2021 AMIA Board of Directors

Officers

Patricia C. Dykes, PhD, RN, FAAN, FACMI
Brigham and Women’s Hospital

Chair/President

Gretchen Purcell Jackson, MD, PhD, FACS, FACMI, FAMIA
IBM Watson Health/Vanderbilt University Medical Center

Chair/President-Elect

Neil Sarkar, PhD, MLIS, FACMI
Brown University

Treasurer

Theresa A. Cullen, MD, FAMIA
Regenstrief Institute

Secretary

Directors

Julia Adler-Milstein, PhD, FACMI
University of California, San Francisco

Tiffany J. Bright, PhD, FACMI
IBM Watson Health

William Brown III, PhD, DrPH, MA
University of California, San Francisco

James J. Cimino, MD
University of Alabama at Birmingham Informatics Institute School of Medicine

Susan C. Hull, MSN, RN-BC, NEA-BC, FAMIA
MITRE Corporation

Laura K. Heerman Langford, PhD, RN, FAMIA
Intermountain Healthcare

Philip R.O. Payne, PhD, FACMI, FAMIA
Washington University in St. Louis

Wanda Pratt, PhD, FACMI
University of Washington

S. Trent Rosenbloom, MD, MPH, FACMI
Vanderbilt University Medical Center
Victoria L. Tiase, PhD, RN-BC, FAMIA, FAAN
Working Group Steering Committee Representative
NewYork-Presbyterian Hospital

Adam Wright, PhD, FACMI, FAMIA, FIAHSI
Vanderbilt University Medical Center

Li Zhou, MD, PhD, FACMI, FAMIA
Brigham and Women’s Hospital/Harvard Medical School

Ex-Officio Board Members

Genevieve Melton-Meaux, MD, PhD, FACMI
American College of Medical Informatics President
University of Minnesota

Josette Jones, RN
Academic Forum Executive Committee Chair
Indiana University

Eileen Koski, MPhil, FAMIA
Informatics Partnership Council Chair
IBM Research

Jonathan R. Nebeker, MD, MS
Health Systems Chair
Veterans’ Health Administration

Lynda Hoeksema, DNP, FNP-BC, RN-BC, FAMIA
Student Working Group Representative
Ohio State University

Tanya Tolpegin, MBA, CAE
Chief Executive Officer
AMIA
AMIA 2021 Annual Symposium Scientific Program Committee

Chair
Adam B. Wilcox, PhD, FACMI
Washington University in St. Louis

Vice Chairs
Randi Foraker, PhD, MA, FAHA, FAMIA
Washington University in St. Louis

Kensaku Kawamoto, MD, PhD, MHS, FACMI, FAMIA
University of Utah

Yves A. Lussier, MD, FACMI
University of Utah

Nadine McCleary, MD, MPH
Dana-Farber Cancer Institute

Members
Joanna Abraham, PhD
Washington University in St. Louis

Paul Aiyetan, MD, MS, PhD
Frederick National Laboratory for Cancer Research

Suzanne Boren, MHA, PhD
University of Missouri

Andrew Boyd, MD
University of Illinois at Chicago

Thomas Campion, PhD
Weill Cornell Medicine

Jin Chen, PhD
University of Kentucky

Yunan Chen, PhD
University of California, Irvine

Amar Das, MD, PhD
Merck
Karen Dunn Lopez, PhD, MPH, RN
The University of Florida

Jose Florez-Arango, MD, PhD, MS
Texas A&M University

Kate Fultz Hollis, MS, MBI
Oregon Health & Science University

Jennifer Garvin, PhD, MBA
The Ohio State University/VA

Tamara Goncalves Rezende Macieira, PhD, BSN
University of Florida

Assaf Gottlieb, PhD
University of Texas Health science center at Houston

Ilana Graetz, PhD
Emory Rollins School of Public Health

Eric Hall, PhD
Geisinger

Elizabeth Heitkemper, PhD, RN
The University of Texas at Austin

Harry Hochheiser, PhD
University of Pittsburgh

Felix Holl, MSc, PhD (candidate)
Neu-Ulm University of Applied Sciences/University of Munich

Julian Hong, MD, MS
University of California, San Francisco

Robert Jenders, MD, MS
University of California, Los Angeles

Suranga Kasthurirathne, PhD
Indiana University School of Medicine/Regenstrief Institute

Halil Kilicoglu, PhD
University of Illinois at Urbana-Champaign

Fabrício Kury, MD
Regeneron Genetics Center
Christoph Lehmann, MD  
UT Southwestern

Bruce Levy, MD  
Geisinger

Carol Macumber, MS, PMP, FAMIA  
Clinical Architecture

Ruth Masterson Creber, PhD  
Weill Cornell Medicine

Mollie McKillop, PhD, MPH  
IBM Watson Health

Xia Ning, PhD  
The Ohio State University Wexner Medical Center

Carlos Luis Parra-Calderón, MSc  
Andalusian Health Service - Virgen del Rocío University Hospital - Institute of Biomedicine of Seville

Eric Poon, MD, MPH  
Duke University Health System

Simon Poon, BSc, ME, MPH, PHD  
The University of Sydney

Fabian Prasser, Prof. Dr.  
Charité, Universitätsmedizin Berlin

Arvind Rao, PhD  
University of Michigan

Blaine Reeder, PhD  
University of Missouri

Renato Marcos Sabbatini, PhD  
HL7 Institute Brazil

Hojjat Salmasian, MD, MPH, PhD  
Brigham and Women's Hospital / Harvard Medical School

Matthew Scotch, PhD, MPH  
Arizona State University

Jane Snowdon, PhD  
IBM Research
Gillian Strudwick, RN, BNSc, MN, PhD
Centre for Addiction and Mental Health/University of Toronto, Canada

Vignesh Subbian, PhD
University of Arizona

Saanie Sulley, MD, PhD
National Healthy Start Association

Carolyn Sun, PhD, RN, ANP-BC
Hunter-Bellevue School of Nursing

Jason Thomas, BS
University of Washington

Thankam Thyvalikakath, DMD, MDS, PhD
Regenstrief Institute and Indiana University School of Dentistry

Jill Tiongco, MD, FAMIA
Montage Health

Umit Topaloglu, PhD
Wake Forest School of Medicine

Ece Uzun, MS, PhD
Brown University

Kavishwar Waghlikar, MD PhD
Harvard Medical School

Theresa Walunas, PhD
Northwestern University

Keith Woeltje, MD, PhD
Washington University School of Medicine

Po-Yin Yen, PhD
Washington University in Saint Louis

Kun-Hsing Yu, MD, PhD
Harvard Medical School

Teresa Zayas Cabán, PhD
Office of the National Coordinator for Health Information Technology

Ping Zhang, PhD
The Ohio State University

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publishers of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they are not responsible for any errors or omissions or for the results obtained from use of such information. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this book is accurate and that changes have not been made in recommended dose or in the contraindication for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
Adapting EHRs to Support Ongoing Provider Diagnostic Calibration

Julia Adler-Milstein, PhD¹, Andrew Olson, MD², Charlene Weir, PhD, MS³, Benjamin Rosner, MD, PhD¹, Robert El-Kareh, MD, MPH, MS⁴

¹University of California San Francisco, San Francisco, CA; ²University of Minnesota, Minneapolis, MN; ³University of Utah, Salt Lake City, UT; ⁴University of California San Diego, La Jolla, CA

Abstract

Timely and accurate diagnosis is a cornerstone of effective and efficient care. Mastery of clinical diagnosis requires ongoing learning and calibration of performance. Our current systems are not well-suited to providing the diagnostic outcome feedback to enable this calibration. The evolving functionality of EHRs has the potential to provide such feedback to practicing clinicians, which would be a significant step toward achieving the goal of life-long diagnostic improvement. Our panel brings together a diverse set of researchers focused on different aspects of improving the diagnostic process using health information technology. The panel will conclude with a conversation about next steps that can be taken in the short term to harness our EHR functionality to better support clinician diagnostic calibration. Learning objectives include: 1) Identify the types of information required for effective diagnostic calibration; 2) Describe the limitations and barriers of current EHRs to provide useful diagnostic outcome feedback; and 3) Describe initial efforts to improve the ability of current EHRs to support ongoing diagnostic calibration of trainees and practicing clinicians.

Panel Description

Diagnostic decision-making takes years to master and clinicians expect to improve their diagnostic skills through practice. However, the learning process requires that clinicians become aware of the outcomes of their diagnostic decisions and identify opportunities to improve in the future. Our healthcare system has become fragmented, with frequent patient handoffs and multiple specialties involved in care that limit the ability for clinicians to see diagnostic outcomes. This lack of outcome feedback is a critical barrier to diagnostic calibration, and thus physicians remain poorly calibrated and often overconfident.(1, 2) Physicians in training recognize the importance of outcome feedback, but encounter significant barriers to obtaining it reliably.(3) Feedback can take a variety of forms, with differing impacts on motivation and learning (both positive and negative). For example, normative feedback (comparison to peers) can be aversive, but also motivating. Whereas task feedback directs attention and increases involvement, it also involves more effort. The technological environment of clinical practice limits information and communication, thereby affecting both diagnostic decision-making and calibration. Healthcare organizations can take steps to enhance their EHR system to support diagnosis and fully utilize the power of health information technology. Practicing clinicians may also require specific training to take full advantage of this technology to improve their diagnostic processes over time.(4)

In this panel, we will describe aspects of how EHRs affect the diagnostic process and will provide practical suggestions for how EHR functionality can be used to facilitate life-long diagnostic calibration. Each speaker will present their work with a focus on how EHRs affect clinicians’ visibility into their own diagnostic processes and outcomes. The four presentations will be followed by a facilitated conversation to discuss the challenges and opportunities of...
developing EHR-based systems to support diagnostic calibration. The panelists represent different institutions (U of Minnesota, U of Utah, UCSF, UCSD) and bring diverse perspectives on the topic. Specifically:

**Julia Adler-Milstein, PhD** (moderator) will introduce the panelists and the topic. She will describe the issue of diagnostic calibration within the National Academy of Medicine model of the diagnostic process. She will present a framework describing current efforts to improve diagnostic calibration and how they are supported by EHRs and EHR data. She will then describe how each of the panelists’ work fits within that framework. Following the presentations, Dr. Adler-Milstein will facilitate the discussion between the audience and panel.

**Andrew Olson, MD** (panelist) will present the results from two projects related to diagnostic calibration. The first project, funded by the Gordon and Betty Moore Foundation, describes the lessons learned from discussing practices of feedback and calibration from other industries (e.g., aviation, meteorology and athletics). These discussions informed the creation of a diagnostic calibration framework. Dr. Olson will discuss how the EHR fits into that framework. The second project involves a non-EHR based educational project to provide diagnostic outcome feedback to medical trainees. Lessons learned from this project can help inform ways to use data within the EHR to create a scalable and sustainable diagnostic feedback system.

**Charlene Weir, PhD, MS** (panelist) will draw on her background in cognitive science and informatics and extensive experience applying cognitive theories to the design of health information technology to describe current barriers and opportunities to use EHRs to facilitate diagnostic calibration. She will integrate the psychological literature on feedback with EHR literature, focusing on how the lack of specification regarding diagnoses can impact “upstream” clinicians which in turn can have a significant impact on diagnostic performance. History and subjective data are critical to accurate diagnosis and pose particular informatics challenges—much of subjective data provided by patients and diagnostic assessments of clinicians are found in large sections of free text which are nearly impossible to find and hard to integrate into a bigger picture. Clinician workarounds for these challenges involve verbal communication, but much of this information is lost, especially during transitions of care. Despite these challenges, Dr. Weir will discuss several potential avenues to improve clinician-EHR collaboration in diagnosis. These include improved feedback systems, more effective data visualization and more helpful representation of clinical problems.

**Benjamin Rosner, MD, PhD** (panelist) will present results from work to use EHR metadata to improve patient attribution—assigning patient-level metrics to specific clinicians. Optimizing attribution is crucial to ensure that each clinician receives diagnostic feedback on the correct set of patients. Ideally, this attribution can be done in an automated manner based on who has taken actions in the patient chart (e.g., who wrote orders, who viewed the chart). In some settings, this will be more straightforward than others. For example, in the ambulatory care setting, a primary care provider (PCP) would likely own most or some degree of attribution, but this may be diagnosis dependent. Where specialists are involved, diagnostic accuracy may be a shared process, involving both the timeliness of referral by the PCP and referral to the correct specialty by the PCP (e.g., refer to Rheumatology vs Orthopedics for joint pain), as well as the specialist arriving at the correct diagnosis in a timely manner. In the inpatient setting, attribution based on who has interacted with the EHR for a given patient grows more complex. A hospitalist may be on service for a week and then hand off a patient’s care to another hospitalist, so both might be attributable to some degree. In team-based care, such as that associated with trainees (interns, residents), using the EHR to determine attribution is also complex. Dr. Rosner will discuss an approach to account for team-based care using EHR metadata from UCSF in which attribution for each patient on the team’s census can be quite accurately determined.

**Robert El-Kareh, MD, MPH, MS** (panelist and organizer) will describe initial results from an EHR dashboard that automates patient diagnostic outcome feedback to emergency medicine (EM) and internal medicine (IM) clinicians within the hospital. The presentation will illustrate how the design, implementation and educational issues raised by the preceding panelists were considered in an active, EHR-enabled feedback system within an academic medical center. Dr. El-Kareh will describe the evolution of the current system and how it is being used to support both targeted educational opportunities for trainees and ongoing reflection of patient outcomes by all clinicians within those specialties.
Topic Rationale

Diagnostic calibration is an essential aspect of high-quality and efficient care, but EHR design has not focused on supporting this process. Evolving functionality of EHRs and the data they contain can be harnessed to facilitate ongoing assessments of diagnostic outcomes at the clinician-level. However, the most effective methods for pursuing this work are yet to be determined. We anticipate that the audience for this panel will be clinical informaticists representing a wide range of healthcare settings who are working to support diagnostic excellence and its impact on patient safety, organizational efficiency and provider well-being.

Statement of Agreement to Participate

All panelists have approved of this submission and agreed to participate.

Panel Participant Details

Julia Adler-Milstein, PhD. Director, Center for Clinical Informatics & Improvement Research. Professor, Department of Medicine, University of California San Francisco
Andrew Olson, MD. Associate Professor of Medicine & Pediatrics, University of Minnesota Medical School
Charlene Weir, PhD, MS. Professor of Biomedical Informatics, University of Utah
Benjamin Rosner, MD, PhD. Associate Professor, Department of Medicine, University of California San Francisco
Robert El-Kareh, MD, MPH, MS. Associate Professor, Department of Medicine, University of California San Diego

References

Abstract

COVID-19 has stimulated innovation and collaboration on an unprecedented global scale. The COVID-19 Knowledge Accelerator (COKA) Initiative is an international volunteer organization with over a hundred participants and 11 active working groups advancing standards, systems, terminologies, metadata frameworks, tools, and demonstration projects for computable expression of biomedical knowledge. COKA is an evolution of the Fast Healthcare Interoperability Resources (FHIR®) for Evidence Based Medicine (EBM) Knowledge Assets (aka EBMonFHIR) project. These organizations are working to find solutions for the current inefficiencies in the scientific dissemination systems we use today. Using structured (computable) results data directly from research and research publications will greatly accelerate evidence synthesis by reducing redundant efforts and enhancing interoperability. A panel of COKA leaders with diverse clinical informatics experience and research endeavors will share their most recent accomplishments and challenges. Participants will learn what it takes to make science computable and how to participate in the COKA initiative.

Panel Description

Our panel brings diverse perspectives from clinical and research informatics, systems engineering, epidemiology, and evidence-based medicine. We will present an overview of the COKA Initiative and highlights of the most impactful developments to date and the most pressing challenges to solve. The panel will engage the audience in participation during the presentation and facilitate ongoing participation after the conference.

Brian S. Alper, MD, MSPH (the overall project lead) will serve as moderator and introduce the origins of the COKA Initiative. In addition to being project lead for COKA, Dr. Alper is the CEO of Computable Publishing LLC which is working to create a paradigm shift in the way we interact with scientific literature. Dr Alper will guide the panel through a discussion of functional applications to make science computable.

Harold Lehmann, MD, PhD is professor of informatics at Johns Hopkins Bloomberg School of Public Health. His research interests span medical informatics, evidence-based medicine, decision making, biostatistics, decision analysis and Bayesian communications. Dr. Lehmann will introduce issues encountered in efforts of the National COVID Cohort Collaborative (N3C) to systematically collect data from electronic health records and harmonize these data as a centralized resource for collaborative research.

Joanne Dehnbostel, MS, MPH is an epidemiologist and former laboratory scientist and is a project leader for Code System Development. She will introduce the challenges with lacking structured vocabularies for science, the open protocols for global collaborative development, and progress achieved in defining code systems for risk of bias, study design, statistic type, and statistical model concepts.

Andrey Soares, PhD, is an Assistant Professor in the Department of Medicine at the University of Colorado Anschutz Medical Campus. His research interests include data interoperability, clinical decision support systems, natural language processing and data analytics with the goal of developing applications and digital solutions to support evidence-based decision making. Dr. Soares will introduce some of the user interfaces and APIs used and developed by the COKA project, and share the current challenges in next-stage developments.

Vignesh Subbian, PhD is a Joint Assistant Professor of Biomedical Engineering and Systems and Industrial Engineering at the University of Arizona. Dr. Subbian also leads the Communications Work Group within the COVID-19 Knowledge Accelerator. Dr Subbian will show the most recent project developments (such as a systematic meta-review analyzing systematic reviews of steroid therapy for COVID-19 and converting all the data to computable evidence) and discuss the challenges in human-machine interaction and how we are overcoming those challenges.

The panel discussion will be a lively Q&A session based on the interests of the audience. In addition the moderator will facilitate a structured dialog that will follow a format approximating:

1) Audience participants are asked to report an unresolved challenge in communicating (finding, transforming, or sending) scientific evidence.
2) The group discusses what may be needed to overcome the challenge, such as a structural element in the schema for data exchange, a change in controlled vocabularies, or an improvement to the instructional materials explaining how to use a particular tool.

3) The group discusses alternatives for overcoming the challenge.

4) The group decides a suggested plan for next steps to solve the challenge or further investigate solutions.

**Importance and Focus**

The topic of COVID-19 is timely, urgent, needed, and attention grabbing. The topic of scientific knowledge acceleration is timely with recent advances in the Mobilizing Computable Biomedical Knowledge community, urgent as it applies immediately to COVID-19 knowledge, needed because it is not happening naturally as we continue to operate in a document-based world not using computers to their full potential for science communication, and attention grabbing because making science computable is a direct interest to anyone engaged in medical informatics.

The participants who would benefit most are researchers and knowledge management professionals who would benefit from being able to express biomedical evidence in computable (interoperable, re-usable, reproducible, shareable) formats.

**Discussion Questions to Enhance Audience Participation**

What would you be able to do if you could get scientific knowledge in a computable form?

What would you do if you could share scientific knowledge in a computable form?

Why are you not sharing scientific knowledge in a computable form now?

If you are, what makes it difficult?

How can you be part of the solution?

**Statement of Participation**

All participants have agreed to take part on the panel.

Using Specific COVID-19 Targets and Patient Care Settings as a Springboard for Driving Global Improvements in the Learning Health System Cycle for COVID-19 and Beyond

Steve Bernstein, BS1; Jerome A. Osheroff, MD2; Julia Skapik, MD3; Christopher Tignanelli, MD4; Matthew Burton, MD5

1Agency for Healthcare Research and Quality, Rockville, MD; 2TMIT Consulting, LLC, Naples, FL; 3National Association of Community Health Centers, Bethesda, MD; 4Department of Surgery, University of Minnesota, Minneapolis, MN; 5Apervita, Inc., Chicago, IL

Abstract

AHRQ formed the ACTS COVID-19 Evidence to Guidance to Action Collaborative in early 2020 as a learning community to help participants respond to the emerging pandemic. This Collaborative was an outgrowth of the AHRQ evidence-based Care Transformation Support (ACTS) initiative, which had spent the previous year developing a shared vision for health IT-enabled, evidence-informed care delivery and transformation, and a draft stakeholder-driven Roadmap for broadly achieving this vision. This panel will outline AHRQ’s goals and process for delivering broad value from the Collaborative and provide perspectives from three participants on how the Collaborative supported their efforts to improve care processes and outcomes for COVID-19 and beyond. After panelist presentations, the second session half will be interactive discussion with attendees (likely including other Collaborative participants) to surface opportunities to leverage efforts such as the Collaborative to accelerate care transformation within and across organizations.

Introduction

In the U.S. healthcare system, the flow of data, evidence, knowledge, and tools to support critical decisions and actions is highly siloed and fragmented. This leads to preventable problems with care and patient outcomes, unnecessary expenditures, suboptimal patient experience, and overburdened clinicians.1 While there have been major investments in health information technology (IT),2 value from these investments,3 and efforts to standardize decision support4,5 there remains a chasm between the degree of transformation achieved in other industries and that seen in healthcare. The COVID-19 pandemic has dramatically highlighted the urgent need to produce a virtuous learning health system (LHS) cycle where the flow from data to evidence to guidance to action and back to data continually improves. Ultimately, the goal – for COVID and beyond – is to achieve the Quadruple Aim6 to simultaneously enhance patient experience, improve population health, reduce costs, and improve clinician experience in care delivery.

The Agency for Healthcare Research and Quality (AHRQ) launched the AHRQ evidence-based Care Transformation Support (ACTS) Initiative7 in 2019 to develop a Roadmap for how to improve access to and use of resources that AHRQ and others provide to improve care delivery and transformation toward the Quadruple Aim. The central goal for ACTS is to ensure that evidence, knowledge, and guidance resources from AHRQ and others are optimally findable, accessible, interoperable, reusable (FAIR) for all who can benefit from them. To achieve this goal, ACTS established a Stakeholder Community to help outline the current state of evidence-informed care delivery and transformation, a shared desired future vision, and a proposed roadmap to get there.

In early 2020, AHRQ launched the ACTS COVID-19 Evidence to Guidance to Action Collaborative in response to the emerging pandemic as a learning community helping participants improve the LHS cycle for COVID-19 and beyond. This collaborative was formed as a step towards implementing the draft ACTS Roadmap approach to achieve the future vision. The central goals of the ACTS COVID-19 Evidence to Guidance to Action Collaborative are:

1) Cross-fertilize.accelerate efforts to develop & deliver COVID-19 evidence-based guidance and tools to patients and care teams
2) Measurably improve care and outcomes for selected targets and settings, and promote scaling to many others
3) Advance tools, standards, and collaborations needed for a knowledge ecosystem that supports LHSs (See Figure)
Leveraging the ACTS COVID Collaborative to Improve Care Delivery/Outcomes and the LHS Cycle

The Collaborative efforts are anchored by a diverse community of stakeholders who meet weekly as a learning community. Collaborative participants include care delivery organizations (CDOs) who are developing, implementing, and evaluating living CDS interventions focused on specific COVID-19 issues, health IT suppliers, standards developers, evidence synthesis and guidance developers, patient advocates, and representatives from many other stakeholder groups. Efforts to improve activities around the knowledge ecosystem/LHS cycle, and the results these activities produce, are centered on specific clinical COVID-19 patient care improvement targets (e.g., severity assessment/triage, use of anticoagulants, and managing Post-acute Sequelae of COVID-19 (“Long COVID”)) being addressed in specific care delivery organizations (e.g., Veterans Health Administration, University of Minnesota, OHSU, health centers).

Collaborative participants gather weekly by web meeting and use online collaboration tools and additional ad hoc meetings to foster learning and collaboration toward improving participants’ ecosystem-related efforts and results, and to define strategies for broader ecosystem cycle enhancements. Organizations focused on the specific topics share their strategies, challenges, successes, needs, insights, tools and approaches. Other participants provide feedback, support, and collaboration, and also benefit from valuable learning shared and related discussions. These activities are seeding execution of the proposed ACTS Roadmap by providing laying foundations for five core Roadmap activities:

- Seeding cross-stakeholder coordination efforts
- Defining and laying the foundation for enhanced ecosystem cycle infrastructure, standards, and tools
- Providing concept demonstrations for enhanced/computable evidence and guidance content & processes
- Providing concept demos for enhanced guidance implementation
- Laying the foundation, including best practices, for evaluation, planning, piloting, scaling

Proposed Panel

The panel’s goal is to build on the valuable dialogue, activities, and collaboration reflected in the ACTS COVID-19 Collaborative to benefit more organizations from this work and accelerate widespread progress toward the ACTS future vision. Annual Symposium attendees typically reflect many key LHS stakeholder groups, and this panel is aimed at such participants that have care transformation – for COVID-19 and beyond – as a focus.

