EHR burden and enable providers to focus on activities they perceive to be more impactful.

**Limitations**

Although we evaluated copy-paste practices for a larger number of providers than has previously been reported, they were all part of the same health system that had a single, well-established EHR. Our study did not assess differences in behavior among clinicians in different roles or stages of training (e.g., medical students vs. resident physicians vs. attending physicians). Additionally, the scope of our analysis was limited to note-writing and copy-paste use among physicians, PAs, and APRNs; many other members of the care team write clinical notes and may use copy-paste in different ways.
Conclusion

We developed a pragmatic approach to assess the use of copy-paste in aggregate, and provide individual training opportunities by including providers’ copy-paste usage statistics into the ongoing professional practice evaluation (OPPE) process that is required for hospital accreditation. This approach enables hospital administrators and other healthcare delivery organization leaders to monitor high-level usage of copy-paste at their institutions, and also provides individual feedback to providers about their copy-paste behavior relative to their peers. We believe that this process provides the appropriate balance in encouraging clinicians to use copy-paste as a time-saving tool while mitigating the associated risks.

Enhancing the IDEAS Framework with Ontology: Designing Digital Interventions for Improving Cancer Patients' Wellbeing

Nicole Veggiotti, MSc¹, Lucia Sacchi, PhD¹, Mor Peleg, PhD²
¹University of Pavia, Pavia, Italy
²Department of Information Systems, University of Haifa, Haifa, Israel

Abstract. Developing effective digital interventions to help patients form healthy habits is a challenging goal. IDEAS is a step-by-step framework that allows developers to draw ideas from intended users and behavioral theories, and ideate implementation strategies for them, followed by rapid prototype development. Based on our long experience with developing generic knowledge-based clinical decision support systems (CDSS) and integrating them with electronic health records (EHR) to deliver patient-specific advice, we observed a challenge that IDEAS is not addressing: the semantic detailing of the clinical knowledge behind the digital intervention and relevant patient data that could be used to personalize the digital intervention. To close the gap, we augmented two steps of IDEAS with an ontology that structures the target behavior as classes, derived from HL7 Fast Healthcare Interoperability Resources standard. We exemplify the augmented IDEAS with a case study taken from the Horizon 2020 CAPABLE project, that uses Fogg’s Tiny Habits behavioral model to improve the sleep of cancer patients via Tai Chi.

1. Introduction

People want to change their behaviors to improve their quality of life and make healthier choices. The most frequent behavior change areas [1] are smoking cessation, sleep quality improvement, weight loss, diet, physical activity, treatment adherence (i.e., adherence to medical recommendations including both taking medication and attending appointments), especially for chronic disease management. Digital interventions delivered through mobile technology can have great potential to facilitate such health behavior changes, as they provide improvements in efficacy, cost-effectiveness, safety, and scalability. Moreover, the literature highlights many successful digital interventions [2] developed for different types of behavioral changes such as Vegethon [3] for nutritional intervention, Happy Ending [4] for smoking cessation, SMART [5] for weight loss goal, and Headspace [6] for mindfulness. These systems cited above all utilize behavioral health techniques [7]. However, we have not encountered any ontologies that allow to detail the properties of the behavioral interventions that make them actionable in a general system.

To support the development of effective digital interventions for behavioral change, Mummah et al. [8] developed a framework and method called IDEAS (Integrate, DEsign, Assess, and Share). This framework uses a step-by-step approach to guide the development process using behavioral theory, design thinking, user-centered design, rigorous evaluation, and dissemination. While we find the IDEAS framework to be extremely constructive and useful, we believe it lacks formal and detailed structuring of digital interventions. In a previous study [9], we extended the IDEAS abstract concepts into concrete backend architectural components and graphical user-interface designs. In this paper, we propose an extension of IDEAS using an ontology to provide a conceptual framework for the definition of the behavior intervention. The behavioral theories exploited by the digital intervention and the clinical evidence for their success guide the structuring of the knowledge base. To structure the ontology, we rely on HL7 standards, and in particular on HL7's Fast Healthcare Interoperability Resources (FHIR) [10] standard. Defining a FHIR-based ontology allows standardizing the knowledge related to digital interventions for behavioural changes, which has not been done so far. Furthermore, this represents a step towards making the intervention actionable as an integrated part of a clinical decision support system (CDSS).

In this paper, we introduce the general methodology that we developed for the construction of such ontology, which is reusable in different application domains and for different target behaviors. We demonstrate our method through a case study taken from the Horizon 2020 CAncer PAatient Better Life Experience (CAPABLE) project (https://capable-project.eu/), where we are using Fogg’s Tiny Habits behavioral model [11] to improve the sleep of cancer patients.
2. Related work

The IDEAS framework

Mummah et al. [8] presented a ten-step guide to the development of effective digital health interventions that provides a disciplined way to incrementally translate behavioral theories into highly relevant and practical interventions. The ten steps are organized into a four-phases process as follows: Integrate phase, including (1) empathize with target users, (2) specify target behavior, (3) ground in behavioral theory; Design phase, including (4) ideate implementation strategies, (5) prototype potential products, (6) gather user feedback, (7) build a minimum viable product; Assess phase, including (8) pilot test to assess potential efficacy and usability, and (9) evaluation of the efficacy in an RCT; and Share phase, to (10) share intervention and findings.