Mr. Bernstein is the AHRQ project officer for ACTS and will describe AHRQ’s goals and context for ACTS and the COVID-19 Collaborative. Dr. Osheroff chairs the Collaborative and will describe the Collaborative strategy and results. Other panelists who are participants will discuss how they have benefitted from the Collaborative, including their activities, learnings and results related to the knowledge ecosystem, and implications from these for the audience:

Dr. Julia Skapik, National Association of Community Health Centers (NACHC), will discuss efforts in health centers related to improving care and outcomes for COVID-19 including Post-acute Sequelae for COVID-19 (PASC/‘Long COVID’), focusing on their challenges, needs and successes related to improving the knowledge
ecosystem cycle for this target. She will also address how the ACTS Collaborative has supported these efforts and implications for others. Dr. Christopher Tiganelli, University of Minnesota (UMN), will discuss efforts with the 12 hospitals in the UMN health system related to anticoagulation use and outcomes for hospitalized patients with COVID-19, also focusing on their challenges, needs and successes related to improving the knowledge ecosystem cycle for this target. He will also address how the ACTS Collaborative has supported these efforts and implications for others. Dr. Matthew Burton, Apervita, lead for the C19HCC Digital Guideline Working Group and contributor the HL7 FHIR Clinical Practice Guidelines (“CPG on FHIR”) Implementation Guide will discuss work to put this Implementation Guide into action with ACTS Collaborative participants (including UMN) to provide living, standards-based computable guidance for COVID-19 targets. He will also discuss challenges, needs, success and opportunities for leveraging initiatives such as the ACTS COVID Collaborative to make standards-based computable guidance widely available for many COVID-19 targets and beyond – including implications for others.

The panel’s second half will be devoted to interactive discussion among panelists and audience members (likely to include other Collaborative participants) to surface opportunities to further accelerate efforts to develop and deliver evidence-based guidance and tools for COVID-19 and beyond to patients and care teams, while simultaneously improving each of the other components of the LHS cycle. Prompts for this discussion include:

- Where do your efforts lie on the LHS cycle, and what challenges have you faced receiving inputs from preceding steps in the cycle, producing your deliverables, and optimizing their value in subsequent steps in the cycle?
- Are there opportunities to enhance the efficiency and effectiveness of your efforts through approaches, tools, standards, and collaborations as outlined in this panel?
- What would specific synergies between your efforts/plans and the Collaborative’s work look like, and what next steps to cultivate them would be helpful?

All participants have agreed to take part in the panel.

Conclusion

The COVID-19 pandemic has focused sharp attention on how far healthcare is from achieving LHSs and the urgency and high stakes for closing this gap. The ACTS COVID Collaborative is taking important steps in this direction, centering its efforts on specific care delivery organizations and their efforts related to addressing specific COVID-19 targets – in ways that can scale learning and other results to many other settings and targets. This interactive panel will build on this work and leave attendees with valuable insights and opportunities to advance their efforts in this area in ways that further accelerate progress toward a shared LHS future vision.

Representation Requires Intentionality: Our Journey to Creating a Diverse Informatics Workforce

Tiffani J. Bright, PhD, FACMI1, Chinyere Agunwa, PhD2, Kim Unertl, PhD, FACMI3, Oliver J. Bear Don’t Walk IV, MS4, Yalini Senathirajah, PhD5

1IBM Watson Health, Cambridge, MA; 2IBM Research, San Jose, CA; 3Vanderbilt University Medical Center, Nashville, TN; 4Columbia University, New York, NY; 5University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Abstract

Cultivating a diverse and inclusive workforce is critical for the biomedical informatics profession, both from a perspective of fairness and equity and to avoid technology that fails to address concerns of significant portions of the population or that introduces unintentional biases. However, having diversity and representation in the informatics workforce requires intentionality and deliberate action to combat systemic inequalities and requires focused efforts to ensure inclusive professional environments. This challenge necessitates active engagement in order to continue our work of transforming health and healthcare to ensure equitable outcomes. This panel reports on the experiences of informaticians and data scientists across academic and industry settings in creating diverse and inclusive environments. The learning objectives are to: 1) describe why a diverse workforce and inclusive working environments are critically important goals of the informatics field; 2) gain an understanding of lessons learned and best practices for broadening participation in informatics; and to 3) learn about resources to support efforts to broaden participation in informatics.

Introduction

Biomedical informatics presents many new opportunities and career directions. However, the field still lacks racial and ethnic diversity and representation; these disparities are present in doctoral programs1. When representation is missing from the informatics workforce, key voices are also missing in the design, implementation, and evaluation of technologies. The absence of these voices may lead to failures in scientific objectivity and the potential loss of innovative solutions to some of the most critical health and healthcare problems we face today, as well as increasing the potential for unintentional incorporation of biases into the design of technology-based interventions. Thus, building a diverse informatics workforce is necessary not only for the profession that will design solutions to solve health care problems, but also for transforming health and healthcare towards equity-centered care. These challenges are not unique to our field; it is time for informatics professionals, individually and collectively, to develop and implement strategies that will build and support diverse and inclusive environments5.

This panel will provide an overview of lessons learned during efforts to broaden the informatics workforce, based on speaking engagements at national conferences, the development of internship programs, and the creation of student outreach events and community college workforce programs. This panel should be of interest to informatics professionals who are interested in: 1) understanding practical strategies needed to build a diverse informatics workforce and 2) learning about resources to support those efforts. Each panelist will talk for 10-12 minutes and cover the following:

1. Why diversity in informatics matters to health and healthcare
2. Intersectionality and how it increases barriers and challenges related to exclusion
3. Pathways into informatics and institutional issues
4. The importance of mentoring, sponsorship, and career advancement

The moderator and panelists include:
Tiffani J. Bright, PhD, FACMI, Biomedical Informatician, IBM Watson Health

Dr. Bright is an informatician with expertise in the development and evaluation of health information technologies and clinical decision support. For the last 15 years, Dr. Bright has built a career spanning academia, public health,
government, and industry, and using her background and expertise as a platform to create a diverse and inclusive informatics and STEM workforce through local and national initiatives. She is also the founder of the AMIA First Look Program, which introduces undergraduate women to the informatics field. She serves as Chair of the AMIA Diversity, Equity, and Inclusion Task Force, the AMIA Board of the Directors, and the Women in AMIA Steering Committee. She is a Fellow of the American College of Medical Informatics (ACMI) and a blackcomputeHER Fellow.

Chinyere Agunwa, PhD, Research Staff Member, IBM

Dr. Agunwa is a Research Staff Member at IBM. She joined IBM Research in December 2015 as a medical image analysis and machine learning researcher on the Medical Sieve Radiology Grand Challenge project. She works on machine learning applications. Dr. Agunwa received her MS and PhD degrees in Electrical Engineering from Stanford University. She graduated with a double major in Computer and Electrical Engineering, and double minor in Computer Science and Mathematics from Louisiana State University (LSU). She has spoken at the Grace Hopper Celebration of Women in Computing, mentored high school girls through the Girls Who Code program, and led student outreach panels.

Kim Unertl, PhD, FACMI, Associate Professor of Biomedical Informatics, Vanderbilt University Medical Center

Dr. Unertl directs the Vanderbilt Biomedical Informatics Summer Program to engage high school and undergraduate students in biomedical informatics research. Her research focuses on clinical workflow, technology usability, and women’s health. She has mentored almost 20 high school and undergraduate students in summer research experiences over the last 10 years and has also mentored medical and graduate students. As part of her summer internship program work, Dr. Unertl developed and implemented a professional development program for summer interns based on the Entering Research curriculum from the Center for the Improvement of Mentored Experiences in Research. She is one of the co-founders of the AMIA High School Scholars Program and also serves on AMIA’s Education Committee.

Oliver J. Bear Don’t Walk IV, MS. PhD student in Biomedical Informatics, Columbia University

Oliver will moderate the panel and describe efforts to increase representation of persons excluded because of their ethnicity or race (PEERs) in STEM fields. Oliver is a PhD student studying the intersection of ethics, bias, and clinical natural language processing (NLP). Their work has been shaped by their Apsáalooke background and an emphasis on using education to give back to vulnerable populations. Oliver’s thesis will use NLP to recover social and behavioral determinants of health from clinical notes and provide best practices for ethically using such information to support healthcare and research. Oliver has served as a mentor and instructor for programs such as IndigiData and the Columbia DBMI Summer Research Program, aimed at increasing the representation of PEER students in STEM fields.

Yalini Senathirajah, PhD. Associate Professor in the Department of Biomedical Informatics, University of Pittsburgh School of Medicine.

Dr. Senathirajah has experience teaching and mentoring students and non-trainees seeking to enter the field, at both majority minority institutions (e.g., Downstate medical center, 85% minority), ivy league academic institutions, and others. Her research involves clinician-facing and patient-facing technology interventions to improve healthcare, particularly among minority, underserved, or otherwise non-mainstream patients. Her work at 9 academic institutions has put her in a position to describe lessons learned. She has acted as formal mentor in the NIH PRIDE program, University of Pittsburgh’s iBRIC and Downstate’s Arthur Ashe programs for research training for minority high school and undergraduate students.

Anticipated Audience

Informatics professionals seeking a deeper understanding of why a diverse and inclusive workforce and environment are crucially important goals for the informatics field. Informatics professionals looking to learn about best practices and resources for broadening participation in informatics.

Discussion Questions

1. How can we ensure that we are not perpetuating the myth of the pathway problem in informatics?
2. What concrete steps can each person take within their own organization to move towards a more inclusive
3. What are some ways organizations can ensure persons historically excluded from health informatics positions of influence based on ethnicity or race (PEERs) are mentored and positioned for career advancement opportunities?

Participant Statement
All panelists have agreed to take part in the panel.

Conclusion
Cultivating a diverse and inclusive workforce is critical for the biomedical informatics profession to advance health and healthcare transformation; this is a foundational step to ensuring informatics-enabled solutions are equity-centered and deliver equitable patient and population outcomes. To achieve these goals, intentional and deliberate action is needed to address systemic inequalities that have resulted in exclusions of individuals due to ethnic or racial background (PEERs) in STEM fields such as biomedical informatics.

Use of Healthcare Information Technology and Data Platforms to Inform Pandemic Response: Perspectives at the Intersection of Academic Healthcare Provider Organizations and Industry Partners

Atul J. Butte, MD, PhD1; Christopher A. Longhurst, MD, MS2; Amy P. Abernethy, MD, PhD3; Gretchen P. Jackson, MD, PhD4,5; Philip R.O. Payne, PhD6

1University of California San Francisco, Bakar Computational Health Sciences Institute, San Francisco, CA; 2University of California San Diego, Departments of Biomedical Informatics and Pediatrics, La Jolla, CA; 3Verily, San Francisco, CA; 4IBM Watson Health, Cambridge, MA; 5Vanderbilt University Medical Center, Departments of Surgery, Pediatrics, and Biomedical Informatics, Nashville, TN; 6Washington University in St. Louis, Institute for Informatics, St. Louis, MO

Abstract
This panel will summarize the collective experience of several academic healthcare provider organizations and industry partners as those organizations sought to understand and respond to the COVID-19 pandemic in the US. Such measures included collecting and analyzing data corresponding to healthcare organizations, public health departments, socioeconomic indicators, and additional signals collected directly from individuals and communities. In addition, our panelists will describe their experiences when seeking to use electronic health record (EHR) derived data, given the critical role of EHRs when seeking to improve clinical care, research and inform public health decision-making. The speakers will also describe their perspective on current challenges in the data ecosystem and the technology infrastructure relevant to the COVID-19 response. Such infrastructure includes registries and clinical data networks to support population-level analyses. Finally, we will propose a specific set of strategic next steps to increase interoperability, overall organization, and efficiencies of such technologies and approaches, improve the delivery of care at the individual and population levels, and prepare for future public health emergencies.

Introduction
Healthcare information technology (HIT) and the data assets derived from such platforms have and continue to be essential to our collective response to the COVID-19 pandemic [1, 2]. The use of such technology and data can inform clinical decision-making [3, 4], enable resource and personnel management [5], and enhance inter-and intra-organizational communications and coordination. Realizing these types of benefits, given the unique challenges presented by the pandemic, have required close collaboration between healthcare provider organizations and industry, as well as engagement by diverse experts, including information technology professionals, informaticians, and data scientists, to name a few of many such roles and viewpoints. These multi-disciplinary collaborations and teams have served to change our collective thinking as to how such entities and individuals can and should interact and how those interactions, in turn, can improve the quality, safety, and outcomes of care, even in emergencies. As such, they are informative not only to how we respond to COVID-19 in the present but also how we re-envision the HIT and data infrastructure and operations of a modern healthcare system that can deliver improved quality, safety, and outcomes of care, in the context of both conventional care delivery, as well as future public health emergencies.

This panel will review the experiences of a group of academically based healthcare provider organizations and industry partners, working in close coordination with regional partners and communities of practice to respond to COVID-19, leveraging existing HIT and data platforms and resources. We will then go on to propose a set of future research and practice directions, informed by those experiences, to ensure we learn from this collective set of “lessons learned” to improve our ability to translate biomedical informatics and data science innovations into widespread use, via the creation and sustainment of cross-sector and stakeholder collaborations.

Topic importance and timeliness
The current challenges and opportunities surrounding HIT and associated data platforms to respond to COVID-19 are compared to previous pandemics, such as SARS and Ebola; there are essential differences in said experiences. These differences are primarily a function of 1) broad adoption and use of electronic health records (EHRs) and associated clinical decision support and analytical capabilities; 2) rapid advances in biomedical data science, spanning a spectrum
from data integration and harmonization to visualization to the application of Artificial Intelligence (AI); and 3) increasing availability of socio-demographic, patient-generated, and sensing data that extend beyond the traditional clinical environment. These new resources and capabilities can and should enable more rapid translation of biomedical informatics and data science innovations from the lab to operational use, as seen in our response to COVID-19. However, a shared “roadmap” for how such “informatics translation” can and should occur does not exist, which may preclude the full realization of the benefits of moving innovative solutions into widespread use. This represents a significant gap in knowledge and practice that has surfaced as a function of the current pandemic and that we must continue to address as we move into our “new normal.” Suppose we are successful in addressing this gap. In that case, as is noted above, we can leverage HIT and data assets in new and innovative ways that can improve conventional care delivery at the individual and population levels and our preparedness for future public health emergencies that may present themselves. This panel will focus on the above issues, as it is intended to catalyze a robust, community dialogue concerning how we can and should evolve the intersection of biomedical informatics and data science with both healthcare provider organizations and industry partners to improve “informatics translational” and ensuing benefits to the patients and communities we collectively serve.

Speakers

Dr. Atul J. Butte (University of California San Francisco)

Atul Butte, MD, PhD is the Priscilla Chan and Mark Zuckerberg Distinguished Professor and inaugural Director of the Bakar Computational Health Sciences Institute (bchsi.ucsf.edu) at the University of California, San Francisco (UCSF). Dr. Butte is also the Chief Data Scientist for the entire University of California Health System, the tenth largest by revenue in the United States, with 20 health professional schools, 6 medical schools, 6 academic health centers, 10 hospitals, and over 1000 care delivery sites.

Dr. Christopher A. Longhurst (University of California San Diego)

Dr. Longhurst serves as Chief Information Officer and Associate Chief Medical Officer for Quality and Safety at UC San Diego Health. As CIO, Dr. Longhurst oversees all operations and strategic planning for information and communications technology. He is responsible for planning and developing all administrative and clinical information systems related to operating UC San Diego Health hospital and clinical facilities, including electronic health records and the MyUCSDChart system. As Associate CMO for Quality and Safety, Dr. Longhurst is focused on building upon current quality improvement efforts and aligning people, processes and technology to achieve UC San Diego Health’s quality and accountability goals.

Dr. Amy P. Abernethy (Verily)

Dr. Abernethy is the President of the Clinical Research Business at Verily, an Alphabet Company founded at the convergence of healthcare, data science and technology, where she has responsibility for the company’s Baseline program and other initiatives to support a broad range of clinical trials and real-world evidence (RWE) studies. Before joining Verily in July, Dr. Abernethy was Principal Deputy Commissioner and Acting Chief Information Officer of the US Food & Drug Administration.

Dr. Gretchen P. Jackson (IBM Watson Health and Vanderbilt University Medical Center)

Dr. Gretchen Purcell Jackson is the Vice President, Chief Health and Science Officer at IBM Watson Health and an Associate Professor of Surgery, Pediatrics, and Biomedical Informatics at the Vanderbilt University Medical Center. She is an internationally recognized informatician and accomplished clinical surgeon with over 25 years of contributions to informatics research, innovations in health information technologies, and surgical science. She is chair-elect for the Board of Directors for the American Medical Informatics Association (AMIA) and an elected fellow of the American College of Medical Informatics (ACMI).

Dr. Philip Payne (Washington University in St. Louis)

Dr. Payne is the Associate Dean for Health Information and Data Science and Chief Data Scientist at the Washington University School of Medicine. In addition, he is the Janet and Bernard Becker Professor and founding Director of the school’s Institute for Informatics (I2). Since March of 2020, Dr. Payne has led the joint COVID-19 analytics workgroup convened by Washington University and its partners at BJC Healthcare. This workgroup has served to not only support the operational needs of Washington University Physicians and BJC Healthcare in meeting the challenges posed by COVID-19 but has also served as the primary data, information, and knowledge “engine” for the St. Louis
Metropolitan Pandemic Task Force, a coalition of elected officials, public health organizations, and HPOs that collectively serve the 3.4M citizens of the St. Louis MSA.

Questions to be addressed:

1) How have cross-organizational and sector partnerships helped to accelerate “informatics translation” during the COVID-19 pandemic, and how can we replicate those outcomes as we enter into a post-pandemic “new normal”?

2) What gaps in current HIT and data platforms have the pandemic surfaced that require further investigation or the development of novel solutions? Similarly, where have we demonstrated that the maturity of HIT and data platforms is sufficient such that further research is not necessarily needed or likely to generate substantial impact?

3) How can healthcare provider organizations work with industry more effectively to accelerate novel HIT development, deployment, and scaling, in more “normative” circumstances than the current public health emergency?

4) How should we prepare both a research and development roadmap and workforce development strategies to ensure that the Biomedical Informatics and Data Science communities are actively engaged in and providing value to these types of efforts?

Conclusion

Our group of panelists represents the type of cross-organizational and sector partnerships that have both enabled successful responses to COVID-19, as that can serve as a template for accelerating future “informatics translation” when we move into a new (non-emergent) normal. By engaging the AMIA community in a dialogue surrounding these issues, we hope to promote the development of a shared “roadmap” that will ensure the success of the impact of Biomedical Informatics and Data Science research and practice in such contexts, both improving conventional care delivery, as well as ensuring we are better prepared for future, analogous public health emergencies.

LEAP 2020: Cutting Edge Health Information Technology Tools for Research

Kevin Chaney, MGS1, Kenneth D. Mandl, MD, MPH2, Kristen Miller, DrPh, CPPS3,
1Office of the National Coordinator for Health Information Technology, Washington, DC;
2Computational Health Informatics Program, Boston Children’s Hospital, Boston, MA;
3National Center for Human Factors in Healthcare, MedStar Health, Washington, DC

Abstract

The utilization of application programming interfaces (APIs) in healthcare has potential to enhance population health, patient care and research. Furthered by regulation issued by the Office of the National Coordinator for Health Information Technology (ONC) and the Centers for Medicare & Medicaid Services (CMS), patients and providers will have greater access to electronic health information. In anticipation of a new generation of health IT, ONC issued the Leading Edge Acceleration Projects (LEAP) in Health IT funding opportunity, to advance well-designed, interoperable, and scalable health IT for care and research. This panel will present findings, learnings, and accomplishments from the LEAP work to-date and discuss objectives of the newest 2020 funded initiatives, focused on reducing provider and health system burden of utilizing health IT, while incorporating data access and use via an API for innovative purposes in support of care and research. The panel will showcase the two most recent innovative initiatives, an effort to build a platform that leverages bulk data to support an ecosystem for research and learning, and a landscape analysis to explore, identify, and describe current open health IT-based tools for research.

Introduction

The Office of the National Coordinator for Health Information Technology (ONC) is at the forefront of the administration’s health information technology (IT) efforts and leads efforts to support the adoption of health information technology and promotion of nationwide health information exchange to improve healthcare. Over the last decade, ONC has made tremendous progress towards advancing not only the adoption and use of health IT across the healthcare ecosystem, but also increasing the rate of growth and innovation through its many programs to bridge policy with operational initiatives that can accomplish its mission.1 Programs such as the Strategic Health Information Technology Advanced Research Projects (SHARP) cooperative agreements2 aimed to close the gap between the promise of health IT and its realized benefits. Hailed as the major achievement from the SHARP program was the Substitutable Medical Applications, Reusable Technologies (SMART) Health IT,3 a standards-based technology platform that enables innovators to create medical applications (apps) that seamlessly and securely run across the healthcare system.4,6

More recently, there has been a rapid progression in the types of technologies and innovations being utilized in all health domains, including personal use for patient generated health data, clinical tools and apps being used at the point of care, and surveillance and population health tools that may include social determinants of health data. As the electronic exchange of health data has matured, the amount and types of health data available has expanded as well. Data standards such as Health Level Seven International’s (HL7®) Fast Healthcare Interoperability Resources (FHIR®) and application programming interfaces (APIs) are facilitating the sharing of health data in an interoperable way while using open standards that even non-healthcare industry technologists can leverage. Despite these advances, there is still much to learn about delivering and presenting emergent data seamlessly to patients and providers in both clinical and non-clinical settings in support of care and research. To better address these gaps and support alignment between the clinical and research ecosystems, ONC released National Health IT Priorities for Research: A Policy and Development Agenda (the Agenda),3 which identifies nine priority areas and corresponding actions. ONC’s is working to advance these priorities through a variety of actionable programs and policies aimed at: leveraging EHR data to support patient- and population-level research, analyses and services; improving patient engagement applications; enhancing consent management platforms; and improving tools to integrate clinical knowledge into routine clinical practice.

Leading Edge Acceleration Projects (LEAP) in Health IT

In 2018, ONC published the Leading Edge Acceleration Projects (LEAP)3 in Health IT funding opportunity. The goal of this three-year funding opportunity is to further a new generation of health IT development and inform the innovative implementation and refinement of standards, methods, and techniques for overcoming major barriers and challenges in the field. This panel presents in detail the focus of LEAP in Health IT funding opportunity and the
ongoing work of the two 2020 LEAP funded projects for Special Emphasis Notice Area of Interest #2: Cutting Edge Health IT Tools for Scaling Health Research. Key aspects of these projects focus on reducing provider and health system burden of utilizing health IT, while incorporating data access and use via an API for innovative purposes in support of care and research. LEAP in Health IT is an example of ONC’s ability to fund projects that seek to overcome challenges that inhibit the development, use, or advancement of well-designed, interoperable health IT affecting care and research.

Panel Objectives and Presenters
This panel will provide an overview of how projects funded under the ONC’s LEAP in Health IT funding opportunity is preparing the U.S. for an interoperable, modular, health IT ecosystem. Panelists will discuss results from projects awarded in 2020, in addition to current and emerging challenges facing the field, results of canonical use case prototypes, and priorities for next steps in alignment with national health IT priorities for research. Each panelist will leave time for discussion around the development, implementation, and use of their respective solution, as well as early legal and policy implications. This panel aims to stimulate a highly interactive discussion and strengthen the community’s knowledge of innovative uses of health IT tools, barriers and solutions for use, and areas ripe for future work.

Mr. Kevin Chaney (moderator and organizer), is a Senior Program Manager at ONC and co-leads ONC’s the LEAP in Health IT program. He will introduce and moderate the session, provide an overview of ONC’s relevant portfolio of work and describe the goals of the LEAP in Health IT program. Mr. Chaney will facilitate discussion with panelists on current use of LEAP in Health IT-funded novel technologies beyond leading-edge health organizations and explore opportunities for mainstream health systems without academic or research affiliations.

Dr. Kenneth D. Mandl (panelist), directs the Computational Health Informatics Program at Boston Children’s where he leads the transformative SMART Health IT initiative and is Principal Investigator of a 2020 ONC LEAP in Health IT project. He will provide an overview of how the SMART/HL7 Bulk Data (Flat FHIR) API has been used to provision data at scale through a cloud-based platform called Cumulus, which can support an apps ecosystem for research and learning. Dr. Mandl is building a health IT ecosystem underpinned by standardized, public APIs. The project relies on the emerging SMART/HL7® FHIR® bulk data export standard, which has already been implemented in EHRs through the Argonaut process, and is an HL7 Standard for Trial Use (STU).

Dr. Kristen Miller (panelist), is the Scientific Director of the National Center for Human Factors in Healthcare at MedStar Health, an Associate Professor of Emergency Medicine at Georgetown University School of Medicine, and Associate Faculty at the Innovation Center for Biomedical Informatics at Georgetown Medical Center. She is the Principal Investigator of a 2020 ONC LEAP in Health IT project. She will provide an overview of MedStar Health’s continued work to advance knowledge at the point of care. She will discuss MedStar’s FHIR Factories, which represent new technology approaches in big data automation to better align the clinical and research ecosystems so researchers can pursue more complex research questions and make faster, more reliable discoveries.

Panel Discussion Questions
- How are advancements from these projects available for other organizations to use and leverage?
- Are there disruptive technologies the field should be prepared for?
- What needs or gaps have these new open health IT-based tools addressed and what remains?
- What technical and policy needs or gaps limit the usage of open health IT-based tools for health care and research?
- Are there health IT infrastructure and/or standards barriers impeding the utilization of these tools?
- How easily can these tools be applied and scaled to other similar aspects in the field (e.g., other risk calculators, bulk data types, consent resources, or patient-engagement technologies)?
- How can ONC broaden the pool of use cases able to utilize these established technologies, standards, and tools (e.g., linking and aggregating research-relevant data sources; improving the ability to match individuals to different data sources; supporting robust de-identification to increase confidence and manage risk)?
- How does ONC ensure that new technologies and tools improve access and use of health information for care and research?

Panel Learning Objectives
1. Participants will understand ONC’s priorities, with a strong focus on the LEAP in Health IT Program, and the newest focal areas of interest.

2. Participants will learn about the technical development and utilization of each LEAP in Health IT project to date.

3. Participants will learn the challenges and barriers experienced by each LEAP in Health IT project and the impact for broader uptake by the field.

4. Participants will learn about technical and policy gaps that are limiting the use of open health IT-based tools.

Conclusion

This panel will discuss the rapid progression of innovative health IT solutions and approaches demonstrated and forthcoming as part of ONC’s LEAP in Health IT initiative. This panel aims to stimulate a rich discussion and gather participant input that will inform and strengthen the innovative work being explored. Discussion will also include the current and future needs and actions required to address emerging technical challenges and policy implications from multiple perspectives.

Statement of Participation

Each of the panelists and the moderator have confirmed that they will participate if this submission is accepted, at the assigned timeslot during the Informatics Summit.

Addressing the Digital Divide to Promote Health Equity

Guilherme Del Fiol, MD, PhD1, Chelsey R. Schlechter, PhD, MPH1, Bryan Gibson, DPT, PhD1, Thomas J. Reese, PharmD, PhD2, David W. Wetter, PhD1

1University of Utah, Salt Lake City, UT; 2Vanderbilt University, Nashville, TN

Abstract

Despite wide adoption of electronic health records (EHRs), a “digital divide” persists between high- and low-resource healthcare settings. However, informatics interventions that specifically target underserved populations can reduce inequities. In this panel, a multidisciplinary group of experts will discuss aspects of a research-practice partnership across multiple federally funded projects that aim to increase the reach and uptake of evidence-based prevention and treatments in underserved populations. Presentations will cover 1) examples of pragmatic clinical trials focused on informatics interventions to increase the uptake of evidence-based prevention and treatments, along with a multisector partnership that supports these implementation studies; 2) rapid-cycle design and adoption of informatics interventions; 3) sociotechnical and EHR adaptation approaches; and 4) population health management approaches. Presenters will cover a broad range of projects, including a study case focused on increasing the uptake of COVID-19 vaccination and testing in underserved communities.

Introduction

Despite wide-spread adoption of electronic health record (EHR) systems among low-resource healthcare settings, a digital divide persists between high-resource systems and low-resource settings such as Community Health Centers (CHCs).1 Rural and underserved settings are ~40% less likely to have comprehensive EHRs; 17% less likely to allow patients to view, download, and transmit their health information; less likely to have adopted patient engagement functions; and have lower digital patient-provider communication.1-3

Panelists will describe a state-wide, multisector partnership that includes multiple pragmatic implementation studies investigating informatics interventions designed for transformative impact, sustainability, and dissemination. This research-practice partnership addresses health inequities and the growing digital divide between high-resource healthcare systems and socioeconomically disadvantaged settings. Informatics interventions include EHR-based clinical decision support (CDS) tools and population health management. Implementation barriers are addressed via sociotechnical assessment of barriers and facilitators; user-centered design; and continuous support throughout implementation and testing. The partnership leverages: 1) ubiquitous information technology (e.g., capabilities required for EHR certification, text-messaging for patient outreach) to address the lack of resources that plague low-resource settings and underserved populations; 2) multilevel interventions (e.g., clinic and patient-levels); 3) sustainable, evidence-based interventions that have demonstrated efficacy among underserved populations; and 4) multisector partners (i.e., CHCs, Primary Care Association, State Department of Health, Academic Institution).

The panel includes a multidisciplinary team of speakers with expertise in health equity, health behaviors, implementation science, sociotechnical methods, and clinical informatics. Each of the speakers will describe a critical aspect of the research-practice partnership with CHCs to address the digital divide: 1) pragmatic clinical trials focused on informatics interventions to increase the uptake of evidence-based prevention and treatments, along with a multisector partnership that supports these implementation studies (Wetter); 2) rapid-cycle design and adoption of informatics interventions (Schlechter); 3) sociotechnical and EHR adaptation approaches (Gibson); and 4) population health management (PHM) approaches (Reese).

Guilherme Del Fiol is an Associate Professor and Vice-Chair for Research at the University of Utah Department of Biomedical Informatics, and a co-chair of the Health Level Seven (HL7) CDS Work Group. He has over 20 years of experience investigating clinical informatics interventions to improve the quality, efficiency, and value of healthcare, with a primary focus on promoting health equity. Dr. Del Fiol will introduce the panel and moderate the session.

David W. Wetter is the Jon M. and Karen Huntsman Presidential Professor at the University of Utah and Huntsman Cancer Institute, Director of the Center for Health Outcomes and Population Equity (HOPE), and Associate Director for Practice Engagement and Translation at the Clinical and Translational Sciences Institute. His work is targeted at eliminating inequities related to chronic and infectious disease through translational research, with a major focus on low socioeconomic status, rural/frontier, and diverse groups.
Dr. Wetter will present examples of pragmatic clinical trials led by the Center for HOPE with a focus on multi-level informatics interventions to increase the uptake of evidence-based prevention and treatments, as well as multisector partnerships that support these implementation studies. Implementation of evidence-based interventions can be challenging and often requires coordination across stakeholders from multiple levels within an organization (e.g., healthcare system leadership, clinicians, patients) and across organizations (e.g., healthcare systems, public health agencies, academic institutions). Community-engaged dissemination and implementation research emphasizes engaging stakeholders (e.g., community members, practitioners, community organizations) with diverse perspectives, and experience to provide tacit knowledge regarding the local context and priorities. The aims of this presentation are three-fold. 1) Describe a cross-sectoral, state-wide, research practice-partnership infrastructure that was developed to improve health inequities. The partnership consists of the state Primary Care Association, CHC systems, the State Department of Health, and an Academic Research Institution. 2) Describe the community-engagement process for the projects undertaken by the partnership. Each project incorporates ubiquitous health information technology at the level of the CHC system and/or the patient and are designed to implement evidence-based interventions to address infectious and chronic disease prevention and control (i.e., tobacco cessation, HPV vaccination, colorectal cancer screening, COVID-19 testing and vaccination). 3) Describe the contribution of the partnership and engagement activities to the development, adaptation, and implementation of health information technology implementation strategies. This partnership and community-engagement process depicts a tangible and replicable example of how expertise, resources, and data can be shared across multisector partners to ultimately capitalize on assets of each partner to accomplish a shared goal of improving population health and eliminating health inequities.

Chelsey R. Schlechter is an Assistant Professor in the Center for HOPE and the Department of Population Health Sciences at the Huntsman Cancer Institute and University of Utah. Dr. Schlechter is an Implementation Scientist whose research focuses on improving population health through the implementation and dissemination of evidence-based interventions for chronic disease prevention and control in community and healthcare settings.

Dr. Schlechter will present the rapid-cycle design and exemplar adaptations for an NIH-funded Radx-UP initiative designed to increase COVID-19 testing and vaccination among underserved populations. Developing, implementing, and adapting digital health interventions to address the evolving COVID-19 pandemic has required a rapid and iterative process. While still allowing rigorous evaluation, rapid-cycle designs enable iterative adaptation of interventions by incorporating data from multiple sources, including policy (e.g., vaccination approvals, eligibility), setting capacity (e.g., clinic testing capacity, vaccine availability), and stakeholder priorities (e.g., infection ‘hot-spots’ for testing/vaccination). The objectives of the presentation are to describe the application of a rapid-cycle design and adaptation process to digital health interventions; provide exemplars of adaptations for an ongoing trial to address COVID-19 among CHC patients (SCALE-UP Utah); and describe how implementation science frameworks can be used to design and evaluate adaptations to digital health interventions.

Bryan Gibson is an Assistant professor of Biomedical Informatics at the University of Utah. Dr. Gibson's expertise is in sociotechnical assessment methods and EHR adaptation to promote uptake of evidence-based interventions in underserved populations.

Dr. Gibson will present 1) sociotechnical methods used to guide the design and implementation of informatics interventions in low-resource settings, including group discussions with CHC leaders, direct observations of clinical workflow and EHR features, surveys of clinical staff, and assessment of EHR capabilities and implementation status at different CHCs; 2) examples of EHR-based tools connecting patients to evidence-based prevention and treatment services, such as CDS reminders coupled with electronic referrals to evidence-based prevention and treatment services; and 3) a study case focused on QuitSMART Utah, a pragmatic, comparative-effectiveness trial investigating the effect of an EHR-based intervention called Ask-Advise-Connect (AAC) on patient enrollment in tobacco cessation treatment. AAC consists of systematically assessing every patient for tobacco use during the visit intake (Ask), offering a connection to a tobacco cessation quitline (Advise), and submitting an electronic referral to the quitline (Connect). AAC has been implemented at 11 CHCs and 39 clinics across Utah using three different EHR products. Dr. Gibson will also explain how sociotechnical methods have been adapted to overcome constrains imposed by the COVID-19 pandemic to support the uptake of evidence-based interventions such as HPV vaccination, colorectal cancer screening, and COVID testing and vaccination.

Thomas J Reese is an Assistant Professor in the Department of Biomedical Informatics at Vanderbilt University, a Board-Certified Ambulatory Care Pharmacist, and a recent fellow in the National Cancer Institute’s Multilevel Training Institute. Dr. Reese serves on the editorial board for JAMIA and as the vice-chair of the AMIA
Dr. Reese’s research is focused on using health information technology to implement evidence-based practice in contextually and theoretically informed ways.

Dr. Reese will describe PHM interventions to increase the uptake of enrollment in tobacco cessation treatment, colorectal cancer screening, HPV immunization, and COVID-19 testing and vaccination among patients from 11 CHC systems comprised of 39 clinics throughout Utah. PHM approaches coupled with ubiquitous technology strategies, such as text messaging, have the potential to reduce health inequities by connecting patients to evidence-based interventions. However, low-resource settings often lack technical resources and expertise required to implement PHM strategies at scale. Multisector partnerships can help lower barriers to the implementation of PHM interventions at low-resource settings. Dr. Reese will describe components of PHM-based interventions, including 1) automatic identification of eligible patient cohorts based on EHR data; 2) automatic patient outreach through HIPAA-compliant text messaging that offers eligible patients a direct connection to vaccination and/or testing; and 3) patient navigation to help address barriers, hesitancy, and logistics. He will also describe rapid PHM interventions to increase the uptake of COVID-19 testing and vaccination.

Relevance to the AMIA 2021 Annual Symposium, Significance of the Topic, and Anticipated Audience

The proposed panel aligns closely with two themes of the symposium’s Late Breaking Submission:

1) Diversity, Equity, and Inclusion and the role of informatics. Reviews of public health programs have concluded that non-targeted evidence-based interventions for prevention may negatively impact health equity, whereas programs that specifically target underserved populations can reduce inequities.\(^4\) In this panel, presenters will share their experience with informatics interventions that are deliberately designed and implemented to reduce health inequities.

2) Informatics response to COVID-19: The COVID-19 pandemic has both exposed and exacerbated health inequities. Informatics has played a critical role in supporting health care organizations address the pandemic, such as in the substantial and rapid expansion of telehealth services. In this panel, presenters will share their experience with the rapid design and implementation of informatics interventions to help reduce health disparities related to COVID-19 testing and vaccination.

The anticipated audience includes individuals interested in clinical informatics and implementation research focused on promoting health equity in rural, low socioeconomic status, and racial/ethnic minority populations.

Discussion Questions for Audience Participation

- How can rapid-cycle designs improve implementation and effectiveness of digital health interventions?
- How can implementation science frameworks be used to benefit implementation of digital health interventions?
- What are key challenges to implementing informatics interventions across multiple EHR systems and healthcare organizations with low technical resources?
- How can population health management approaches be implemented at scale, minimizing dependencies on local technical resources and without increasing clinician workload?

Participation statement

All panelists have agreed to take part in the panel.

Reliable insights regarding medication outcomes from real world data—key principles of an evidence generation framework

Panelists: Sebastian Schneeweiss, MD, ScD1 Keith Marsolo, PhD2 Shirley Wang, PhD1 Robert Ball, MD, MPH, ScM3 Moderator: Rishi J Desai, PhD1

1 Division of Pharmacoepidemiology and Pharmacoeconomics, Brigham and Women’s Hospital and Harvard Medical School, Boston, MA
2 Department of Population Health Sciences, Duke University, Durham, NC
3 Food and Drugs Administration, Silver Springs, MD

Abstract (144/150)

Availability of richer clinical information on a wide-scale from electronic health records (EHRs), often stored in unstructured form, and advances in informatics methodology have opened up new opportunities to address questions related to medication safety and effectiveness that are unanswerable with structured information from other sources such as administrative insurance claims. However, generating decision-grade evidence from real-world data, including EHRs and insurance claims, requires a robust framework rooted in state-of-the-art principles of causal study design and analysis. This session will identify challenges and opportunities for addressing medication safety and effectiveness questions using real-world data sources. At the conclusion of this session, participants will be able to recognize the importance of robust design principles, careful data curation, and transparent reporting practices in deriving reliable insights regarding medication safety and effectiveness from real world data to inform regulatory actions or clinical practice recommendations.

Description of the panel

The Food and Drug Administration (FDA)’s Sentinel System uses distributed analytic tools and curated real-world longitudinal health insurance claims data for more than 100 million people from participating healthcare systems to generate insights regarding the safety of medical products. The FDA Sentinel Innovation Center was launched in 2019 to create a Medical Data Enterprise to enhance the Sentinel infrastructure by incorporating EHR data from at least 10 million lives. In this panel, Dr. Rishi J Desai, who is the Operations Chief of the FDA Sentinel Innovation Center, will first introduce the challenges in creating a national infrastructure comprising of various data streams including health insurance claims and linked EHRs that can enable timely assessments of pressing safety questions in a moderated discussion section (15 minutes). Following the introductory remarks, panelists will provide a detailed overview of ongoing activities to address these challenges in the following 4 sessions with active audience participation at the end of each session.

1. Causal inference principles guiding non-randomized studies of medication outcomes, by Dr. Sebastian Schneeweiss (20 minutes): This session will cover aspects related to design and analytic principles to allow emulation of
target trials from non-randomized data. Parameters including choice of the study design, choice of appropriate time horizon for the study to avoid time-related biases, clearly identified eligibility and observability based on the data available, and sensitivity analyses to quantify the impact of various design choices on study results will be covered. Dr. Schneeweiss will describe learnings from the RCT-DUPLICATE initiative,¹ which aims to evaluate the circumstances in which non-randomized studies conducted using real-world data can generate reliable causal inference.

2. Data curation in EHRs to maximize their value for clinical research, by Dr. Keith Marsolo (20 minutes): EHR data sources are heterogeneous in their content, structure, completeness, and quality. While a common data model can help to impose a standard organization of the data across multiple sites, mapping of source values into the model can lead to omissions, data errors, and other data quality issues. Moreover, even though a data model standardizes the data elements, a lack of semantic interoperability across sites may remain. Dr. Marsolo will describe data curation initiatives in the National Patient-Centered Clinical Research Network (PCORnet®) data infrastructure to assure data quality and reduce variability of information across participating sites.²

3. Transparency initiatives, by Dr. Shirley Wang (20 minutes): Transparent communication of study specifications in a pre-registered protocol, akin to a trial protocol, is a key feature that could help with increasing confidence in results from the non-randomized investigations. Dr. Wang will describe the STaRT-RWE reporting tool,³ which is developed as an instrument for designing and conducting reproducible studies using real world data; set clear expectations for transparent communication of methods; reduce misinterpretation of prose that lacks specificity; allow reviewers to quickly orient and find key information; and facilitate reproducibility, validity assessment, and evidence synthesis. Additionally, Dr. Wang will also cover principles guiding the current practices for quality control and transparent sharing of analytic codes in the Sentinel system.

4. A regulator’s perspective on evidence generated from real-world data, by Dr. Robert Ball (15 minutes): The FDA and other regulatory agencies around the world routinely face the challenging task of considering regulatory action based on results from non-randomized investigations of medication outcomes conducted using routinely collected healthcare data. Generating valid inference from non-randomized studies often using secondary healthcare data is complex owing to multiple potential sources of bias. Dr. Ball will outline the key considerations for evaluating results from non-randomized studies from a regulator’s perspective.

As regulators and policymakers move towards optimizing decisions impacting health of populations using evidence generated from real-world data, the issues discussed in this session are timely and ripe for wider dissemination and discussion in the clinical research and informatics communities. Ideas discussed in this panel will lead to a
stimulating exchange with the audience regarding the current and future role of informatic research community in addressing the unmet research needs.

A list of discussion questions to enhance audience participation

1. What are some key features of a robust evidence generation framework utilizing real-world data?
2. When is evidence generated from real-world data good enough to recommend regulatory or policy decisions?
3. What are the key informatics innovations that could facilitate broader and more efficient use of EHRs in medication safety and effectiveness research?
4. What are some key pitfalls to avoid when interpreting medication safety and effectiveness evidence generated from real-world data?

By the end of the session, the audience can expect to gain a deeper understanding of the challenging task of creating and maintaining a national infrastructure to enable efficient and reliable evidence generation regarding safety of medical products using real-world data. Further, this session will provide participants with a greater appreciation of the multidisciplinary nature of the evidence generation framework which requires application of principles from various disciplines including medicine, epidemiology, biostatistics, and informatics.

Statement:

Dr. Rishi Desai confirms that all panelists have reviewed the proposal and agreed to participate in the proposed panel.

Mental Functioning Ontologies

Guy Divita, MS¹, Maryanne Sacco MA¹, Janna Hastings, PhD²,³, Piper Ranallo PhD⁴

¹Rehabilitation Medicine Department, National Institutes of Health Clinical Center, Bethesda, Maryland, USA; ²Department of Clinical, Educational and Health Psychology, University College London, UK; ³Department of Computer Science, Otto-von-Guericke University Magdeburg, Germany; ⁴Six Aims for Behavioral Health, Minneapolis MN

Abstract

Mental functioning is an important component of health and health care. However, documentation of mental functioning is included mostly within unstructured parts of the medical record, is sparse, and is hard to extract. In addition, the field lacks a clear definition of mental functioning. We aim to raise the visibility of this domain within the informatics community, to establish a common definition of mental functioning, and to push for standardized terminologies for mental functioning so that health care providers can document mental functioning more consistently and accurately. This exploratory panel will facilitate awareness of those engaged in creating and using ontologies related to mental functioning, illuminate the direction the community is heading, and elicit use cases for these ontologies.

Learning Objectives

1. Define mental functioning and differentiate key concepts and their relationships for ontology building.
2. Explain how mental functioning ontologies are addressing gaps in current terminologies and classifications representing mental functions and mental functioning such as in SNOMED and the WHO ICF.
3. Examine how mental functioning ontologies can be applied to real world case examples from clinical practice, behavioral medicine, and disability determination adjudication.

Introduction

Mental functioning is an inherently complex domain, spanning multiple disciplines, data types, descriptive levels, and approaches. This complexity has brought considerable challenges to efficient knowledge discovery, integration across disciplines, and translation into the clinic [1]. Different vocabularies and semantic frameworks are used across these different descriptive levels, and it is difficult to gain an integrated and actionable overview of what is known. Interoperable and interconnected ontologies offer a technological platform for synthesizing across perspectives and integration of evidence and data [2]. Ontologies also have the potential to improve the reproducibility and findability of data within disciplines, accelerating the process of scientific discovery and translation into the clinic [3]. This panel brings an international perspective on developments in building ontologies to represent mental functioning. We will discuss clarifying the scope and definition of mental functioning, identifying concepts and their relationships, and establishing standardized terminologies that reflect current science and that are grounded in use cases. The panelists come from divergent and complimentary backgrounds with experiences in mental health informatics, mental and behavioral terminologies, and clinical practice. In our presentations we will illustrate how our different perspectives and skills can work together to support a common goal of transforming existing knowledge resources towards constituting a jointly interoperable framework of mental functioning ontologies.

The Panelists

Guy Divita/Maryanne Sacco

We are developing a mental functioning ontology based on two theoretical foundations. The ontology of mental functioning builds upon the frameworks of functioning from the International Classification of Functioning, Disability and Health (ICF)[4] and Open System Theory [5]. An ecological perspective is incorporated that provides concepts and their relationships and a terminology that aligns with how an individual’s functioning in everyday life activities while interacting within their environment is lived and described. Our long-term goal is to use the ontology to find mental-functioning mentions within text using machine learning-based extraction and classification tools that we
subsequently build. A terminology is derived from the ontology which is used for concept extraction within clinical documents to support our use case.

![Ecological Ontology of Mental Functioning](image)

**Figure 1.** Ecological Ontology of Mental Functioning

**Janna Hastings, PhD**

In her contribution to this panel session, Dr. Hastings will discuss the OBO Foundry [6] strategy for ontology interoperability and present the Mental Functioning and Emotion ontologies and their context and interrelationships to other OBO Foundry ontologies. Dr. Hastings will discuss how ontology re-use enables downstream integration and translation and mention some evidence synthesis efforts in the domain of behavioral medicine that are re-using these semantic frameworks. For example, the Human Behaviour-Change Project[7] has developed an artificial intelligence system for extracting and automatically synthesizing evidence on the effectiveness of behavior-change interventions from the literature of randomized controlled trials, and this project re-uses parts of the Mental Functioning Ontology to systematically annotate mental-functioning-related determinants of behavior change.

![The Mental Functioning Ontology upper level aligned to BFO](image)

**Figure 2.** The Mental Functioning Ontology upper level aligned to BFO.[8]

**Piper Ranallo, PhD**

In her contribution to the panel session, Dr. Ranallo will address clinical applications for ontologies of mental function. She will discuss the work of the SNOMED International Mental and Behavioral Health Clinical Reference Group[9]
she Chairs, as they have worked to define mental functions, processes and states from both an ontological perspective and concrete clinical perspective. She will discuss linkages between the representation of mental functions in SNOMED and the NIMH’s Research Domain Criteria (RDoC) framework, and provide an overview of how clinical ontologies currently represent the relationship between mental functions and the psychometric instruments and tasks used to measure and quantify them. She will provide overview of the landscape of (and gaps in) existing terminologies and ontologies relative to psychometric assessment instruments and tasks used to measure mental function. She will emphasize the need to improve our understanding of the distinction between mental functions, processes and states and the value proposition of improving the representation in existing clinical terminologies such as SNOMED.