Fogg’s Tiny Habits behavioral model

Fogg Behavioral Model (FBM) [11] is especially suitable to help patients turn interventions into habits. The model includes three main concepts: motivation, ability, and triggers. If all are present, they allow the behavioral change to occur and become a habit. Fig. 1 shows the core concepts of FBM. The vertical axis represents the motivation, which is driven by three different core motivators (pleasure/pain, hope/fear, and acceptance/rejection). The horizontal axis presents the ability of the subject to perform the behavioral task. Ability is affected by six different elements, called simplicity factors (time, money, physical effort, brain cycles, social deviance, and non-routine). The target behaviour has a trigger that prompts the subject to perform the behavioral task. Triggers can be a spark, a facilitator, or a signal.

This representation suggests, as the model asserts, that a person is able to achieve a target behavior if s/he has high motivation, high ability, and an effective trigger at the same instant; this places the person to the top-right of the curve, which is the actionable part where habits are formed. Note that in Fig. 1, three virtual interventions are shown as blue squares. Deep Breathing is not actionable as it is below the curve. In order to allow a person to adopt a behavior, we can increase her motivation or increase her ability by making the needed behavior smaller and easier to do.

Patient data models facilitating personalized decision support

In a previous CDSS that we developed, MobiGuide [12], we defined a patient model that included the patient’s clinical data, patient-reported symptoms, personal preferences, psychosocial context, and personal events. The model is both dynamic, as it reacts to current data from real-time monitoring of patient’s reporting and sensors tracking, and it is also highly adaptive to the personal preferences and contexts of the individual patient. The adaptive part of the model allowed us to suggest digital interventions that best fit with the patient’s characteristics. The model complied with HL7’s Virtual Medical Record.

Since that time, HL7 has released a more robust standard called Fast Healthcare Interoperability Resources (FHIR) [10]. It leverages existing logical and theoretical models to provide a consistent, easy to implement, and rigorous mechanism for exchanging data between healthcare applications. To achieve this goal, FHIR uses generic Resources (i.e., Patient, Observation), that define the properties of all exchangeable information.

3. Methods

We augmented two steps of the IDEAS framework with an ontology structuring digital interventions for behavioral change. An ontology is an explicit and formal specification of a shared conceptualization representing a consensual and shared knowledge of an abstract model of a world's domain or phenomenon [13]. By defining classes in the ontology, we can specify the main concepts related to digital non-pharmacological evidence-based interventions, which we call "virtual capsules". In addition, we also represent a patient model useful for creating personalized interventions.

To define the structure of the classes in the ontology, we leverage the SNOMED-CT vocabulary and HL7 FHIR resources (a) Patient, (b) Medication_Request, (c) Medication, and (d) Dosage. The ontology provides a way to model a structured conceptual framework representing knowledge on specific concepts and the relations among them. This provides an instrument that allows more expressiveness that simply extending "isolated" FHIR resources. Moreover, using an ontology would allow extending and using the model with standards other than HL7 FHIR. Our framework is generalizable because it in principle allows representing any kind of non-pharmacological intervention. It is in fact possible to add other types of capsules targeting a wide variety of behaviours and goals.

To conform to the Basic Formal Ontology [14], Patient is an Independent_Continuant, Medication is a Process_Profile, Medication is an Object, and Dosage is a Generically_Dependent_Continuant. Medication_Request models an order for the medication and the instructions for administration of the medication to a patient, including dosage which also includes timing. Although, as observed in [15], FHIR does not address non-pharmacological behavioral interventions, we extend FHIR by using the analogy between pharmacological treatments and virtual Capsules representing behavioral interventions. These two types of interventions share several characteristics, except for the fact that pharmacological interventions use drugs, whereas the interventions in the capsules are lifestyle changes related to cognitive behavioral therapies or physical activity. Therefore, in our ontology, both Medication and virtual Capsule are modeled as subclasses of a new, more general class, called Treatment_Option (Fig 2b). Similarly, Treatment_Request (Fig 2a) is a new class that generalizes Medication_Request and the new analogous subclass Capsule_Request. As in FHIR, Treatment_Request includes dosage information. Fig 2c shows instances of Dosage for a Medication_Request and for a Capsule_Request.

Similar to the FHIR Medication resource, Treatment_Option has a codable concept that specifies the preferred name and controlled clinical vocabulary code (e.g., SNOMED-CT code) for the medications or the digital behavioral intervention (e.g., Mindfulness, Tai Chi), for which internal codes are used.

In addition, the Treatment_Option class structures the interventions by providing a goal-based and evidence-based view. The goal of Treatment Option was inspired by the Goal structure for CDSSs developed by Kogan et al. [16], which uses the relationship may_treat of the National Drug File Reference Terminology (NDFRT) [17]. Hence Treatment option has the property may_treat, whose domain is FHIR Observation (e.g., "may treat sleep problems" or "may treat fatigue"). For the Capsule subclass, goals are extended to wellbeing dimensions by adding the property fits_wellbeing, whose domain is Wellbeing_Dimension (i.e., mental, social, physical, spiritual, functioning, and global wellbeing [18]). The evidence-based view provides Treatment_Option with a property to cite evidence that the proposed intervention is effective for the goal (reference_effectiveness).