Why the topic is timely, urgent, needed, and Anticipated Audience
There are increasing efforts in the health informatics community to establish a more unified terminology of mental functioning to support information extraction to meet diverse needs of stakeholders interested in mental functioning. Greater clarity is needed to define mental functioning concepts and their relationships. The target audience includes researchers and stakeholders in mental functioning and mental health, as well as informaticians that are interested in ontologies and terminologies in general.

Discussion Questions
1. What are your plans for collaboration across these different ontology development efforts?
2. What is the role of person factors within a mental functioning ontology?
3. What aspects of mental functioning make it harder to represent than other clinically relevant information?
4. How does the existence of multiple, inconsistent theories of mental function impact development of a single, coherent ontology of mental functioning?
5. How is clinical data captured and encoded in an EHR or clinical research system?
6. How are clinical terminologies such as SNOMED relate to research-driven ontologies such as the Foundry collection?
7. What implications does a mental functioning ontology have for clinicians?
8. Are there additional perspectives to consider that would dissect mental functioning into different components? For instance, would a neurologist, social worker, priest, pathologist, coroner, police officer, have new and or different facets than those represented here?
9. Can you offer some guidance/solutions to the problem of multiple, inconsistent theories of mental function?

Participation Statement
Guy Divita, Maryanne Sacco, Janna Hastings and Piper Ranallo assert that they agree to take part in this panel.

Addressing Bias in the Application of Machine Learning on Real-World Data

Hossein Estiri, PhD1,2, Yuan Luo, PhD3, Hongfang Liu, PhD4, Suzanne Tamang, PhD5,6,7, Harold Lehmann, MD, PhD8

1Lab of Computer Science, Massachusetts General Hospital, Boston, MA; 2Harvard Medical School, Boston, MA; 3Northwestern University Feinberg School of Medicine, Chicago, IL; 4Department of Artificial Intelligence and Informatics, Mayo Clinic, Rochester, MN; 5Stanford Center for Population Health Sciences, Stanford, CA; 6Department of Biomedical Data Science, Stanford University, Stanford, CA; 7Program Evaluation Resource Center, Office of Mental Health and Suicide Prevention, Department of Veterans Affairs; 8Johns Hopkins, Baltimore MD

Abstract

Applications of artificial intelligence (AI) and machine learning (ML) are transforming medicine towards an information processing discipline. Computer systems can now offer fast, cheap, and [in some cases more] precise diagnostic and prognostic decision support tools. Despite all the upside, AI/ML algorithms may also aggravate the various forms of biases that exist in today’s healthcare. This panel is designed to discuss the varied forms that algorithmic bias in AI/ML systems can take, including gender bias, racial prejudice, and age discrimination, across different areas of research in clinical informatics. The panel presentations will emphasize on lessons learned and informatics tools to measure and address bias in the application of AI/ML to real-world clinical data.

Introduction and Background

With the advent of large scale clinical data and the advancement of computational power, Machine Learning (ML) and Artificial Intelligence (AI) are increasingly applied to clinical data for knowledge discovery. “Bias” (“Systematic deviation of results or inferences from truth”) is a central concern in the analysis of observational data in general, and, therefore, clinical data, in particular. Such biases include, missingness, reliability, and manifestations of recording processes, access to healthcare, and patient interactions with the healthcare system[1]. AI/ML algorithms applied to these data can inadvertently be subject to such biases.[2,3] The fairness (or lack thereof) of resulting models is a concern that derives from methodological biases and that makes the models potentially cause social harm. Bias in analysis has been a concern of epidemiologists at least since Berkson’s bias was described[4] and since David Sackett made an initial list of potential biases in 1979.[5] In epidemiology, many methods for dealing with biases either in design or in analysis have been proposed.[6] At the same time that causal reasoning was returning to epidemiology, it was pursued by computer scientists as counterfactual reasoning, with many theorems and algorithms proved and designed to put such reasoning into practice.[7] The typical context has been regression-based analysis. With the popularity of AI and ML, those disciplines have now to implement in these novel contexts these age-old concerns.[8]

Panel Description

The panel will include a review of various biases that may be present in clinical data, and provide examples of how such biases are present in specific projects, how they were addressed, and successful the debiasing turned out to be. The panel will also discuss the historical and future implications of addressing (and not addressing) bias in AI/ML algorithms developed on clinical data.
Dr. Harold Lehmann will lead the panel discussion and will begin by setting the scene for the role of bias, and in doing so will help the audience better understand the importance of bias in the analysis of real-world data. This scene setting will include a taxonomy of biases that is applicable to all observational studies. Dr. Harold Lehmann is a Professor of Biomedical Informatics and of Medicine at the Johns Hopkins University School of Medicine.

**Presenters**

**Measuring Bias in Prediction of COVID-19 Outcomes (Estiri)**

Dr. Hossein Estiri is an Assistant Professor of Medicine at MGH lab of Computer Science and Harvard Medical School. In his presentation, Dr. Estiri will describe results from the measurement of various biases in modeling COVID-19 adverse outcomes using the MLHO framework,[9] including hospitalizat and ICU admissions, mechanical ventilation, and mortality. Clinical data often include more information for patients who have more clinical records -- i.e., more data. This is associated with demographic characteristics as a proxy for age, health state, and access to healthcare. AI/ML algorithms therefore can have inherent biases by providing more reliable predictions for patients with more clinical data. In his efforts designing the MLHO framework, we designed and implemented technical infrastructures to investigate bias. He will describe the results of investigating various biases (by demographics and healthcare utilization factors) in prospective evaluation of predictive models that utilize longitudinal (pre-Covid) medical records to predict Covid-related hospitalizat and ICU admissions, mechanical ventilation, and mortality. Finally, he will also discuss the informatics tools built in the MLHO framework to measure bias along with discrimination and reliability of binary classification algorithms.

**Mitigating Bias through People-Centered Health Data Science (Liu)**

Dr. Hongfang Liu is the Dr. Richard E. Emslander Professor of Biomedical Informatics at Mayo Clinic and a fellow of American College of Medical Informatics (FACMI). Her research interests include big data empowered analytics and informatics to facilitate real-world translation and implementation. She has committed to open science and has led the Open Health Natural Language Processing (OHNLP) effort which aims to develop and disseminate open source NLP tools to facilitate the use of real-world data for clinical and translational science research and health care delivery improvement. She has collaborated broadly with team science research experience in bioinformatics, software engineering, big data, cancer research, epidemiology, and clinical research. Dr. Liu will discuss the importance of people-centered AI/ML when conducting research in applying AI/ML techniques for real-world data. Drawing upon her experiences in translating NLP solutions to real-world use cases, she will discuss the importance of team science, open science, and citizen science to advance AI/ML for common good.

**Observing ML model biases in both EHR datasets and epidemiological datasets (Luo)**

Yuan Luo, PhD, is an Associate Professor at the Department of Preventive Medicine, Division of Health Biomedical Informatics at Feinberg School of Medicine in Northwestern University. He is Chief AI Officer at Northwestern University Clinical and Translational Sciences Institute and Institute for Augmented Intelligence in Medicine. His research interests include machine learning, natural language processing, time series analysis, computational phenotyping and integrative genomics, with a focus on biomedical applications. He won the American Medical Informatics Association (AMIA) New Investigator Award in 2020. He is currently an editor with JAMIA Open, JBI, Plos One, JHIR. He served on the AMIA Membership and Outreach Committee. Dr. Luo will discuss that ML models trained on datasets that lack demographic diversity could potentially yield sub-optimal performance when being applied to the underrepresented populations (ethnic minorities, lower social-economic status), thus perpetuating health disparity. Drawing from experiences of investigating this issue in both EHR datasets and epidemiological datasets, he will talk about disparities in ML model performances in racial, gender, and insurance subgroups. He will also discuss approaches to design models that proactively adjust for potential biases and to include subgroup reporting in their studies.
Racial and Ethnic Bias in Real World Risk Prediction  (Tamang)

Suzanne Roberta Tamang, PhD, is the Assistant Faculty Director of Data Science at the Stanford Center for Population Health Sciences and an Instructor in the Department of Biomedical Data Science, Stanford University. In addition to her academic role at Stanford, she is a Health Science Specialist/Statistician with the Office of Mental Health and Suicide Prevention, Department of Veterans Affairs, where she leads an inter-agency group charged with operationalizing natural language processing and information extraction tools within the Veterans Health Administration, for suicide and overdose prevention. Dr. Tamang will discuss recent work with the VA’s “REACH VET” suicide prevention program and the FDA’s Office of Minority Health and Health Equity on the assessment of racial and ethnic bias within real world risk prediction tools, using the VA’s stratification tool for opioid risk mitigation (STORM) as a use case. This includes a framework developed with Stanford Data Science for Social Good students to support joint work between data scientists and subject matter experts to quantify racial and ethnic bias presented by the deployment of advanced predictive analytics within mental health operations, for the purpose of developing strategies to ensure health equity.

Discussion Questions

1. What are the key biases that arise in the analysis of observational/real-world data?
2. How can different biases present themselves in AI/ML applied to clinical data?
3. How can bias be measured in AI/ML models developed on clinical data?
4. What are effective ways to model and correct for biases in clinical data?
5. What informatics tools are needed to help analysts address any biases in their data?
6. What tools are needed to help analysts convey detected biases in their models to non-technical subject matter experts, for the purpose of developing strategies to address such biases?

Panel Organizer Statement: All participants have agreed to take part in the panel and discuss the topics as outlined above.

Transforming Healthcare through Patient-Generated Health Data Integration

Chun-Ju Hsiao, PhD1, Deborah Cohen, PhD2, Ida Sim, PhD, MD3, Leslie Lenert, MD4, Danielle Lavallee, PharmD PhD5
1Agency for Healthcare Research and Quality, Rockville, MD; 2Oregon Health & Science University, Portland, OR; 3University of California - San Francisco, San Francisco, CA; 4Medical University of South Carolina, Charleston, SC; 5British Columbia Academic Health Science Network, Vancouver, Canada

Abstract

With the advancement of digital technologies, patients can easily collect their own health data outside of the clinical setting to track and manage their health. While these technologies are promising, many ambulatory care practices lack the technical infrastructure, functional workflows, workforce capacity, and training to support the intake and use of patient-generated health data (PGHD). This panel will feature opportunities and recommendations regarding PGHD integration in ambulatory care settings. Specifically, the panel will feature findings from a recent environmental scan and guidance from a practical guide as well as examples from two health systems that use different technical approaches to collect and integrate PGHD with electronic health records. The learning objectives include: (1) understanding the current state and recommendations of PGHD integration, and (2) learning different technical architectures and workflows that support the collection and integration of standardized PGHD either self-reported by patients or directly from devices.

Panel Description

Patient-generated health data (PGHD) are “health-related data created, recorded, or gathered by or for patients (or family members or other caregivers) to help address a health concern.”[1] PGHD such as patient-reported outcomes (PRO), health-relevant behaviors (e.g., sedentary time, physical activity, sleep quality), anthropometrics (e.g., height, weight), and physiological measures (e.g., heart rate) can be collected through a variety of tools including patient portals, mobile applications (apps), and devices.

The potential for PGHD to impact health care delivery is significant. Ambulatory care clinicians base their decisions on information received from the patient, traditionally from data collected in the clinical setting. PGHD offers insights into the day-to-day health of an individual, providing patients and clinicians the ability to employ better strategies to prevent and manage acute and chronic conditions, through monitoring for remission and relapse. In addition, clinicians and scientists can use these data to generate and apply analytical techniques to improve risk prediction and diagnoses.[2]

The ongoing COVID-19 pandemic bolstered the need to collect and integrate PGHD with electronic health records (EHRs). Many ambulatory care face-to-face visits were replaced with virtual visits. While virtual care has the capability of ensuring patient access, virtual visits make it difficult to collect data essential for diagnosis and chronic disease monitoring. Clinicians now need to rely on patients to collect vitals and other health data that they previously collected in clinic. However, not all ambulatory care practices have the resources and capacity to support the intake of such data. Barriers include technical challenges related to accuracy of measurements, data provenance, interoperability, and privacy and security concerns in the data lifecycle (i.e., collection, transmission, storage, and analysis). Nevertheless, standardized interoperable data interfaces are quickly becoming important tools in the integration of PGHD into EHRs. These include standards such as Substitutable Medical Applications and Reusable Technologies (SMART) and Fast Healthcare Interoperability Resources (FHIR). Clinicians also face other challenges such as recommending valid and equitable devices from an increasing number of options, and prohibitive costs or inadequate information technology literacy for many patients.

This panel will share the current state of PGHD integration in ambulatory care settings from a recent environmental scan as well as recommendations from a PGHD integration guide. The guide provides considerations in various aspects including legal and compliance, technical architecture, operations, patient population, privacy, and security. The panel will also feature PGHD integration examples from two health systems that use different technical approaches (e.g., application programming interfaces, SMART on FHIR apps, CDS Hooks, and SMART Marker framework). Each of
the health systems developed different architectures to support the collection and integration of standardized PGHD either self-reported by patients or directly from devices. The presentations will be followed by a discussant-led conversation to stimulate thoughts about opportunities and best practices in collecting and integrating PGHD with EHRs, with a particular focus on how to work with different practices to achieve successful implementation and use of PGHD data for clinical care. The panelists represent different institutions and have been conducting research related to PGHD integration.

Chun-Ju Hsiao, PhD (organizer and moderator) is a health services researcher within the Digital Healthcare Research Division at the Agency for Healthcare Research and Quality (AHRQ). She leads AHRQ’s PRO initiative where she manages a portfolio of grants that aim to collect and use PRO data through innovative health information technology strategies. She also led a multi-agency project where AHRQ developed a new app and modified an existing app using the PRO FHIR Implementation Guide.[3] The two apps were pilot tested in ambulatory care practices and yielded valuable lessons learned in collecting and integrating standardized PRO data. Dr. Hsiao also oversees a project to develop a practical guide regarding PGHD implementation for ambulatory care practices. She will introduce the speakers and the topic including the rationale and motivation for bringing this panel together.

Deborah Cohen, PhD (panelist) is Professor of Family Medicine at the Oregon Health & Science University. Her areas of expertise include studying primary care innovation, with a focus on how health information technology is used and can be optimized in this setting. Dr. Cohen will present her team’s work on PGHD. She will highlight key findings from a systematic review of the literature on implementation of PGHD in ambulatory care settings, and describe the guide that she and her team are creating to help support ambulatory care leaders, at multiple levels, with decisions related to implementation of PGHD.

Ida Sim, MD, PhD, (panelist) is Professor of Medicine at the University of California, San Francisco (UCSF) and is Director of Digital Health for the Division of General Internal Medicine. She has worked in mobile health since the field’s earliest days, as Co-Founder of Open mHealth, a non-profit organization for open data exchange standards in mobile health. She has led multiple projects integrating PGHD into primary care at UCSF. Dr. Sim will present the panel’s first PGHD integration example. She will present on a generic PGHD architecture that is being used to integrate standardized PRO and sensor data. In one project that aims to improve outcomes among patients with multiple chronic conditions, self-reported PRO and PGHD data (e.g., depression, physical function, pain, blood pressure (BP), heart rate (HR), and oxygen saturation) are captured in SMART Marker format and made available as FHIR resources to a clinician-facing SMART-on-FHIR visualization app. Another project extends the same architecture to demonstrate device-agnostic (i.e., regardless of device model, make, location, and connectivity) integration of Bluetooth BP data. Using a cloud infrastructure based on FHIR, Open mHealth, and other standards, the system authenticates, ingests, harmonizes, and serves up BP and HR data from the BP cuffs as FHIR observation resources.

Leslie Lenert, MD (panelist) is Assistant Provost for Data Science and Informatics and the Chief Research Information Officer of the Medical University of South Carolina (MUSC). Dr. Lenert works as a “health systems engineer” to create advanced social technical processes (including technology-based solutions) that address critical problems in clinical medicine and population health. Dr. Lenert will present the panel’s second practical PGHD integration example. He will present on apps developed at MUSC for the remote care of patients with COVID-19. Built on MUSC’s strong foundation of telehealth care, Dr. Lenert will describe the development of EHR tools for prescribing either a tethered EHR-portal app or iOS and Android apps for remote care of COVID-19 patients’ symptoms, pulse oximetry data, and temperature as well as alerting telehealth nurses of changes in patient’s status. One of the unique features of this architecture was the use of Clinical Decision Support (CDS) Hooks based triggers within the EHR to prescribe iOS and Android apps. “Deep-linkages” were used to automatically configure iOS and Android apps to work with sensors providers selected in the EHR. The tethered app was used for the care of more than 1300 patients during the “first wave” of the pandemic. Work with the iOS and Android apps was expanded to create a novel system for surge capacity for critical care using an Internet-of-Things approach.

Danielle Lavallee, PharmD, PhD (discussant) is the Scientific Director at the British Columbia Academic Health Science Network. Her research focuses on patient-centered approaches to healthcare delivery including the use of PGHD to support shared decision-making. Dr. Lavallee’s work includes developing guidance for health systems on the integration of PRO data (ePRO toolkit), understanding opportunities, barriers, and priorities for health system integration of PGHD, and evaluating the use of mobile health for supporting post-operative care management. Dr.

60
Lavallee will lead the panel and the audience, in a conversation about challenges and opportunities in collecting and integrating PGHD with EHRs, focusing on technical and organizational considerations. Discussion questions may include:

- What are the pros and cons of different technical approaches presented today?
- What is required in terms of expertise and resources to integrate PGHD with EHRs?
- How might you use the SMART Markers framework?
- What is the utility of PGHD?
- What qualities should PGHD have?
- How could you decide which PGHD to collect and integrate?
- What are some potential impacts of using PGHD on clinic workflow?
- What type of conditions do (and do not) need long-term PGHD collection? For those that do, how do you keep patients engaged in submitting PGHD?
- How to streamline patient authentication?
- What evidence will support continued advancement for integrating PGHD into care?
- How to collect and use PGHD with a health equity lens?

**Topic Rationale:**

Providing person-centered care to ensure that health services are respectful of, and responsive to, the preferences, needs, and value of people is an HHS priority. The increase of social networking, cloud-based platforms, connected devices, and smartphone apps provide simplified means for people to collect and share data outside the traditional clinical environment. While these technologies are promising, the ability for ambulatory care practices to successfully collect these data in collaboration with patients, transfer data to their EHRs, and use them effectively to inform treatment decision making in clinics poses many challenges. The COVID-19 pandemic heightens the need to support ambulatory care practices in this complex process of collecting and using PGHD because many face-to-face visits have been replaced with virtual visits. This panel covers the current state and recommendations of PGHD integration, and features different technical architectures and workflows that support the collection and integration of PGHD.

**Statement of Agreement to Participate**

All panelists have approved of this submission and agreed to participate.

Abstract

The industry panel covers the journey of harnessing a multi-stakeholder collaborative process to form a FHIR Accelerator which leverages HL7® FHIR® standards to transform health care, highlighting change management and the paradigm shift in how organizations work internally and with their business partners.

After this session, the learner should be better able to:

- Learn how a multi-stakeholder initiative, the HL7 Da Vinci Project, is helping the industry use standards to solve health care interoperability problems and meet federal requirements
- Understand how the multi-stakeholder FHIR Accelerator methodology could be adopted by other communities with minimal change.
- Learn how to engage with the Da Vinci Project, join the growing collaborative community and directly access the free and open resources.
- Learn about the challenges, benefits and lessons learned of real-world implementations of the standards-based strategies and how organizations can use Da Vinci work to solve problems and meet federal interoperability and access rules.
General Description

During this 90-minute session, the panel will discuss the formation of the HL7 Da Vinci Project as a FHIR Accelerator. Via several convener and implementer viewpoints, the presenters will detail the journey of assembling and harnessing a multi-stakeholder collaborative process to form an Accelerator to leverage standards. By bringing providers, payers and partners together, the collective expertise and efforts of industry experts are leveraged to identify and solve problems using technology. The panel will share all aspects of the journey, from the initial concept of convening an Accelerator to identifying stakeholders, outlining processes and ultimately launching implementations to meet industry data-exchange needs as well as federal interoperability and patient access rules.

The panel will also share how Symposium attendees can engage with the Da Vinci Project, join the growing collaborative community and directly access the free and open resources. Lessons learned from the project are instructive for other organizations and communities of practice who want to implement FHIR in their own workflows. The journey fundamentally is not about technology but transforming health care, highlighting change management and the paradigm shift in how organizations work internally and with their business partners.

Dr. Viet Nguyen, Technical Director for Da Vinci, will facilitate the panel. He has been with Da Vinci Program Management Office since the inception of the Project and will provide an overarching and longitudinal view of the processes. As the Chief Executive Officer of HL7, Dr. Jaffe will discuss the standards organization’s perspective and the genesis for creating the Accelerator program, highlighting Da Vinci’s four-year journey as one of the first FHIR Accelerators that has produced 10 implementation guides to date. Dr. Jaffe will also discuss the challenges that FHIR accelerators put on the standards process as well as the Accelerator program’s future direction and will illustrate how the multi-stakeholder accelerator methodology could be adopted by other communities with minimal change.

Dr. Kassakian will discuss the experience of implementing FHIR from an academic medical center perspective. Ms. Taylor will discuss the experience of implementing FHIR as a multicenter provider organization. Ms. Lindberg will provide a payer perspective in implementing FHIR and coordinating workflow with provider partners. Participants will each detail their experiences as project members and implementers, representing providers and payers. The panelists will outline their organizational history with FHIR, challenges, benefits, lessons learned regarding participating in the Accelerator and FHIR adoption, current implementations and future plans.

Explanation of Why the Topic of Panel is Timely and Anticipated Audience

As the shift to value-based care continues, the need for payer-provider collaboration has become essential. By bringing providers, payers and partners together to identify and solve problems using standards-based strategies, industry can address pain points and improve care, reduce burden, streamline and automate workflow, liberate data and measure quality. The maturation of HL7 FHIR and the federal interoperability and patient access rules to implement FHIR has provided a catalyst for increased adoption and incentive to derive value from FHIR and interoperability.

The anticipated audience for this panel includes physicians, nurses, dentists, pharmacists, and other clinicians; health information technology professionals; computer scientists and systems developers; policy makers; public health professionals; biomedical engineers and bioinformaticians; consultants and vendor representatives; academic researchers and scientists; and other professionals involved in the collection and dissemination of health information.

Discussion Questions

Is your organization participating in a multi-stakeholder collaborative effort like one of the HL7 Accelerators?

If so, what are the benefits?

What challenges have you experienced and how did you overcome them?

How did you define the scope of your project?

What factors did you consider when selecting your use cases?

How did you agree upon priorities?
Panel Organizer Statement

All panelists named in this submission have agreed to take part on this panel during the AMIA 2021 Annual Symposium, which will occur October 30 – November 3, 2021 in San Diego.
Panel Proposal: Privacy-Preserving Federated Biomedical Data Analysis

Xiaoqian Jiang, PhD, 1 Luca Bonomi, PhD, 2 Jaideep S. Vaidya, PhD, 3 Li Xiong, PhD 4 Lucila Ohno-Machado, MD, PhD, 2
1 School of Biomedical Informatics, University of Texas Health Science Center at Houston, Houston, TX
2 Dept. of Biomedical Informatics, University of California San Diego Health, La Jolla, CA
3 Dept. of Management Science and Information Systems, Rutgers University, Newark, NJ
4 Dept. of Biomedical Informatics, Mathematics, and Computer Science, Emory University, Atlanta, GA

Abstract

Federated learning has emerged as a powerful complement to centralized healthcare data repositories due to their flexibility, nimbleness, and decentralized gatekeeping capabilities. Many biomedical data networks (e.g., pSCANNER1, PCORNet2, eMerge3, SCOR4, etc.) have been established to enable the use of electronic health records (EHR) and genomic data for research. In these settings, data are often distributed across different institutions. Due to privacy or other concerns, patient-level data cannot be transmitted outside some institutions, so a mechanism to support data analysis without sharing patient-level data is needed. This naturally leads to the development of privacy-preserving federated biomedical data analysis. Various technologies have been emerging to support studies across distributed networks. The goal of this panel is to provide the AMIA community with 1) an overview of current progress and technical developments in federated biomedical data analysis; 2) discussions of novel techniques for computing in horizontally or vertically partitioned datasets; and 3) insights into practical deployment, current challenges, and opportunities.

General Description of the Panel and the Issues

Various organizations such as governmental agencies, hospitals, and financial companies collect and share various person-specific data for research and business purposes. Often, data from different sources need to be integrated to gain better insights and deliver high-quality research outcomes. The Shared Pathology Informatics Network (SPIN) initiated by the National Cancer Institute aimed to provide an interface to cancer researchers to access pathology specimens’ data stored across multiple healthcare institutions. The pSCANNER clinical data research network (CDRN) aims at connecting 24 million patient data from geographically distant institutions to facilitate clinical and comparative effectiveness research. Data analysis can be very straightforward if biomedical data of interest are collected and deposited in a centralized repository. Alternatively, institutions can use a federated data analysis framework to obtain information on demand. The challenge here is to simultaneously enforce privacy (protected health information is under the regulation of HIPAA privacy and security rules and the common rule), while maintaining data utility (ideally, this translates into producing the same results as if data analyses were conducted in a centralized repository). These challenges call for the development of advanced health information technologies to support federated data analysis. In this proposed panel, we will focus on the discussion of federated data analysis and the protection of its research outcomes.

Structure of the Proposed Panel

The goal of this panel is to review recent research in the field of privacy-preserving federated biomedical data analysis. The panel will be hosted by Dr. Lucila Ohno-Machado, who is the Professor of Medicine and Chair of the Department of Biomedical Informatics at UCSD. Since 2010, Dr. Ohno-Machado has led the NIH-funded integrating Data for analysis, Anonymization and SHaring (iDASH) project. Dr. Ohno-Machado is also the PI of the PCORI-funded pSCANNER clinical data research network, which is designed to allow distributed analyses on data derived from electronic health records of over ten health systems. Dr. Ohno-Machado will provide a review of the needs for federated data analysis in biomedical research and an overview of federated data analysis methodology.
The panel will include four recognized researchers in biomedical data privacy and security. Each of these researchers will provide insight into a different aspect of federated biomedical data analysis and convey their experience with different applications.

The first panelist will be Dr. Xiaqian Jiang from the University of Texas Health Science Center at Houston. Dr. Jiang will share his experience on federated data analysis modeling\textsuperscript{10–13} for the iDASH and pSCANNER projects. The second panelist will be Dr. Luca Bonomi from UCSD. He has been working on privacy-preserving data linkage\textsuperscript{17} and genomic data sharing\textsuperscript{17,18}. He will introduce the applications of these algorithms. The third panelist will be Dr. Jaideep Vaidya from Rutgers University. He will share his expertise in privacy-preserving data mining\textsuperscript{14} and the development of various federated data analysis models for vertically and horizontally partitioned databases\textsuperscript{15,16}. The fourth panelist will be Dr. Li Xiong from Emory University. She was the PI of the PCORI-funded project Building Data Registries with Privacy and Confidentiality for Patient Centered Outcomes Research and will introduce the opportunities and challenges of developing differential privacy technologies\textsuperscript{19} in protecting outcomes of biomedical research in a distributed setting. This is important because the outputs of federated data analysis may still pose privacy risks if disclosed to the public. Thus, the final outcomes (e.g., estimated parameters) also need protection. If we want to expose these outcomes to the public, strong privacy protection like the one provided by differential privacy techniques is necessary to mitigate the risk. Dr. Lucila Ohno-Machado will moderate the panel from UCSD, who is the PI of pSCANNER, iDASH, and RADx-rad projects.

Urgency of the Topic and Relevance for AMIA

Health systems and other institutions that want to participate in research but are unable to transmit patient-level data beyond their local environments or ‘enclaves’ can do so by employing distributed analytics such as the ones we will describe. Patient privacy is protected when only privacy enhanced results of computation need to be transmitted. Using data from multiple institutions has many advantages for research, including increased diversity of populations and increased sample size. For example, when dealing with hypothesis testing and regression models, one may require many samples to increase the statistical power. Oftentimes, data are horizontally distributed (e.g., different institutions need to study similar patients to determine the effectiveness of a new procedure)\textsuperscript{20}. Data owners would like to collaborate for federated data analysis without sharing patient-level data. One way is to use meta-analysis to combine results from local studies through weighted average, but it is often criticized for example, several small studies do not predict the result of a single large study\textsuperscript{21}, and sources of bias are not controlled by the method\textsuperscript{22}. Unlike meta-analysis, federated data analysis guarantees could achieve accurate results as if data analyses are conducted in a centralized manner. In addition to horizontally partitioned data, different stakeholders might have different pieces of patient data, for example, EHR data in clinics, genome data from the same patient population in a sequencing center, claims data in an insurance company. In this setting, data are vertically distributed. Federated data analysis over vertically distributed patient information supports the use of these data in biomedical research, but it is a harder task than computing on horizontally partitioned data.

This panel will address biomedical data privacy for clinical data research networks, where a large portion of the AMIA community is currently involved. The anticipated audiences include but are not limited to healthcare privacy policymakers, biomedical researchers, as well as other stakeholders (e.g., patients, clinicians, etc.)

Discussion questions

Potential discussion questions include, but not limited to:

What are the challenges and opportunities of federated data analysis in protecting the privacy of biomedical research studies?

How to enforce data quality in a federated data analysis?

How to link patient data across vertically partitioned datasets?

What kind of data analyses can be supported in a federated manner?
How can secure computing be used to enhance privacy protection in a federated network?
How can differential privacy techniques be used to support federated data analytics?

Statement from the Organizer
All panelists have approved this proposal’s writing and have agreed to take part in this panel.

Evolving Challenges in Patient Matching

Abel N. Kho, MD, MS\(^1\), Shaun J. Grannis, MD, MS, FAAFP\(^2\), Adam Culbertson, MS, MS\(^1\), Molly Murray, MS\(^3\), Yu Deng\(^4\), BS

\(^1\)Center for Health Information Partnerships, Northwestern University, Chicago, IL, USA; \(^2\)Regenstrief Institute, Indianapolis, IN, USA; \(^3\)Pew Charitable Trusts, Philadelphia, PA, USA

Abstract

COVID-19 data tracking and reporting efforts have highlighted the vital importance and ongoing challenges associated with linking patient data using demographic variables. Currently, match rates between organizations can be as low as fifty percent, resulting in barriers in information exchange, introducing safety risks, and increasing costs. The difficulty of patient matching is multifactorial and includes the variation in quality and availability of matching variables across healthcare organizations and time as well as restrictions in access to patient unique identifiers due to data security and privacy concerns. Participants in this panel discussion will present 1) current lessons learned and evolving challenges to successful patient matching 2) current state-of-art patient matching approaches and promising new methods 3) recent policies and legislation affecting patient matching 4) privacy, security, and ethics issues over patient matching especially during COVID vaccine tracking 5) the changing nature of patient matching features available over the past 10 years across a diversity of care settings and how these features were impacted by the COVID-19 pandemic.

Introduction

The Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 and the Federal Health IT Strategic Plan set the adoption and meaningful use of electronic health records (EHR) as the key objectives (1). Since 2009, the use of basic EHR systems and the possession of certified EHR technology has increased significantly (2). Despite the wide adoption of EHR, the lack of interoperability between different healthcare organizations has hampered care coordination, health information exchange and more efficient patient care (3). Such challenges have compounded during the COVID-19 pandemic where fast data tracking, reporting efforts are required. Accurate patient matching is the key to improve EHR interoperability. The Office of the National Coordinator (ONC) for Health Information Technology reported that the rates of record matching can be as low as 50 percent among provider records exchange (4).

The challenge of accurately matching patient records comes from many aspects. Concerns over data security and more restricted government policy on Protected Health Information (PHI) limits the access to patient unique identifiers that many linkage methods rely on (5). Variation in data quality also imposes a significant challenge to patient matching (6,7). Ideally, linkage variables should be unique, accurate, complete (non-missingness), and consistent across sites and time. However, in real world data, erroneous entry, missingness, and information updates (e.g. patient address) are common for many demographic variables. Data standardization is another common problem in patient matching (8). Matching variables are often captured in varying formats in healthcare organizations and health information systems (7). Currently, several organizations including the Agency for Healthcare Research and Quality (AHRQ) and the ONC, have proposed best practice approaches for data standardization (8). However, there is no consensus on which specific data standardization method should be used.

In this session, the panelists will provide an overview of the evolving field of patient matching, including current and emerging trends in patient matching methods (e.g. unique patient identifiers, empowered patient solution, data standardization, referential matching), recent policies and legislation related to patient matching, potential security and privacy risks that inconsistent patient matching may cause, as well as recent work quantifying the changing nature of patient features available over the past 10 years across a diversity of care settings and how these features were impacted by the COVID-19 pandemic.

Panelists and Topics

1) Moderator: Abel Kho, MD, MS, FACMI is a Professor of Medicine and Director of the Center for Health Information Partnerships and the Institute for Augmented Intelligence in Medicine at Northwestern University. Dr. Kho has expertise in integrating EHR data across diverse care settings, with a focus on privacy preserving record linkage methods, as part of several national networks including PCORnet 2.0, the All of Us Research Program, and N3C. He will moderate the discussion and provide an overview of the changing nature of person identity and some of the persisting challenges to successful patient matching.
2) Shaun J Grannis, MD, MS, FACMI is the Sam Regenstrief Professor of Medical Informatics, Indiana University School of Medicine, and Vice President for Data and Analytics, Regenstrief Institute. Dr. Grannis collaborates with national and international healthcare stakeholders to advance interoperability and data sharing capabilities. He has provided identity management consultancy to low- and middle-income countries, as well as the World Health Organization and the Office of the National Coordinator for Health Information Technology. Dr. Grannis will present recent methods for identifying optimal fields for standardization and matching. He will describe how these methods affect real-world patient matching accuracy using datasets from various data sources, including public health data sources (including COVID-19 laboratory results and vaccinations), health information exchange, vital records, and newborn screening data.

3) Adam Culbertson, MS, MS, has worked on patient matching for several years. He served a term as the HIMSS Innovator in Residence working with the Office of the National Coordinator for Health IT and the CTOs office to advance patient matching through the patient matching challenge. He was the lead author on the Building Blocks of Interoperability, a study of the different data elements that can be used for patient matching. He has contributed to numerous articles, policy forums, and a frequent speaker on the topic patient matching.

4) Molly Murray, MPA, is an Officer on Pew’s Health Information Technology project. Her work focuses on research and advocacy related to interoperability and patient matching. She will provide an overview of current regulations and policies, as well as recent proposed legislation relevant to patient matching.

5) Yu Deng, BS, is a PhD candidate in biomedical informatics at Northwestern University. Her research focuses on improving patient outcome and quality of care using EHR data. Yu Deng will present her recent work showing how the COVID-19 pandemic has affected the types of patient features currently collected.

Panel Rationale

Currently the ability to match a patient's records across the medical system is foundational to improving care and lowering cost. The issue of patient matching has been identified as one of the leading barriers to interoperability in the Nations Road Map to Health IT (3). In 2020 Senators Maggie Hassan (D) and Bill Cassidy(R), introduced a bipartisan bill called the Patient Matching Improvement Act to help make improvements to patient matching by requiring the use of the “United States Postal Service (USPS) standard, to improve data quality of address features used for matching (9). The current COVID pandemic has accelerated the need to solve the nation's patient matching bottleneck and at the same time brought privacy and security issues to the forefront. The need to contract trace and maintain immunization registries for public health, and track who has received immunizations (first and second dose) while maintaining data privacy and security have made the issue a crucial challenge in our COVID response. There is growing consensus that our nation's patient matching challenge must be solved. However, there still is no consensus on what approach would best link the disparate patient data that is scattered across the healthcare system. This panel discussion will provide a forum for leading thought leaders in industry, academia and government to convene to advance the national patient matching dialogue.

This panel will explore the evolving challenges and opportunities to the art of patient matching; the impact of data standardization on patient matching; the variation in availability of patient features over the past 10 years and across multiple healthcare organizations, the challenges and opportunities of patient matching raised by the COVID-19 pandemic, as well as the ethics and privacy issues with patient matching.

This panel comprises a multi-disciplinary team reflecting complementary perspectives on the policy and technology required to develop effective informatics approaches to improve patient matching. Dr. Kho will moderate the session and provide an overview of the current and persisting challenges in patient matching. Dr. Shaun Grannis will compare and contrast the impact of data standardization vs algorithm performance on patient matching. Mr. Culbertson will describe the changing nature and availability of patient features for patient matching from a diversity of care settings. Yu Deng will present recent work showing how the COVID-19 pandemic has affected the types of patient features currently collected. Molly Murray will provide an overview of current policies and recent proposed legislation relevant to patient matching.

The anticipated audience for this presentation are individuals interested in understanding the evolving challenges to patient matching, the current trends in patient matching algorithms, the impact of data standardization on patient matching, and the dynamic shifts in demographic feature availability over the past 10 years and the recent impact of COVID-19 on these features.
Discussion questions

The goal of the panel will be to present expert and research informed viewpoints on specific aspects of record linkage and engage the audience in subsequent discussion. Each speaker will present for 15 minutes. Then once the short presentations are completed there will be an interactive panel with audience participation and questions and comments from the audience. Topic and questions for discussion will include:

- What are the emerging technologies and algorithms that can be leveraged for the purpose of improving the availability and quality of patient features available for matching?
- How can patient matching improve COVID vaccine tracking? How does HIPAA, ethics and other concerns come into play in COVID vaccine tracking?
- How does the availability of demographic variables for matching change in the past 10 years and what is its impact on patient matching?
- How can data standardization algorithms (e.g. the USPS standard) be applied to improve the quality of features used for patient matching?
- What will the latest innovations be in patient matching? What are some alternatives (e.g. the CMS Blue Button initiative, patient unique identifier) in patient matching in addition to data quality improvement and data standardization?
- How can we better engage patients in the patient’s matching process to ensure patients data is their own and how they can protect their privacy through efficient consent policies and technology?
- What data privacy, data security and ethics issues do different patient matching methods bring?
- What are the policy considerations and the role of federal agencies (e.g. ONC, NIST, and CMS) to improve patient matching?

Organizer Statement

All of the participants in this panel have reviewed this abstract for this panel and have agreed to take part in the panel should it be accepted.

The COVID-19 Pandemic as Catalyst: The Acceleration of Registry Science in the 21st Century to Address Novel Challenges

Steven E. Labkoff, MD, FACP, FACMI, FAMIA1, Leon Rozenblit, JD, PhD2, Rachel Richesson, Ph.D., MPH, FACMI3, Helen Burstin, MD, MPH, MACP

1. The Multiple Myeloma Research Foundation, Norwalk, CT, 2 Prometheus Research, an IQVIA Company, New Haven, CT, 3 University of Michigan, Medical School, Ann Arbor, MI, 4 Council of Medical Specialty Societies, Chicago, IL

Abstract:
With the rise of the pandemic, there has been a renewed focus on the construction and utilization of patient registries. Having evolved gradually for over 75 years, registry use has been reshaped by this crisis. Registry use continues to grow because EHRs, while important for patient care and administrative issues to run a healthcare institution, often do not collect enough of the right data about specific medical issues. Clinical registries have been stood up and repurposed to address the need for rapid information on the appropriate management of COVID-19, especially for patients with secondary conditions, including cancer and autoimmune diseases. For example, in rare diseases, registries are often the only mechanism to collect enough relevant data to estimate the prevalence, understand the presentation and progression. Registry Science is the branch of Informatics that bridges the gap between clinical care and clinical research through high-quality, focused data assets. This panel will discuss how registry science has emerged and advanced in the past 20 years and highlight important use cases and informatics and data challenges, up to and including how the COVID-19 pandemic is raising the profile and need of Registry Science.

Introduction:
As the US has seen a meteoric rise in the use of EHRs over the last 15 years, there has been a concomitant rise in the construction and utilization of medical registries. One might think that this would not be the case as EHRs are generally considered to be the source of all clinically-relevant medical data for the care of patients. However, as it turns out, in 2021, EHRs are not nearly as good at generating data sets for clinical research as are registries. The rise of personalized medicine, the need for research into rare diseases, FDA REMS mandates for safety, and above all, the COVID-19 pandemic has all contributed to the growth and need for registries.

Where EHRs collect data for clinical care, they seldom collect as complete or focused a data set as is needed to answer research questions about a specific disease or cohort. One problem that registries need to solve is to identify and aggregate patients with the same diagnosis and bring together relevant and detailed data for analysis. EHRs, while excellent at collecting data for analysis and clinical care of the individual patient, often fall short, especially for a rare disease or rare event cohorts. For a rare disease that only has an incidence of 30,000 new cases, as is the case with multiple myeloma, no single institution likely has enough cases to perform sufficient clinical research. Likewise, in the case of a massive epidemiologic study, aggregating data from “all-comers” from all EHRs remains a challenging, if not
impossible task. Further, because EHRs are designed for documenting the care of an individual patient, they don’t routinely assess or record information that may be critical for research in a specific area.

In this panel, panelists with extensive and varied experience will describe the evolving paradigm for clinical registries, including ongoing challenges related to data acquisition and standardization, harmonization, cloud-based computing, and the growing importance of patient-generated data, including patient-reported outcomes. Panelists will discuss how the nature and needs for registries have evolved through COVID-19 and will consider their roles in understanding and treating rare diseases, detecting adverse drug events, and delivering personalized medicine. They will also discuss how modern registries collect and aggregate data from disparate sources as well as the data analytics needed to deal with large genomic and immunome files that are becoming standard in these registries.

Panelists:
Steven Labkoff, MD, FACP, FAMCI, FAMIA is the Chief Data Officer of the Multiple Myeloma Research Foundation in Norwalk, Connecticut. He is the program sponsor and chief architect of the Multiple Myeloma Research Foundation’s (MMRF) CureCloud Direct-to-Patient Registry (CC-DTP). He is responsible for the MMRF’s 2 petabytes of myeloma data. Previously he was Head of Medical Strategy at Purdue Pharma where he managed Medical Affair’s Big Data Program. Previously he was VP Life Sciences at Intelligent Medical Objects where he worked on vocabulary and ontology tools for Life Sciences. As AstraZeneca’s Executive Director of Research and Development Informatics he built 3 informatics departments including Real World Evidence, Biomarkers, and Clinical Trial Decision Support. He spent 13 years at Pfizer in Business Technology and Medical Affairs where he built the informatics infrastructure for the Infectious Diseases Institute, Kampala, Uganda, an outpatient HIV hospital. He is an ACMi fellow and has served on AMIA’s Executive Committee and served on various AMIA working groups and committees. He founded the AMIA Industry Advisory Counsel and ran both national and international workstreams on Secondary Healthcare Data Use.

Leon Rozenblit is Senior Director (and founder) of Prometheus Research, an IQVIA company, a registry-focused informatics company in New Haven, Connecticut, and he has been directly involved in a leading role in designing and building dozens of registries across the US. On a day-to-day basis, his organization builds and manages patient registries and agile, integrated data hubs for multiple medical specialty societies and patient advocacy groups, and is the technology partner on the CureCloud Direct-to-Patient registry. Having to take into account varying data standards and data models is a daily concern for his organization and his clients. He will speak to the myriad of issues that comprise the successful implementation of such repositories, from a standard and data model perspective.

Rachel Richesson, Ph.D., MPH, FACMI, is a professor of Informatics and Learning Health Sciences at the University of Michigan Medical School. She has coordinated the implementation of data standards for a number of multi-national multi-site clinical research and epidemiological studies, including the NIH Rare Diseases Clinical Research Network (RDCRN), Type 1 Diabetes TrialNet, and The Environmental Determinants of Diabetes in the Young (TEDDY) study, and the national distributed Patient-Centered Outcomes Research Network (PCORnet). Dr. Richesson helped design the RDCRN Contact Registry to facilitate research in over 150 different rare diseases, and she serves on advisory boards for several rare disease registries and patient advocacy groups. Currently, Dr. Richesson co-leads the Electronic Health Records Core
for the NIH Health Systems Research Collaboratory, which is developing best practices for using EHR data in pragmatic clinical trials, including data quality assessment, clinical phenotyping methods, and selection of study endpoints. She is highly engaged in national discussions related to the development of Health Information Technology standards and policy to support clinical research, and participates in multiple standards development organizations, including Health Level Seven (HL7) Patient Empowerment and Vocabulary working groups.

Helen Burstin, MD, MPH, MACP is the Chief Executive Officer of the Council of Medical Specialty Societies (CMSS) which represents 45-member specialty societies with collective membership of 800,000 U.S. physician members. CMSS works to support and strengthen specialty societies and catalyzes improvement through convening, collaboration, collective voice, and action. Many CMSS member societies support clinical registries. CMSS has identified the digital transformation of registries and research as a major strategic priority. With support from the Gordon and Betty Moore Foundation, CMSS recently hosted a webinar series on COVID-19 and Clinical Registries. Dr. Burstin formerly served as Chief Scientific Officer of The National Quality Forum (NQF). A former AMIA board member, she now serves on the boards of AcademyHealth and the Society to Improve Diagnosis in Medicine. Dr. Burstin is a Clinical Professor of Medicine at George Washington University.
Panel Proposal: Multi-Modal Data Science for Healthcare: State of the Art, Challenges, and Opportunities

Yuan Luo, PhD\textsuperscript{1}, Fei Wang, PhD\textsuperscript{2}, Benjamin Glicksberg, PhD\textsuperscript{3}, Jessilyn Dunn, PhD\textsuperscript{4}, Nigam Shah, MBBS PhD\textsuperscript{5}

\textsuperscript{1}Moderator, Northwestern University, Chicago, IL, USA
\textsuperscript{2}Cornell University, New York, NY, USA
\textsuperscript{3}Icahn School of Medicine at Mount Sinai, New York, NY, USA
\textsuperscript{4}Duke University, Durham, NC, USA
\textsuperscript{5}Stanford University, Palo Alto, CA, USA

Abstract

The United States Precision Medicine Initiative aims to utilize information from multiple modalities—phenotypic, omic, imaging, and environmental—to develop an individualized and comprehensive view of a patient’s pathophysiologic progression, to identify unique subtypes of patients, and to administer personalized therapies. The rapid growth of multiple data modalities, when linked to the right patients, may provide a comprehensive view of the patients’ pathophysiology and offer a basis for meaningful subtyping of these patients. This panel will draw on their extensive experiences working with multi-modal data for healthcare problems to provide their perspectives on the best practices and pitfalls to avoid.

Background

Precision medicine aims to utilize information from multiple modalities (e.g., phenotype and omics) to develop an individualized and comprehensive view of a patient, to identify unique disease endotypes (sub-phenotypic patient group sharing pathophysiologic and mechanistic processes of a disease), and to administer personalized therapies\textsuperscript{1}. Existing efforts are often based on only a pre-selected set of biomarkers from a single modality. However, the different data modalities, when linked to the right patients, may provide a holistic view of the underlying pathophysiology of these diseases and offers a basis for meaningful subtyping. The rich information contained in multi-modal patient data sources asks for effective and efficient computational approaches for analyzing them.

To effectively integrate multiple data modalities, significant challenges arise from each modality separately and from the integration process. Regarding the phenotype data, the higher-order temporal trend features need to be properly modeled instead of modeling of atomic features (snapshot measurements). Although recent deep learning methods (e.g., recurrent neural networks) are increasingly used for modeling data longitudinality, these systems are often regarded as black-boxes and lack interpretability. Moreover, most data-driven methods are not able to capture a group of abnormal physiologic trends that can reflect (multi-)organ dysfunctions.

Regarding omics, GWAS studies have identified thousands of SNPs (atomic features) associated with different diseases or phenotypes. However, little is known about the molecular mechanisms of how these variants contribute to disease pathogenesis. One of the major roadblocks is that the majority of GWAS SNPs are located in the non-protein coding regions, most of whose functions remain poorly understood. For example, in hypertension, while GWAS from numerous consortia identified 118 independent loci associated with hypertension and additional loci associated with heart failure; exome sequencing, proteomic, and transcriptomic analyses of heart failure and hypertension are less mature and less informative on molecular mechanisms. Linking genomic and transcriptomic signatures to disease endotypes may provide additional mechanistic understanding of pathogenesis and identify future targets for therapy.

Intended Audience

Biomedical informatic researchers and practitioners.
Topics for Discussion

Yuan Luo, PhD, will talk about his experiences in integrating multi-modal healthcare data when investigating different diseases. For example, he will talk about using hybrid matrix factorization to integrate both the phenotypic and genomic features to derive informative subgrouping of hypertension patients. He will also talk about their efforts in using autism spectrum disorder (ASD) to demonstrate the clinical utility of integrating omic and phenotypic data for endotype discovery. By combining healthcare claims, electronic health records, familial whole-exome sequences, and neurodevelopmental gene expression patterns, one can identify a subgroup of patients with dyslipidemia-associated ASD, which informs early screening and early intervention.

Benjamin Glicksberg, PhD: There have been many efforts to try to apply machine learning to aid in the COVID-19 pandemic. In this presentation, I explore several machine learning studies conducted to predict clinically-relevant events for COVID-19 patients at the Mount Sinai Health System – one of the largest and most diverse health systems in New York City. I identify strategies and novel frameworks to improve predictive performance of these models, which could be applied outside of the context of COVID-19. I describe how these research efforts utilized multi-modal patient data (Electronic Health Records, free-text notes, biomedical imaging, and electrocardiogram waveforms) and were applied across several clinical domains.

Jessilyn Dunn, PhD: Mobile and Digital Health are poised to not only make it possible to rapidly detect, prevent, and manage many diseases, but also ensure equitable healthcare access. However, progress has suffered because mobile and digital health data presents unique bioinformatic challenges; Specialized tools are needed for data annotation, pre-processing, organizing, and exploratory and hypothesis-driven analysis and validation that will enable machine learning and multi-modal data integration. Our team built the Digital Biomarker Discovery Pipeline (DBDP.org), which transforms large volumes of mHealth data into digital biomarkers for disease detection, monitoring, and prevention. Digital biomarkers are digitally collected data (e.g. mean resting heart rate) that are transformed into indicators of health outcomes (e.g. fitness) and can be used to provide biomedical insights or improve health decision-making.

Nigam Shah, MBBS PhD: Widespread adoption of electronic health records (EHRs) has fueled the development of using machine learning to build prediction models for various clinical outcomes. Patient representation schemes inspired from language modeling increase the accuracy of clinical prediction models by transferring information learned from the entire patient population to the task of training a specific model. However, as the development of predictive models spans multiple modalities, it is essential to investigate advanced representation schemes that can handle EHR as well as imaging data together. Using the example of predicting long-term outcomes after pulmonary embolism, we will discuss the trade-offs required in learning models spanning both imaging and EHR data. We will discuss the key considerations for evaluating the usefulness of patient representations spanning multiple modalities.

Fei Wang, PhD, will talk about deep clinical risk prediction with patient data from multiple modalities, and the siamese deep modal architecture for the scenarios where the sample sizes are not large.

Timing for the Panel

Multi-modal data science has shown great successes in many domains with big data sets. However, its impact on healthcare applications is still very limited. As diverse large biomedical data are being collected, people can foresee potential success of combining them and triangulating the various streams of evidence in healthcare. We assemble a group of pioneers in researching advanced machine learning models to combine multi-modal data for healthcare problems to provide their perspectives in this topic and collectively discuss the best practices and pitfalls to avoid multi-modal data science for addressing healthcare problems.

Discussion Questions

• What are the major successes of multi-modal data science in healthcare?
• What are the challenges in using machine learning models for combining multi-modal biomedical data sources?
• How to provide interpretable models in the presence of multiple modalities of data?
• What are the common mistakes in using multi-modal data for addressing healthcare problems?
• What are practical solutions of data missingness as this problem is amplified with the integration of several modalities as described?

• In addition to interpretability, what are the challenges with multimodal representations for validation and applying models to new patients?

• How do differences in data veracity across modalities affect implementation and performance of multi-modal models?

Panel Lineup

Moderator: Yuan Luo, PhD, is an Associate Professor at Department of Preventive Medicine, Division of Health Biomedical Informatics at Feinberg School of Medicine in Northwestern University. He is Chief AI Officer at Northwestern University Clinical and Translational Sciences Institute and Institute for Augmented Intelligence in Medicine. His research interests include machine learning, natural language processing, time series analysis, computational phenotyping and integrative genomics, with a focus on biomedical applications. He won the American Medical Informatics Association (AMIA) New Investigator Award in 2020. He is currently an editor with JAMIA Open, JBI, Plos One, JHIR. He served on AMIA Membership and Outreach Committee. Dr. Luo is a fellow of the American Medical Informatics Association (AMIA).

Fei Wang, PhD, is currently an Associate Professor of Health Informatics in Department of Population Health Sciences. His major research interest is developing AI algorithms for solving medical problems, such as clinical risk prediction and disease subtyping. So far he has published more than 250 papers on top venues in AI (such as AAAI, KDD), clinical medicine (such as JAMA Internal Medicine and Annals of Internal Medicine) and health informatics (such as AMIA and JAMIA). His papers have received around 15,000 citations and his H-index is 60. He has received numerous awards including NSF CAREER award, IEEE health informatics leadership award, as well as the awards from industries including Google faculty research award, Amazon machine learning for research award (twice) and Sanofi iDEA award. He has been the PI on numerous grants from federal agencies NSF, NIH, ONR and private foundations such as MJFF. Dr. Wang is a fellow of the American Medical Informatics Association (AMIA).

Benjamin Glicksberg, PhD, Benjamin Glicksberg is an Assistant Professor of Genetics and Genomic Sciences and a member of the Hasso Plattner Institute for Digital Health at the Icahn School of Medicine at Mount Sinai. He helped found and serves as the head of data science for the Mount Sinai Clinical Intelligence Center. He uses machine learning on bio- and clinical informatics frameworks to personalize medicine. This work often involves integrating multi-omic data including genomics, imaging, and clinical information, particularly involving Electronic Health Records. He completed his PhD in Neuroscience at the Icahn School of Medicine at Mount Sinai in 2017 and post-doctoral work at the University of California, San Francisco in 2019.

Jessilyn Dunn, PhD, Jessilyn Dunn is an Assistant Professor of Biomedical Engineering and Biostatistics Bioinformatics at Duke University. Her primary areas of research focus on biomedical data science and mobile health; her work includes multi-omics, wearable sensor, and electronic health records integration and digital biomarker discovery. Dr. Dunn is the Director of the BIG IDEAs Laboratory, whose goal is to detect, treat, and prevent chronic and acute diseases through digital health innovation. Dr. Dunn was an NIH Big Data to Knowledge (BD2K) Postdoctoral Fellow at Stanford and an NSF Graduate Research Fellow at Georgia Tech and Emory, as well as a visiting scholar at the US Centers for Disease Control and Prevention and the National Cardiovascular Research Institute in Madrid, Spain.

Nigam Shah, MBBS PhD Nigam Shah is Professor of Medicine (Biomedical Informatics) at Stanford University, and serves as the Associate CIO for Data Science for Stanford Health Care. Dr. Shah’s research focuses on combining machine learning and prior knowledge in medical ontologies to enable the learning health system. Dr. Shah was elected into the American College of Medical Informatics (ACMI) in 2015 and was inducted into the American Society for Clinical Investigation (ASCI) in 2016. He holds an MBBS from Baroda Medical College, India, a PhD from Penn State University and completed postdoctoral training at Stanford University.

Panel Organizer Statement: We affirm that all panel participants have agreed to participate and have contributed to the preparation of this document.
Panel Proposal: Graph Based Machine Learning for Healthcare: State of the Art, Challenges, and Opportunities

Yuan Luo, PhD\textsuperscript{1}, Fei Wang, PhD\textsuperscript{2}, Marinka Zitnik, PhD\textsuperscript{3}, Shuiwang Ji, PhD\textsuperscript{4}
\textsuperscript{1}Moderator, Northwestern University, Chicago, IL, USA
\textsuperscript{2}Cornell University, New York, NY, USA
\textsuperscript{3}Harvard University, Boston, MA, USA
\textsuperscript{4}Texas A&M University, College Station, TX, USA

Abstract

Analysis with graphs is a classic topic in data mining and many techniques have been proposed in the past. Recently, because of the rapid development of data mining and knowledge discovery, many novel graph based machine learning algorithms have been proposed and successfully applied in healthcare. This panel will reflect on the graph based machine learning algorithms developed recently and how they have been applied in healthcare. They will discuss on using the graph based machine learning models to integrate knowledge graphs with real world data. The panel will also discuss a set of potential issues and challenges such as interpretability, fairness and security.

Background

Graph is a natural representation encoding both the features of the data samples and relationships among them. For example, biomedical relations (including events) can be universally represented as graphs by converting biomedical concepts to nodes and syntactic/semantic links to edges. Other propositional representations may require specific interpretation of the graphs. For instance, representing the negation of a proposition may require the introduction of nested graphs, and to give special semantics to a relation labeled NOT. Furthermore, although composition leads to complexity (e.g. n-ary relations or nested relations), by adopting a graph-based representation, we can focus on common graphical patterns that provide good ways to capture relations. Graph based machine learning has been a popular tool for analyzing interconnected data entities. Analysis with graphs is a classic topic in data mining and many techniques have been proposed in the past. In recent years, because of the rapid development of data mining and knowledge discovery, many novel graph based machine learning algorithms have been proposed and successfully applied in a variety of areas. Different from conventional statistical methodologies which typically assumes the data objects are independently and identically distributed (i.i.d.), graph algorithms can model both the data features and relationships simultaneously. This is particularly important for applications with complex and heterogeneous data.

The goal of this panel is to reflect on the graph based machine learning algorithms developed recently and how they have been applied in healthcare. In particular, the panel will cover both the technical advances and the application in healthcare. On the technical aspect, we will discuss deep network embedding techniques, graph neural networks, knowledge graph construction and inference, graph generative models and graph neural ordinary differential equation models. On the healthcare side, we will discuss how these methods can be applied in predictive modeling of clinical risks (e.g., chronic disease onset, in-hospital mortality, condition exacerbation, etc.) and disease subtyping with multi-modal patient data (e.g., electronic health records, medical image and multi-omics), knowledge discovery from biomedical literature and integration with data-driven models, as well as pharmaceutical research and development (e.g., de-novo chemical compound design and optimization, patient similarity for clinical trial recruitment and pharmacovigilance). The panel will also discuss a set of potential issues and challenges such as interpretability, fairness and security. In particular, the panel will discuss methods for learning disentangled graph representations that capture rich notions of graph topology. They will highlight advances in few-shot learning, yielding models that generalize to completely new graphs and never-before-seen labels using only a handful of nodes or edges. We will ground the graph based ML in examples (e.g., genetic medicine) that have helped healthcare to spark the interest in a wide audience. We will also ensure there is balance between technical details, application and security.

Intended Audience

Biomedical informatic researchers and practitioners.
Learning objectives

The panels aims to benefit participants for:

- Understanding graph based machine learning as an effective means to model and predict complex relations in order to advance biomedical science and improve human health (basic level)
- Understanding recent advances in algorithms and methods used in graph based machine learning (intermediate level)
- Addressing the fundamental challenges in graph based machine learning such as producing fair and stable representations that can be interpreted meaningfully (advanced level)

Topics for Discussion

Yuan Luo, PhD, will discuss graph neural network-based method for text classification covering clinical notes and biomedical literatures, including both long text such as documents and short text such as relations in sentences. He will discuss how to automatically extract relational information out of text into a graph representation and how to learn features from graphs. He will demonstrate that these methods lead to progressively improved performance by integrating lexical, syntactic and semantic information.

Fei Wang, PhD, will discuss the potential of machine learning algorithms on deriving hypothesis and improving quality of biomedical knowledge graphs. He will also talk about how to interact between the inference on knowledge graphs and real world data to achieve mutual performance boosting.

Marinka Zitnik, PhD, will discuss recent efforts to expand the scope and ease the applicability of graph representation learning in healthcare. She will discuss methods for learning disentangled graph representations that capture rich notions of graph topology. She will highlight advances in few-shot learning, yielding models that generalize to completely new graphs and never-before-seen labels using only a handful of nodes or edges. She will also mention efforts at the interface of trustworthy AI and graph machine learning that produce fair and stable representations that can be interpreted meaningfully. Finally, she will discuss applications in disease diagnosis, treatment recommendations, and the development of safe and effective therapeutics.

Shuiwang Ji, PhD, will discuss methodological developments of graph neural networks, including expainability, 3D graphs, generation, and applications into molecular property prediction and drug discovery, molecular graph generation.

Timing for the Panel

Graph based machine learning has shown great successes in many domains with big data sets. This panel will summarize the popular graph based mining technologies that have already been widely applied in healthcare research. As diverse large biomedical data are being collected, people can foresee potential success of combining them and triangulating the evidences in healthcare. We assemble a group of pioneers in researching advanced graph based machine learning for healthcare problems to provide their perspectives in this topic and collectively discuss the best practices and pitfalls to avoid in graph based machine learning for addressing healthcare problems.

Discussion Questions

- What are the major successes of graph based machine learning in healthcare?
- What are the challenges in using graph based machine learning models?
- How to provide interpretable models in the presence of graph based machine learning?
- How to build trustworthy graph machine learning models that produce fair and stable representations?
- How to use graph based machine learning models to leverage knowledge graphs to efficiently inference on real world data?
• What are the common mistakes in using graph based machine learning for addressing healthcare problems?

Panel Lineup

Moderator: Yuan Luo, PhD, is an Associate Professor at Department of Preventive Medicine, Division of Health Biomedical Informatics at Feinberg School of Medicine in Northwestern University. He is Chief AI Officer at Northwestern University Clinical and Translational Sciences Institute and Institute for Augmented Intelligence in Medicine. His research interests include machine learning, natural language processing, time series analysis, computational phenotyping and integrative genomics, with a focus on biomedical applications. He won the American Medical Informatics Association (AMIA) New Investigator Award in 2020. His PhD Thesis was awarded the inaugural Doctoral Dissertation Award Honorable Mention by AMIA in 2017. He is currently an editor with JAMIA Open, JBI, Plos One, JHIR. He served on AMIA Membership and Outreach Committee. His publications appear in leading journals including Nature Medicine, JAMIA, JBI, JAMA Open etc. He has published in and served as PC members for top AI and informatics conferences including AAAI, IJCAI, AMIA, AMIA Joint Summits, IEEE ICHI (track chair) etc. His research is funded by multiple NIH R01 and R21 grants (PI or MPI). Dr. Luo is a fellow of the American Medical Informatics Association (AMIA).

Fei Wang, PhD, is currently an Associate Professor of Health Informatics in Department of Population Health Sciences. His major research interest is developing AI algorithms for solving medical problems, such as clinical risk prediction and disease subtyping. So far he has published more than 250 papers on top venues in AI (such as AAAI, KDD), clinical medicine (such as JAMA Internal Medicine and Annals of Internal Medicine) and health informatics (such as AMIA and JAMIA). His papers have received around 15,000 citations and his H-index is 60. He has received numerous awards including NSF CAREER award, IEEE health informatics leadership award, as well as the awards from industries including Google faculty research award, Amazon machine learning for research award (twice) and Sanofi iDEA award. He has been the PI on numerous grants from federal agencies NSF, NIH, ONR and private foundations such as MJFF. Dr. Wang is a fellow of the American Medical Informatics Association (AMIA).

Marinka Zitnik, PhD, is an Assistant Professor at Harvard University with appointments in the Department of Biomedical Informatics, Broad Institute of MIT and Harvard, and Harvard Data Science. Zitnik investigates machine learning, focusing on graph representation learning, data fusion and knowledge graphs, few-shot learning, and their applications to network biomedicine and development of safe and effective therapeutics. Zitnik has published extensively in top AI/ML venues (e.g., NeurIPS, ICLR, ICML) and leading interdisciplinary journals (e.g., Nature Methods, Nature Communications, PNAS). She has organized numerous workshops and tutorials in the nexus of deep learning, drug discovery, and medical AI at leading conferences (NeurIPS, ICLR, ICML, ISMB, AAAI, WWW). Her research won Bayer Early Excellence in Science Award and numerous best paper and research awards from the International Society for Computational Biology. She was named a Rising Star in Electrical Engineering and Computer Science (EECS) by MIT and also a Next Generation in Biomedicine by the Broad Institute, being the only young scientist who received such recognition in both EECS and Biomedicine.

Shuiwang Ji, PhD, is currently an Associate Professor in the Department of Computer Science & Engineering, Texas A&M University, leading the Data Integration, Visualization, and Exploration (DIVE) Laboratory. He received the Ph.D. degree in Computer Science from Arizona State University in 2010. His research interests include machine learning, deep learning, data mining, and computational biology. Ji received the National Science Foundation CAREER Award in 2014. Currently, he serves as an Associate Editor for IEEE Transactions on Pattern Analysis and Machine Intelligence (TPAMI), ACM Transactions on Knowledge Discovery from Data (TKDD), and ACM Computing Surveys (CSUR). He regularly serves as an Area Chair or equivalent roles for AAAI Conference on Artificial Intelligence (AAAI), International Conference on Learning Representations (ICLR), International Conference on Machine Learning (ICML), International Joint Conference on Artificial Intelligence (IJCAI), ACM SIGKDD Conference on Knowledge Discovery and Data Mining (KDD), and Annual Conference on Neural Information Processing Systems (NeurIPS). Ji is a Distinguished Member of ACM and a Senior Member of IEEE.

Panel Organizer Statement: We affirm that all panel participants have agreed to participate and have contributed to the preparation of this document.
Stewardship Considerations in the Development and Implementation of Shareable SMART on FHIR Applications: Case Studies on Multiple Chronic Condition Care Planning and Chronic Pain Management

Laura Haak Marcial, PhD¹, Saira Haque, PhD, MHSA¹, Kensaku Kawamoto, MD, PhD, MHS², David A. Dorr, MD, MS³, Roland Gamache, PhD, MBA⁴; ¹RTI International, Research Triangle Park, NC; ²Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; ³Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR; ⁴Agency for Healthcare Research and Quality, Rockville, MD

Abstract

Healthcare management and treatment decisions are complex, with uncertain tradeoffs for patients and evolving evidence and guidelines for providers. For patients with multiple chronic conditions and those suffering from chronic pain, the challenges are more complex. This panel will discuss the development and implementation of three SMART on FHIR applications and will detail the development and implementation trade-offs and stewardship considerations needed to move from the sandbox environment to the test and production environments in these real-world settings.

The objectives of the presentation are to understand the complex challenges health systems face in integrating shareable SMART on FHIR applications, to evaluate the potential pitfalls and barriers to standards-based approaches for developing and implementing CDS using FHIR resources, and to assess the advantages for interoperability and knowledge sharing using the FAIR principles (findable, accessible, interoperable and reusable) and the CDS five rights based on the progress in the areas of CDS and FHIR based applications.

Background

Shareable clinical decision support (CDS) artifacts and other solutions that rely on access to fast healthcare interoperability resources (FHIR), such as those represented in the United States Core Data for Interoperability (USCDI), can be limited by the level of support and access to these FHIR resources. To describe these issues three real-world use-cases will be presented that highlight the implications of developing and implementing shareable Substitutable Medical Apps, Reusable Technologies (SMART) on FHIR solutions.

More than 25% of Americans have multiple chronic conditions (MCC), accounting for more than 65% of U.S. health care spending.¹ These individuals have complex health needs handled by diverse providers, across multiple settings of care. As a result, their care is often fragmented, poorly coordinated and inefficient. Therefore, easy data collection & retrieval (through eCare plans) is particularly important for people with MCC. Similarly, chronic (non-cancer) pain affects as many as one in three American adults² and one in ten American adults indicates this issue significantly disrupts their “work, social, and/or self-care activities.”³ These issues are linked to the use of opioids and the related co-morbidities and mortality of opioid use.⁴ The COVID-19 pandemic has further complicated MCC management and chronic pain and opioid management.⁵

The emergence of shareable interoperable solutions that leverage Health Level 7 International (HL7) standards like SMART on FHIR makes it possible to provide integrated solutions for improved care management. These shareable interoperable solutions can be extended with CDS by leveraging tools such as Clinical Practice Guidelines (CPG) on FHIR, CDS Hooks and clinical quality language (CQL). The Agency for Healthcare Research and Quality (AHRQ) has supported work on three projects:

1. The first project utilizes shareable, interoperable, and publicly available resources to address care plan management for patients with MCC through the development and pilot implementation of provider- and patient-facing tools for eCare plan management.
2. The second project leverages shareable, interoperable, and publicly available CDS tools, based on the CDC opioid guidance, to address chronic pain management with the development and pilot implementation of provider- and patient-facing tools to support shared decision making around chronic pain management.
3. The third project has developed an application for the translation of hypertension guidelines and protocols into tailored, interoperable, sharable CDS. The application supports providers and patients in making patient-centered
decisions about clinical actions based on how they interpret variation in conflicting guidelines for treatment in practice.

While the development of SMART on FHIR solutions is still emerging, this area shows a great deal of promise for enhancing focus and attention on disease management. Shareable CDS solutions are a novel way to build and propagate computable evidence-based practices in a variety of settings and EHR vendor systems. In practice, creating these interoperable tools has been limited to the sandbox environment where conditions are constrained. Moving these shareable solutions into real world environments has been limited to date. This panel discusses the real-world implications of developing and implementing shareable SMART on FHIR solutions to address multiple chronic conditions including chronic kidney disease, chronic pain, and hypertension and the challenges, opportunities, and ongoing management considerations which will need to be addressed to continue to expand into other contexts, vendor systems, and disease domains.

Learning Objectives

- Describe some of the complex challenges health systems face in integrating shareable SMART on FHIR applications with a focus on stewardship (ongoing management) and issues spanning multiple projects and implementing institutions.
- Provide key facilitators and barriers regarding stewardship of shareable standards-based approaches for developing and implementing CDS using FHIR resources.
- Assess the advantages, across projects and health systems, for interoperability and knowledge sharing using the FAIR principles and the CDS five rights based on the progress in the areas of CDS and FHIR based applications.

Speaker Contributions

- Dr. Gamache is a Staff Fellow at AHRQ. He will serve as the panel moderator and introduce the panel participants. To set the objectives of the panel, he will describe the major objectives of the work that AHRQ supports and promotes for shareable and interoperable CDS based on the CDS five rights and the FAIR principles.
- Dr. Kawamoto is Associate Chief Medical Information Officer of University of Utah Health. He will provide an overview of relevant standards including FHIR, SMART, CDS Hooks, and Clinical Quality Language (CQL). He will also provide examples of the use of these standards in a number of operationally deployed clinical applications.
- Dr. Marcial is a Health Informaticist at RTI International. She will highlight some of the implementation challenges associated with implementing the Clinical Decision Support for Chronic Pain Management (CDS4CPM) solution with specific reference to the key stewardship considerations identified in working with the health systems implementing shareable solutions.
- Dr. Haque is the Senior Director, Clinical Informatics Medical Outcomes Specialist at Pfizer. She will highlight experiences with implementation, use and evaluation of SMART on FHIR apps across organizations. She will focus on discussion of a patient-facing and provider-facing FHIR app to support e care plans for patients with MCC within and across organizations.
- Dr. Dorr is the Chief Research Information Officer at Oregon Health & Science University. He will discuss the process of implementation of these applications, the need for local validation and usability testing, and the evaluation process for effectiveness of these applications. He will focus on applications for high blood pressure, goal setting, and self-management support.

Expected Discussion and Discussion Questions

Panelists will stimulate discussions on issues of stewardship associated with shareable interoperable SMART on FHIR applications. Discussion questions include:

1. What kinds of resources will require special attention for long term (beyond the pilot period) of implemented shareable SMART on FHIR applications?
2. What are evaluation considerations for SMART on FHIR apps?
Attestation
The panel moderator has assurances from all participants that they will be available to participate at AMIA 2021.

Abstract

Amidst significant barriers to scaling SARS-CoV-2 diagnostic testing during the pandemic, laboratories across the US developed a variety of solutions to expand access to testing and operate efficiently. In this panel, informaticists working in the domain of laboratory medicine will share their experiences scaling laboratories rapidly to address the needs of their communities and regions during the pandemic. Recurring themes in healthcare informatics will be discussed in the context of the pandemic: building vs. buying solutions, the benefits and drawbacks of HL7 as the standard mechanism to communicate orders and results, and the requirements for communicating actionable genomic information for infectious diseases. By exploring these themes, attendees will be able to consider developing and yet-to-be-developed informatics solutions to strengthen our healthcare and public health infrastructure.

Introduction

Throughout the first year of the COVID-19 pandemic few challenges were as prominent as scaling up and providing access to SARS-CoV-2 laboratory testing across the US. Clinical and public health laboratories across varying settings had to respond to an unprecedented need for testing amidst supply chain constraints, limited federal resources, and regulatory barriers. In the absence of clear solutions to manage the flow of orders, results, and data, laboratories performing SARS-CoV-2 testing were required to develop a variety of solutions to challenges in their setting and support the necessary response\(^1,2,3\).

The pandemic response re-introduced the common consideration of trade-offs in adopting the approach of building solutions vs. working with vendors to upgrade/purchase solutions and prompted organizations to ask: when is purpose-built custom software the best solution compared to an existing electronic health record system in meeting the needs for high throughput testing? Each of the organizations in this panel pursued different approaches in addressing the need to scale testing quickly and safely. Collecting and exchanging the information required for the public health response also emerged as an ongoing challenge. The traditional route of developing HL7 orders and results interfaces between laboratories and other entities often was not an agile approach at scale. These challenges clearly indicate the need for a more centralized approach to coordinating information flows, such as establishing a universal patient identifier, but did also allow collaborative problem-solving between laboratories and partners to evolve. In addition to navigating the challenges of providing accurate and rapid diagnostic services, disease surveillance focused on viral genomic sequencing emerged as an additional component of the broader public health response. The data generated by these activities largely exists and is exchanged outside of the standard data exchange mechanisms between laboratories and public health authorities, which has introduced an emerging need for informaticists to address.

In this panel, informaticists representing clinical laboratories across a variety of sizes and settings will discuss the challenges they faced in supporting the testing response and consider the current state of health information systems and the tradeoffs encountered in the context of an unprecedented pandemic. Each panelist will provide a short summary of the problems their organization needed to solve and discuss the solutions that were developed as well as the work that still needs to be done to improve the health of their population and of the public. By revealing different needs and challenges faced by a variety of organizations, the panel will consider the most prominent needs at the interface of laboratory services and the US public health infrastructure.
Panel Moderator:

**Patrick C. Mathias, MD, PhD** is an Assistant Professor in the Department of Laboratory Medicine and Pathology and an Adjunct Assistant Professor in the Department of Biomedical Informatics and Medical Education at the University of Washington School of Medicine. He serves as the Vice Chair of Clinical Operations and the Associate Medical Director of Informatics for the Department. His service work spans the configuration of the LIS and EHRs as well as the development of analytics and data science resources to support laboratory medicine and pathology quality improvement and research. As moderator, Dr. Mathias will outline the broad challenges of high-throughput test coordination and information exchange for laboratories and consider the remaining unsolved problems in which future development should be invested.

Panelist 1: Rapid implementation of high-volume community-based SARS-CoV-2 PCR testing in Washington State

**Noah G. Hoffman, MD, PhD** is an Associate Professor at the University of Washington and Head of the Informatics Division in the Department of Laboratory Medicine and Pathology. Dr. Hoffman is trained as a Clinical Pathologist, and his areas of specialization include medical informatics, bioinformatics, and software development for the clinical laboratory. Dr. Hoffman will describe the implementation and iterative improvement of the high volume SARS-CoV-2 PCR testing services developed in partnership between the University of Washington and local health authorities throughout Seattle, King County, and Washington State. Solutions to coordinating testing leveraged a combination of existing commercial systems, rapidly-developed custom applications and databases hosted both on premises and in the cloud, and third party practice management software for scheduling and data collection. The discussion will include a consideration of the organizational features and capabilities that contributed to the success of this collaboration, resulting in over one million test results delivered to date.

Panelist 2: Making an elephant dance: how the pandemic required a large national laboratory to adopt a startup mentality, to rapidly spin up new operational processes and associated software

**Brian Jackson, MD, MS** is Associate Professor of Pathology, and Adjunct Associate Professor of Biomedical Informatics, at the University of Utah. He is the medical director for IT, Business Development and Support Services for the University’s national laboratory business (ARUP Laboratories). Dr. Jackson will describe how COVID-19 testing required ARUP Laboratories to rapidly adopt new processes that were not anticipated within existing IT systems. In one use case, ARUP was asked to provide testing services for professional sports leagues as well as the 2020 U.S. vice presidential debate. This required development of an app for capturing patient demographics at the testing site and associating the patient id with a barcoded specimen. In another use case, ARUP received barcoded samples associated with orders captured by a third party system developed by a major software vendor unfamiliar with healthcare IT standards. This created a number of operational and IT challenges in order to reconcile this data in near-real-time for rapid testing.

Panelist 3: A wake up call for laboratory data interoperability

**Amrom Obstfeld, MD, PhD** is an Assistant Professor in the Department of Pathology and Laboratory Medicine at Children’s Hospital of Philadelphia and the Medical Director of Pathology Informatics for the Department. He serves as the primary liaison for informatic related issues spanning laboratory and clinical domains in addition to leading informatic and analytic projects within the Department. In this session Dr. Obstfeld will discuss the important role and significant challenges of interfacing SARS-CoV-2 test results during the coronavirus pandemic. Because of the critical nature of SARS-CoV-2 test results, the pandemic put a focus on the importance of health information exchange and data sharing between labs, hospitals and public health agencies. Nevertheless the urgent and rapidly evolving nature of the crisis often exacerbated long standing semantic and syntactic interoperability challenges which were superimposed upon a significantly deregulated laboratory environment. After systematically considering these barriers potential mitigation strategies will be discussed.

Panelist 4: Preparing for the new age of next generation sequencing based global pathogen epidemiology: How a hospital system in Houston became a leader in COVID-19 sequencing surveillance
S. Wesley Long, MD, PhD is an Associate Professor of Pathology & Genomic Medicine at Houston Methodist Hospital. He is the medical director of Diagnostic Microbiology and Pathology Informatics. Dr. Long will discuss how he prepared to leverage his research laboratory to sequence all of their hospital system’s COVID-19 isolates starting in January of 2020. As a part of this, he will discuss how they identified the ARTIC protocol and GISAID global network for COVID-19 epidemiology, how they leveraged and adapted existing pipelines for bioinformatics as well as protocols for sequencing. In particular, he will discuss the central tension between the need for local sequencing intelligence as well as the demands of public health authorities and global research groups. He will illustrate the importance of rapid iteration, nimble workflows, and overcoming supply chain issues to meet institutional goals as well as provide useful information to the global community to fight a growing pandemic.

Discussion Questions

1. What were the most significant obstacles laboratories, healthcare organizations, health jurisdictions, and communities faced in increasing access to testing?
2. What capabilities were required to rapidly develop solutions to scale testing to the necessary volumes and settings?
3. How should traditional healthcare informatics resources be reconfigured to respond rapidly to quickly changing needs?
4. What are the strengths and limitations of existing data exchange mechanisms between laboratories, healthcare organizations, and public health authorities?
5. How does data from new laboratory methods such as viral genomic sequencing fit into the broader landscape of health information exchange?

Learning Objectives

The panel will examine the current state and the future needs of providing laboratory services to healthcare organizations and the public to support the pandemic response as well as broader public health activities.

• Describe the standard architecture used to transmit laboratory data between clinical information systems.
• List the stakeholders involved and information sources required to communicate actionable information to public health jurisdictions.
• Compare the structure of emerging laboratory data types such as sequencing data with existing and developing standards for information exchange.

Target Audience

This panel will be of interest to informaticists working in the domains of information exchange and interoperability as well as those implementing EHRs to support population health scale efforts.

Panel Organizer Statement

All panelists have agreed to participate in this panel.

ABSTRACT

The National Institutes of Health recognizes the importance of biomedical informatics innovations in accelerating data-driven discovery in biomedical science, clinical care and patient self-management. Of key importance is accessing information in the electronic health record. In the past three years, the NIH has expressed its public commitment to encourage researchers to adopt informatics innovations such as common data elements (CDEs), the Observational Medical Outcomes Partnership (OMOP) common data model, and standards such as the Fast Healthcare Interoperability Resource (FHIR) and the United States Core Data for Interoperability (USCDI). Policy statements are most effective when they are accompanied by operational procedures and vocal leadership direction. The purpose of this panel is to demonstrate the strength of informatics know-how among the leadership of the NIH, identify existing commitments by the NIH to ensure accelerating the research value of clinical health records, and to glean insights of strategies the NIH should consider as they develop the informatics infrastructure for the future of biomedical discovery.

DESCRIPTION OF THE PANEL

For the first time in its 133-year history, the National Institutes of Health (NIH) has major biomedical informatics leadership. The NIH recognizes that the future of biomedical discovery rests in part on being able to leverage the knowledge embodied in clinical information records. For example:
More so than ever before, understanding the natural history of a pandemic and ensuring best practices in being able to treat it relies on gleaning important insights from clinical records. More importantly, the ability to quickly and efficiently access clinical information provides an opportunity to titrate clinical trials in response to in-the-moment understandings of the course of illness and response to care for patients.

Better understanding of the long-term course of the pandemic and its clinical sequelaes rests on being able to track patients across time. Clarifying the impact of novel vaccines or clinical therapeutics would be enhanced by being able to integrate participant information across any and every study in which the participant is represented.

There is increasing recognition about research that emphasizes the re-usability and machine-actionability of large-scale data for applications such as machine learning and artificial intelligence. At the same time, there is appreciation for the importance of interdisciplinary approaches to collaboration across diverse social, cultural, economic, academic, and industrial backgrounds and communities.

The NIH is deeply engaged in exploring the value of contemporary and emerging informatics innovations including cloud based reusable platforms/datasets, common data models, and the effective development and use of artificial intelligence and machine learning approaches to biomedical research and clinical practice.

Each of these requires effective deployment of informatics innovations into the research process.

AMIA’s Clinical Research Informatics community has done much to enhance the integration of biomedical informatics concepts into the research process. Much progress has been made in the efforts to structure information for clinical and translational research and common data elements. Incremental progress must be praised, but to engage the operations of the world’s largest biomedical enterprise requires multiple points of engagement. Specifically, expanding the critical mass of leadership with expertise in biomedical informatics is essential for instituting enterprise-wide change.

The National Library of Medicine (NLM) has long served as the voice of biomedical informatics at the NIH. Innovations such as the Unified Medical Language System and the development of innovative clinical information systems to extract clinically specific phenotypes served the biomedical enterprise. The NIH has adopted many of the NLM-advocated strategies for data alignment and information reuse, including common data elements. The next step in the process is to engage the NIH in an enterprise commitment to the use of clinical data standards (USCDI, FHIR). The final step is engagement in the operational level of the NIH enterprise, and that requires instantiation at the highest levels of NIH leadership – the ability to translate the operational goals of the various institutes and centers (ICs). This requires people knowledgeable in biomedical informatics to sit at the table with the directors across all of the NIH.

Perhaps as evidence of the importance of biomedical informatics in the research enterprise, NIH now has directors of three institutes and/or major operations who hold standing in the biomedical informatics community. The number of American College of Medical Informatics fellows among the NIH staff is expanding. Not only does this allow a ‘community of conversation’ but embedding informatics expertise across the NIH has accelerated the acceptance of, and the valuing of, biomedical informatics in the biomedical research enterprise.

In this panel, three NIH Directors with background in biomedical informatics, as well as an experienced NLM intramural investigator, will discuss perspectives on these topics and how they are evolving at NIH.
DISCUSSION: CHALLENGES AWAIT US

The panel will end with a discussion period involving panelists and audience members. This will focus on collecting insights from participants about approaches for the NIH to consider in developing informatics infrastructure for the future of biomedical discovery. Special characteristics of the NIH, particularly the diversity of research cultures across 27 institutes and centers, do not lend themselves to highly orchestrated solutions. Design thinking, which involves engaging both program staff and the extramural community, will more likely lead to solutions that allow at once for local specification while promoting trans-NIH integration. Additionally, any solutions proposed by the NIH will need to align with business and clinical operations in over 3000 health care delivery systems; human factors approaches that support specification of operational practices and leverage rather than disrupt local cultures will only arise through effective analysis and modeling. This panel is designed as much to share the NIH perspective as it is to glean wisdom and guidance from the AMIA community.

In summary, the NIH investigators are ready to engage with clinical data for the purposes of research, but many challenges remain. The first challenge rests in arriving at a common nomenclature to address the broad range of clinical data. The second challenge must address the problem of interoperability for research – and how do we ensure that data generated in the course of care become useful for clinical research? Additional concerns arise in how the original consent for data collection and whether future research reuse considerations may be adequately addressed at the point when consent is obtained.

Abstract

Individuals whose activities and experiences will be most impacted by a new technology should have input into the design process. These individuals offer invaluable expertise with respect to perspectives and preferences for the workflow or chain of activities the technology is intended to impact. How well a technology fits into a specific workflow influences its adoption and use. Collaborative design is increasingly important to capture and better reflect individualized activities and experiences. At the same time, there are pragmatic challenges such as participant trust, recruitment, and engagement in the co-design process. Moreover, the COVID-19 pandemic has pushed researchers to find novel and creative ways of co-designing with end-users. In this panel, we will discuss co-design core concepts and research trends in biomedical informatics through practical examples from the research experiences of a diverse set of panelists.

Introduction

Designing health information technologies with patients, providers, and citizens (co-design), who are the intended end-users of these solutions, generally makes them more acceptable and usable. The value of co-design is that it can highlight the sociotechnical and cultural aspects of clinical care and patient self-management that may ultimately change behaviors and improve outcomes\(^1\). Approaches to identifying these aspects include participatory research design (community collaboration and engagement across all research stages), participatory design (focused and purpose driven collaboration with end users), and user-centered research (participation around specific design features). Given these differing approaches, there remains an opportunity for better clarity on the different ways of engaging with patients, caregivers, and the community for co-design. Challenges in this area include, for example, the effort required to build partnerships with relevant communities, especially if the medical establishment has historically marginalized them. In addition, many informatics tools currently in practice are limited in realizing the value of co-design by their focus on technology and deterministic evaluation outputs rather than the social or psychological aspects of users they intend to impact. In this panel, we explore concepts, ideas, and approaches to co-design across a wide variety of populations to identify common methodological themes and opportunities. For example, co-design may be more useful when it is seen as part of an iterative development process for generating new knowledge about a phenomenon rather than a method to achieve a specific outcome metric.

We will focus on three population use cases in co-design: marginalized and hard-to-reach populations, the elderly, and those with disabilities. The patient or caregiver perspective will be emphasized. We plan to talk about the role of co-design in technology-based interventions that span the trajectory from independence to emergency care to longer term care needs. Approaches and challenges in co-design methods across these use cases will be examined. For example, we will discuss the development of in-home technology and care delivery models to support aging safely in place. Ways of eliciting cancer care patient needs for integrative oncology services will also be covered.

At the end of this panel session, attendees can expect to better understand: (1) what co-design is and how it may best be viewed and applied; (2) aiding selection of co-design methods, (3) learning how to engage diverse groups in co-design, and (4) leveraging multiple modes of user engagement.

All panelists have agreed to take part on the panel.

This panel is endorsed by the AMIA Consumer and Pervasive Health Working Group Leadership.
Multimodal Co-creation for Personal Health Information Management

Active engagement in personal health activities requires access to actionable, understandable, relevant, reliable, and up-to-date, evidence-based information that meets the user’s specific health context and literacy level. However, lack of well-designed tools to enable such access is a significant problem for efficient personal health information management support across activities for a) episodic self-care, b) during complex treatment and frequent interactions with the health system, or c) continuous self-management. We will contribute experiences from co-creation workshops with video material, interviews and experiences to represent user voice to design accessible and universally designed digital tools where the users can 1) collect relevant health information, 2) complement or annotate according to personal, situational need, 3) collaborate with trusted partners and the health care team, and 4) choose to share but retain control of “what to share, with whom, and for how long”. A shared concern is to strike the best balance of digital health literacy capacity, availability of information for collaboration, integrity, confidentiality and personal preferences for trust, and legal requirements for data protection.

Co-design Methods, Opportunities, and Challenges in Mobile App Development

The explosion of digital health technologies has challenged traditional institution-centric care. Virtual care has rapidly evolved, creating reciprocal relationships between patients and providers where patients are involved in the production process. For example, in telehealth, patients use videoconferencing, document symptoms, and capture data using digitally enabled medical devices. For this reason, the people using the solution may be best positioned to help create it through the use of co-design principles. There are opportunities to use co-design methods when developing digital health solutions and care delivery models to share responsibility and achieve value for all stakeholders. Methods and findings from a virtual co-design study will be presented. The co-design study focused on identifying patient needs for integrative oncology services as a foundation for mobile application development. Opportunities and challenges associated with the use of co-design methods will be explored using case examples from the study.

Choosing and Chaining Co-design Methods: Concepts and Concrete Examples

What should researchers and practitioners consider when choosing co-design methods for a particular problem, context, and set of stakeholders? This presentation offers guidance on bringing together multiple co-design methods to increase the depth and rigor with which design ideas are generated, elaborated, and evaluated. This guidance will be grounded in a case study of a series of future workshops, storyboarding workshops, and focus groups that characterized the design space for improving patient-provider communication about patients’ personal values and health priorities. Analyzing the case studies through the lens of design theory on hybrid spaces4 and inventive methods5, as well as standards for high quality qualitative health research (credibility, transferability, dependability, and confirmability6), this presentation offers theoretical concepts and concrete examples to guide researchers and practitioners in matching co-design methods to the design context.

Participatory Research with Underserved Populations

Challenges and lessons-learned related to scoping a joint research focus, building long-standing relationships, and engaging in participatory interactions using virtual platforms, particularly as related to underserved populations will be discussed. Negotiating publications and traditional academic outputs in the context of such partnerships will also be covered. Attendees should be able to describe the challenges associated with participatory design-based approaches to informatics research in home and community-based settings and associated strategies to overcoming them.

Moderator and Panelist Biographies

Mollie Mc Killop, PhD, MPH (panel moderator) is a biomedical informatician at the Center for AI, Research and Evaluation (CARE). In this role, Mollie provides technical, informatics, and evaluative leadership in the design, development, and execution of research evaluation studies across IBM Watson Health, focusing on consumer-facing offerings in the payer and government market segments. Mollie is also the publications and publicity co-chair for the AMIA Consumer and Pervasive Health Working Group.

Anne Moen, RN, PhD, FACMI, FIAHSI (panelist) is professor at the Faculty of Medicine, University of Oslo, Oslo,
Rosemary Kennedy PhD, RN, MBA, FAAN (panelist) is Chief Health Informatics Officer at Connect America. She is a recognized informatics domain expert holding many leadership roles through her work with the AMIA and Technology Informatics Guiding Educational Reform Board. Dr. Kennedy is widely presented and published in the field of nursing informatics, clinical documentation, and terminology standards. She is a fellow in the American Academy of Nursing and a recipient of the HIMSS Nursing Informatics Award and Modern Healthcare Top 25 Women in Healthcare Award. She served as Vice President of Health IT for the National Quality Forum in Washington DC and Chief Nursing Informatics Officer for Siemens Healthcare Solutions.

Andrew Berry, PhD (panelist) is a design researcher focused on improving health equity for people with complex health and social needs. He is a National Library of Medicine Postdoctoral Fellow in Biomedical Informatics with a Ph.D. in Human Centered Design & Engineering and applied industry experience in technical services at Epic. He uses a mixed-methods approach, with a focus on qualitative, human-centered, and participatory methods for research and design.

Rupa Valdez, PhD (panelist) is an Associate Professor of Biomedical Informatics and Engineering Systems and Environment at the University of Virginia. Her research draws heavily on participatory design and community-engaged approaches to understand and design systems to support patients and their social networks (e.g. family, friends, neighbors) with managing health at home. Much of this work focuses on underserved populations, including racial and ethnic minorities, people with disabilities, and people living in under-resourced settings.

Discussion Questions
1. What does co-design mean to you?
2. How have you built trust with the communities you work with?
3. What excites you the most about community collaboration, co-design, or participatory research?
4. What do you think the future of the field of co-design in informatics looks like?
5. How do you choose which co-design methods are appropriate for which applications or populations?
6. For those who are new to the field, what would you recommend for both career development and building expertise?
7. How do you think we can move the field forward so that more informatics tools include a co-design development approach that is inclusive and useful for all?
8. What are the biggest challenges you face in co-design research and how have you worked to overcome these challenges? What are the biggest opportunities in the field?

Balancing Access to Federal Data Sets with Enhancing Privacy and Security

Lisa B. Mirel, M.S.1, Stephanie Garcia, M.P.H.2, Stefan Jaeger, Ph.D.3, Ziv Yaniv, Ph.D.4, Patricia Keenan, Ph.D.5, Susan Lumsden, M.S.6

1 Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Atlanta, GA; 2Office of the National Coordinator for Health Information Technology, U.S. Department of Health and Human Services, Washington, DC; 3National Library of Medicine, U.S. Department of Health and Human Services, Bethesda, MD; 4National Institute of Allergy and Infectious Diseases, U.S. Department of Health and Human Services, Bethesda, MD; 5Agency for Healthcare Research and Quality, U.S. Department of Health and Human Services, Rockville, MD; 6Assistant Secretary for Planning and Evaluation, U.S. Department of Health and Human Services, Washington, DC;

Abstract
The Office of the Secretary Patient-Centered Outcomes Research Trust Fund (OS-PCORTF) portfolio is charged with building data capacity for the conduct of patient-centered outcomes research (PCOR). Federal data sets may contain sensitive information, such as patient-level identifiers. Therefore, access to federal data sets for research is often limited due to privacy protection concerns. This panel features four OS-PCORTF projects in the Department of Health and Human Services’ (HHS) that balance access to data with privacy and security concerns, including privacy preserving record linkages between federal data sets, synthetic data to eliminate the risk of re-identifying anonymized data, developing training data sets to improve research capacity for machine learning, and developing publicly available databases with social determinants of health (SDOH) data at the small-area level. Panelists will each provide an overview of their project, describe the contributions to ensure high-quality health care-related data, and discuss informatics-related opportunities to protect privacy.

Learning Objectives
1. Learn methods to protect privacy when one needs access to data to conduct PCOR.
2. Identify contributions by the federal government on the use of informatics to support PCOR.

Panel Description
This panel will highlight four OS-PCORTF collaborative projects focused on an overarching goal of developing and assessing promising methods to protect privacy while making federal data sets more accessible. Specifically, the projects focus on (1) using privacy preserving record linkages between federal data sets; (2) using synthetic data to eliminate the risk of re-identifying anonymized data; (3) developing training data sets to improve the research capacity for machine learning; and (4) developing a consolidated set of databases with social determinants of health (SDOH) factors at the small-area level as opposed to the individual-level.

Lisa B. Mirel, M.S., from the Centers for Disease Control and Prevention (CDC), National Center for Health Statistics (NCHS), will speak about her work on the project, “Data Linkage: Evaluating Preserving Privacy Methodology.” The project aims to conduct a methodological assessment of privacy preserving record linkage techniques (PPRL). The National Hospital Care Survey data will be linked to the National Death Index using PPRL techniques and then compared to the linkage results using a standard linkage algorithm that rely on the exchange of unencrypted identification data. The project will assess how the use of PPRL may affect the quality of the linked data (precision and recall) and further affect the inference (estimates) in secondary analysis of those data. This assessment will inform the health data ecosystem on the evaluation of PPRL methodology and may increase the linkage activities at NCHS.

Stephanie Garcia, M.P.H., from the Office of the National Coordinator for Health Information Technology (ONC), will present the project, “A Synthetic Health Data Generation Engine to Accelerate Patient-Centered Outcomes Research.” High-quality health care-related data are often difficult to access because of cost, patient privacy, or
other legal and intellectual property restrictions. As conceptualized in another OS-PCORTF project, “Privacy and Security Blueprint, Legal Analysis and Ethics Framework for Data Use, and Use of Technology for Privacy,” researchers and developers often depend on anonymized data to test theories, data models, algorithms, or prototype innovations to protect privacy. However, the risk of re-identification of anonymized data is high, especially with rare conditions. Further, due to a variety of interoperability issues, it is often difficult to bring data together from different resources for the purpose of robustly testing analysis models, algorithms, or assisting in the development of software applications. Use of synthetic data eliminates the risk of re-identifying anonymized data—which can occur when using de-identified datasets—and bypasses the interoperability challenges that can stem from combining disparate data sources for PCOR. The project will enhance the capabilities of Synthea™, an open-source software that creates large amounts of clinically realistic, synthetic patient health records. The project will increase the number of synthetic patient health records by developing data generation modules for opioid, pediatric, and complex care use cases.

Stefan Jaeger, Ph.D., from the National Library of Medicine (NLM) will present work he conducted with Ziv Yaniv, Ph.D., from the National Institute of Allergy and Infectious Diseases, on an interagency project between NLM and ONC titled “Training Data for Machine Learning to Enhance Patient-Centered Outcomes Research (PCOR) Data Infrastructure.” Artificial Intelligence (AI) and associated innovative technologies like machine learning consume large amounts of data in varied, complex formats to identify effective treatments, potentially accelerating clinical innovation by speeding up the research lifecycle and the application of evidence in clinical settings. Machine learning relies on training data sets and training algorithms to “learn” how to identify patterns with little human intervention. The project will improve research capacity for machine learning by curating high-quality training data sets. The training data sets will use HHS research data, including linked clinical data. The project will develop a use case for detecting drug resistance in tuberculosis patients, leveraging federal data assets from the National Institute of Allergy and Infectious Diseases (NIAD).

Patricia Keenan, Ph.D., from (AHRQ), will present AHRQ’s work on the project, “Enhancing Patient-Centered Outcomes Research (PCOR): Creating a National Small-Area Social Determinants of Health (SDOH) Data Platform.” For many decades, researchers have emphasized the importance of SDOH and have developed many different conceptual models to explain the inter-relationship between individual, family, and societal factors on the health of an individual. However, SDOH data may not always be easy for providers to collect at the patient level and patients may not always want to share individual-level SDOH data. This project makes SDOH data available for public use by developing a consolidated set of publicly available national standardized databases on valid and reliable SDOH factors at the small-area and other geographic levels. The project is building on existing federal databases maintained by agencies such as AHRQ, Health Resources and Services Administration (HRSA), CDC, Assistant Secretary for Planning and Evaluation (ASPE), and the National Institutes of Health (NIH). Data elements will span the SDOH landscape and include measures of social context, economic context, education, physical infrastructure, and healthcare context.

Following the presentation, Ms. Susan Lumsden will moderate a Q&A between the panelists and audience members.

**Timeliness of Topic**

To answer complex research questions aimed at improving value and whole-person care requires the ability to link data sets and aggregate data from disparate sources. However, data breaches erode trust among patients and participants to share their data and have huge financial implications. In 2019, 64% of Americans were concerned about how the government uses the data collected. In 2020, the average cost of a data breach in the healthcare industry was $7.13 million. The risk of data breaches emphasizes the importance of measures that protect privacy among clinical and federal data sets. There is a need to balance access with enhancing privacy and security so that researchers can access representative data sets to conduct robust PCOR. The projects featured on this panel contribute to the availability of federal data or leverage federal data to offer alternatives, which can ultimately improve PCOR and ultimately health outcomes. The panel will hopefully spur more strategies that enhance privacy and security and inform how research and health care entities can better balance data access with security.

**Discussion Questions**

1. How have interagency collaborations enhanced the work in privacy preservation?
2. What are real world applications of the methods from each project?
3. What are next steps for the projects and how will findings and resources be disseminated?
All participants have agreed to take part in the proposed panel.

Abstract

While the fight against the SARS-CoV-2 virus has ramped up with new vaccines and therapeutics, there is a growing urgency to study and address another side of the pandemic, the shapeshifting syndrome often known as the post-acute sequelae of COVID-19 (PASC). This panel is designed to share the experiences and innovative approaches of the Consortium for Clinical Characterization of COVID-19 by EHR (4CE) to study and model the PASC across an internationally diverse group of healthcare institutions. The panel will discuss the organization of 4CE, computational phenotyping to identify cases of post-COVID syndromes, the identification of temporal phenotypic pathways, and the application of sociobehavioral agent-based network models to explore those pathways for prediction and intervention in population contexts.

Introduction and Background

A collection of persistent physical (e.g., fatigue, dyspnea, chest pain, cough), psychological (e.g., anxiety, depression, post-traumatic stress disorder), and neurocognitive symptoms (e.g., impaired memory and concentration) can appear and last for weeks or months in patients after acute COVID-19.1–3 These Post-Acute Sequelae of SARS-CoV-2 infection could impede the ability of some coronavirus patients to work and function normally,4–7 costing the U.S. economy billions of dollars annually in medical bills and lost incomes for an unforeseeable future. While the exact number of people afflicted by post-Covid syndrome is unknown, it represents a significant public health burden because of the large magnitude of the COVID-19 spread globally. Further, the extent to which the post-acute sequelae of COVID-19 represents a new syndrome unique to COVID-19, or an overlap with the recovery from similar illnesses, is unknown. Furthermore, little is known about COVID-19 phenotypes and subphenotypes, especially in a temporal context and how these phenotypes emerge in sociobehavioral contexts.

In March 2020 an international effort called the Consortium for Clinical Characterization of COVID-19 by EHR (4CE) was launched. It used a federated model, where local experts in informatics, statistics and clinical medicine were engaged at more than 340 hospitals across 9 countries on 4 continents to run analyses locally at each site (sharing only aggregate results) and to iteratively improve the data quality in the local databases. The 4CE network was created to study EHR-derived data from multiple institutions and was based upon experience that it can only be successful if you trust the findings. This means being able to go back to each site and talk to the people who know the data best, to develop and refine the research questions and understand the local clinical guidelines, coding practices, data quality problems, and other factors that affect the data, and compare it to the EHR directly though Chart Review.

Panel Description
Dr. Shawn Murphy will lead a panel discussion on the Post-Acute Sequelae of SARS-CoV-2 Infection across the 4CE consortium, and in doing so will help the audience better understand the possibilities of leveraging EHR data to identify the phenotypes and its subtypes within the U.S. and internationally. Dr. Murphy is a Professor of Neurology and Biomedical Informatics at Harvard Medical School, Chief Research Information Officer at Mass General Brigham, and the Associate Director of the Lab of Computer Science at MGH.

The panel will include a review of studies across the 4CE consortium to understand temporal patterns of analysis that are able to tease out events sequences that allow observing the unique characteristics of a disease as it progresses. The panel will also discuss the future implications of international collaborations to address the post-Covid sequelae using large scale clinical data.

Given the global public health significance of the Post-Acute Sequelae of SARS-CoV-2 infection and the international outreach of the 4CE consortium, the proposed panel is well suited for the AMIA members and audience.

**Presenters**

**Post-Acute Sequelae - the Italian case (Bellazzi)**

Dr. Riccardo Bellazzi is Professor of Bioengineering and Medical Informatics, Director of the Department of Electrical, Computer and Biomedical Engineering of the University of Pavia, and director of the LISRC labs of the ICS Maugeri hospital in Italy. Starting from the experience coming from the 4CE initiative, in which we collected EHR data coming from more than 4,100 italian patients, Prof. Bellazzi will discuss the organizational aspects related to the data collection and curation of long-Covid patients highlighting differences and similarities between the Italian and US case, and he will also address some computational challenges of long-COVID phenotyping.

**Computational Phenotyping to Identify Post-Covid Syndrome in Outpatient Population (Estiri)**

Dr. Hossein Estiri is an assistant professor of medicine at MGH lab of computer science and Harvard Medical School. Many of the post-Covid symptoms could have multiple causes. Yet, the extent to which the post-acute sequelae of COVID-19 represents a new syndrome unique to COVID-19, or an overlap with the recovery from similar illnesses, is unknown. In his presentation, Dr. Estiri will describe application of computational phenotyping for identifying the clinical records that positively associate with a patient having tested positive for COVID-19 in the past. He will introduce approaches for effectively leveraging large scale clinical data to study and model the post-acute sequelae of COVID-19 (PASC). Finally, Dr. Estiri will present novel diagnosis and biomarkers of the PASC identified through the application of the computational phenotyping to COVID-mart clinical data from the Mass General Brigham in Boston.

**Temporal Trajectories and Careflows models to analyse Post-Covid clinical pathways (Dagliati)**

Dr. Arianna Dagliati is an assistant professor of Bioengineering and Medical Informatics at the Department of Electrical, Computer and Biomedical Engineering of the University of Pavia. Patients affected by post-Covid symptoms might undergo heterogeneous clinical courses both from the physiopathological and process-of-care points of view. Temporal phenotyping based on discrete events sequences allows observing the characteristics of a disease as it progresses, especially in relation to care processes. Other approaches
capture interactions between disease changes over time from continuous multivariate data and define trajectories as key features to characterize disease subtypes. Using data from two Italian hospitals in the Lombardy region, Dr. Dagliati will describe the application of temporal phenotyping methods to derive post-Covid phenotypic paths from multivariate trajectories and sequential patterns, and how the integration of these approaches might enable clinicians to identify early warning signs of progression in specific post-Covid patients.

**Modeling Post-COVID Chaos: Dynamic Non-linear Models of Post-Covid Trajectories for Hypothesis Exploration (Holmes)**

Dr. John H. Holmes is Professor Medical Informatics in Epidemiology in the Department of Biostatistics, Epidemiology, and Informatics and Associate Director of the Institute for Biomedical Informatics at the University of Pennsylvania Perelman School of Medicine. He specializes in novel machine learning approaches to mining biomedical data and in agent-based simulations of temporal phenomena. Using data from the University of Pennsylvania Health System, Dr. Holmes will present sociobehavioral agent-based modeling methods to explore various temporospatial scenarios affecting patient trajectories as approaches to predicting and intervening on post-COVID sequela.

**Discussion Questions**

1. What are the Post-Acute Sequelae of SARS-CoV-2 Infection?
2. What are the differences in COVID post-acute sequelae between the U.S and Italy?
3. How can computational phenotyping be applied to define the post-COVID phenotypes?
4. How can heterogenous longitudinal data be used to explain post-COVID syndrome and its progression?
5. How can computational phenotypes be integrated into clinical care for post-covid follow up?

**Panel Organizer Statement:** All participants have agreed to take part in the panel and discuss the topics as outlined above.

Abstract

Social isolation and loneliness are underappreciated health risks associated with higher rates of mortality, depression, and cognitive decline, particularly in older adults, and are exacerbated by the COVID-19 pandemic. This panel discusses implications of the National Academies of Science, Engineering, and Medicine, report entitled “Social Isolation and Loneliness in Older Adults: Opportunities for the Health Care System.” The report outlines numerous roles for informatics in addressing this public health challenge, including infrastructure for coordination among community providers, and clinical and community interventions. The panel will review the recommendations and their relationship to social determinants of health, discuss how the pandemic has intensified and expanded the public health risks related to social isolation and loneliness, and how informatics may play a role both in addressing risks and creating resilient systems for future pandemic threats. The audience will be engaged in a discussion to identify strategies for effective implementation of the recommendations.

Panel Description

Social isolation (an objective lack of social contact with others) and loneliness (the subjective feeling of being isolated) are significant yet underappreciated public health risks. Approximately one-quarter (24 percent) of community-dwelling Americans aged 65 and older are considered to be socially isolated, and a significant proportion of adults in the United States report feeling lonely (35 percent of adults aged 45 and older and 43 percent of adults aged 60 and older).¹⁻³ Research has shown that social isolation significantly increases a person’s risk of mortality from all causes, a risk that may rival the risks of smoking, obesity, and lack of physical activity.⁴ Social isolation has been associated with a 29 percent increased all-cause risk for mortality and a 25 percent increased risk for cancer mortality.⁵,⁶ Loneliness has been associated with a 59 percent increased risk of functional decline and 45 percent increased risk of death.³

With support from the AARP Foundation, the National Academies of Sciences, Engineering, and Medicine Committee on the Health and Medical Dimensions of Social Isolation and Loneliness in Older Adults issued a report in February, 2020.⁷ The committee’s charge consisted of two parts: 1) to examine how social isolation and loneliness affect health and quality of life in adults aged 50 and older, particularly among low-income, underserved, and vulnerable populations, and 2) to identify opportunities for clinical settings of health care to help reduce the incidence and adverse impacts of social isolation and loneliness. As an outcome of the study, the committee outlined five goals, each with implications for informatics:

1. Develop a more robust evidence base for effective assessment, prevention, and intervention strategies for social isolation and loneliness;

2. Translate current research into health care practices in order to reduce the negative health impacts of social isolation and loneliness;

3. Improve awareness of the health and medical impacts of social isolation and loneliness across the health care workforce and among members of the public;

4. Strengthen ongoing education and training related to social isolation and loneliness in older adults for the health care workforce; and

5. Strengthen ties between the health care system and community-based networks and resources that address social isolation and loneliness in older adults
Learning Objectives

After attending this panel audience members will better be able to:

1. Describe the health impacts of social isolation and loneliness in older adults.
2. Describe and assess technology’s role in mitigating the health impacts of social isolation and loneliness using electronic health records and other technology-based interventions.
3. Discuss what COVID-19 has taught us about older adults and barriers to technology use and what safeguards can be put in place to create more resilient health systems.

The panel comprises three members of the NASEM committee. Panelists will review the report and the recommendations and describe how they fit within the larger context of social determinants of health. The panelists will then engage the audience in a discussion to identify strategies for effective implementation of the recommendations.

Dr. Novak will moderate the panel, introducing the topic and discussing how existing and emerging technology infrastructure can support the ecosystem of health care and community providers in implementing report’s recommendations. She will also describe the potential role of predictive analytics in identifying populations at risk, and the related social and practical implications.

Dr. Perissinotto will review the implications for technology used in clinical settings. She will specifically focus on how assessments can be integrated into electronic medical records, including choice of tools, the use of discrete data fields and potential barriers to implementation. She will review lessons from the COVID-19 pandemic related to older adults and technology use.

Dr. Demiris will describe committee findings related to technology interventions (including mHealth applications, conversational agents, other artificial intelligence and social connectivity tools) and current evidence as to the effectiveness of such systems. He will also discuss ethical implications associated with the design and implementation of informatics tools to address loneliness and social isolation in community settings and recommendations for system designers of future tools.

Relevance

As health care organizations continue to refine the implementation of electronic health record (EHR) tools to monitor and influence the social determinants of health, it is necessary to engage informaticists and clinicians in dialogue to ensure informed deployment and use of the tools. This NASEM report and its implications for a range of technologies and clinical practices is a catalyst for the informatics community to engage in such a dialogue. We anticipate this panel to be of interest to data scientists, clinicians, clinical informaticists, and health care operational and IT leaders.

Discussion Questions

1. What technology infrastructure innovations can accelerate effective coordination between health care providers and community service organizations?
2. What are the barriers to implementing effective assessments in various types of clinical settings?
3. What are the best uses of mHealth for reducing social isolation and loneliness?

Panel Participants

Laurie Lovett Novak, PhD, MHSA

Dr. Novak is Assistant Professor and Director of the Center of Excellence in Applied Artificial Intelligence in the Department of Biomedical Informatics (DBMI) at Vanderbilt University Medical Center. Her research aims to improve the beneficial alignment of technology and social life. Current work is focused on developing and implementing AI tools in a variety of clinical environments and creating new ways of understanding and supporting patient and caregiver management of chronic illness in everyday life. Dr. Novak is an expert in designing and conducting research on the clinical work activities of patients, caregivers, and clinical personnel. She serves as a social science resource for DBMI, advising and teaching others on topics such as qualitative methods of research,
formulation of research questions that relate to technology, work, and society, and facilitation of research and design partnerships between computational scientists and clinicians.

**Carla Perissinotto, MD**

Dr. Carla Perissinotto is the Associate Chief for Geriatrics Clinical Programs at UCSF and Medical Director for the UCSF Care at Home practice which provides geriatrics and palliative care to homebound adults. In her roles, Carla strategically oversees and manages both inpatient and outpatient clinical programs which include Care at Home, Geriatrics consultations, the Acute Care for the Elderly (ACE) unit at Moffitt-Long Hospital, Orthopedic Co-Management programs, the surgical Prehab clinic, and community partnerships. Carla is an Associate Professor in the Division of Geriatrics, Department of Medicine. Carla is Board Certified in Internal Medicine, Geriatrics and Palliative Medicine. Carla is dedicated to working in both community and academic settings that serve diverse patients. From 2008-2017, Carla served as a primary care and consulting Geriatrician at the Over60 Health Center in Berkeley. Carla has also gained national and international recognition for her research and advocacy on the effects of loneliness on the health of older adults and is currently focused on academic-community partnerships to understand implementation of loneliness interventions.

**George Demiris, PhD, FACMI**

George Demiris is a PIK (Penn Integrates Knowledge) University Professor in the School of Nursing with a joint appointment in the Department of Biostatistics, Epidemiology and Informatics in the Perelman School of Medicine at the University of Pennsylvania. His research focuses on the use of information technology to support older adults and their family caregivers and explore innovative solutions to promote independent aging and patient and family engagement. He is a co-founder of the Hospice Caregiver Research Network, an initiative led by researchers from various academic disciplines committed to designing and testing interventions to support family caregivers of patients at the end of life. Another area of his research includes the use of behavioral sensing, “smart home” and “Internet of Things” technologies to promote independence for community dwelling older adults and their families. Such emerging technologies introduce challenges and opportunities in terms of engaging older adults in decision making, making sense of vast amounts of data and promoting effective data visualizations as well as addressing ethical considerations.

Stakeholder-driven “Art of the Possible” Patient Journeys for COVID-19 and Beyond; Current and Future Steps to Fully Realize this Vision

Jerome A. Osheroff, MD1; Brian S. Alper, MD2; Christopher Tignanelli, MD3; Julia L. Skapik, MD4

1TMIT Consulting, LLC, Naples, FL; 2Computable Publishing LLC, Ipswich, MA; 3Department of Surgery, University of Minnesota, Minneapolis, MN; 4NACHC, Bethesda, MD

Abstract

The ACTS COVID-19 Evidence to Guidance to Action Collaborative is an open learning community supported by AHRQ to help participants respond to the current pandemic. During summer 2021, the Collaborative is describing a compelling ‘art of the possible’ future vision where interoperable and computable healthcare evidence, guidance and data drive whole person care for COVID-19 and other clinical conditions. The future vision includes highly desirable but not yet widely realized patient journeys, as well as needed enhancements to the national / global healthcare knowledge ecosystem to widely realize these outstanding healthcare experiences, processes, and results. This panel will describe this future vision, steps that presenters and others are taking toward realizing it, and additional action needed. After panelist presentations, the second session half of the panel will be interactive discussion with attendees to surface additional opportunities for collaboration and other steps to refine and fully realize the shared future vision.

Introduction

In the U.S. healthcare system, the flow of data, evidence, knowledge, and tools to support critical decisions and actions is highly siloed and fragmented. This leads to preventable problems with care and patient outcomes, unnecessary expenditures, suboptimal patient experience, and overburdened clinicians. Ultimately, the goal – for COVID and beyond – is to achieve the Quintuple Aim to simultaneously enhance patient experience, improve population health, reduce costs, improve clinician experience, and achieve equity in care delivery.

In early 2020, AHRQ launched the ACTS COVID-19 Evidence to Guidance to Action Collaborative in response to the emerging pandemic as a learning community to help participants enhance their efforts to put evolving evidence and guidance for COVID-19 into practice more quickly, efficiently, and effectively. Scores of participants are actively engaged in sharing strategies and tools, synthesizing a shared future vision for a learning health systems approach to the pandemic and beyond, and defining steps to broadly realize that vision. The Collaborative’s capstone deliverable is a concept demonstration illustrating an “art of the possible” journey for a patient with multiple chronic conditions who develops COVID-19, is hospitalized, and subsequently develops “Long COVID” as a complication. This healthcare journey illustrates tools and activities across the continuum of care that are highly desirable and needed to achieve the quintuple aim, but not yet widely realized. The concept demonstration uses this case example as a springboard to describe a knowledge ecosystem that enables efficient flow from evidence to guidance to action to data and back to evidence to produce an effective ‘Learning Health System (LHS)’ cycle (shown below).

Scores of Collaborative participants from government agencies, care delivery organizations, health IT suppliers, specialty societies, standards development organizations, evidence and guidance suppliers, patient advocates, and many other stakeholder groups are working together to synthesize the future vision details and the tools, activities, systems, and infrastructure to broadly realize it. This includes describing steps Collaborative participants and others are taking to drive progress toward this future vision and the needed ecosystem enhancements. The concept demonstration includes a series of deep dives into each area of the LHS/Knowledge Ecosystem Cycle and illustrates how each piece contributes to the patient journey and how all the parts must coordinate to deliver continually improving LHS cycles and the quintuple aim.

Thirty-six organizations representing diverse LHS stakeholder groups have already provided support letters indicating their support for an earlier articulation of the ACTS future vision and Roadmap to broadly achieve it. The letters indicate a desire to collaborate with other stakeholder to realize the vision, including exploring ways to coordinate.
strategies and investments toward that end. AMIA is one of the organizations that provide such a letter⁴, and this proposed late breaking session can help surface specific opportunities that AMIA could pursue to achieve its objectives while accelerating progress toward industry-wide goals.

Proposed Panel

This session builds on the panel session “Using Specific COVID-19 Targets and Patient Care Settings as a Springboard for Driving Global Improvements in the Learning Health System Cycle for COVID-19 and Beyond.” That panel (already on the program) focuses on why the Collaborative was formed, how it has added value to participants’ efforts to address the pandemic and broader LHS needs, and implications for attendees. This proposed ‘Late Breaking Session’ panel focuses on details of the concept demonstration – i.e., a desirable, consensus patient journey for COVID-19 and beyond, and what the needed knowledge ecosystem infrastructure looks like and how to realize it.

Panelists include individuals who have played central roles in the Collaborative and its concept demonstration efforts. The proposed panel’s goal is to showcase the Collaborative’s concept demonstration and through discussion with attendees, identify opportunities to benefit more organizations from the Collaborative’s efforts and accelerate widespread progress toward the future vision. Annual Symposium attendees typically reflect many key LHS stakeholder groups, and this panel is aimed at such participants that have care transformation – for COVID-19 and beyond – as a focus.

Dr. Osheroff, an independent consultant under a contract supporting AHRQ, chairs the Collaborative and will describe the concept demonstration processes and goals, and provide an overview of the future state patient journey. The portion of the patient journey addressing the use of anticoagulation for patients hospitalized with COVID-19 – and other targets - will be addressed by the subsequent panelists.

Dr. Brian Alper, CEO of a company to make science machine interpretable and lead of international volunteer evidence-based medicine standards initiatives, will demonstrate how computable evidence and guidance related to
using anticoagulation in hospitalized patients with COVID-19 supports the patient journey. He will also discuss steps needed to broadly enhance the evidence to guidance part of the LHS cycle for COVID-19 and beyond.

Dr. Christopher Tignanelli, University of Minnesota (UMN), will describe the desired future vision for localizing computable guidance provided by trustworthy sources; putting it into practice via interoperable pathways and clinical decision support interventions; and evaluating results via electronic clinical quality measures. He will describe steps UMN is taking toward realizing this future vision, and broader efforts needed to fully realize the vision.

Dr. Julia Skapik, Medical Director, Informatics for the National Association of Community Health Centers (NACHC) will describe efforts by NACHC and its partners to implement the consensus future patient journey in the healthcare safety net, and enhance the underlying knowledge ecosystem that supports these journeys.

The panel’s second half will be devoted to interactive discussion among panelists and audience members to surface opportunities to further accelerate efforts to achieve this future vision, and leverage steps currently underway toward this vision to enhance attendee efforts. Prompts for this discussion include:

- What areas of the patient journey and future vision resonate?
- Are there opportunities to leverage the vision, steps, and activities described to advance your current work, and to align your efforts to build this future vision and underlying knowledge ecosystem?
- What would that alignment look like and what would be needed to achieve this collaboration?

All participants have agreed to take part in the panel.

**Conclusion**

The COVID-19 pandemic has focused sharp attention on how far healthcare is from optimally putting evidence into practice and navigating other LHS cycle steps - and the urgency and high stakes for closing this gap. The ACTS COVID Collaborative leveraged current efforts and built a concept demo that shows the art of the possible – using a compelling patient journey to demonstrate the future vision of an ecosystem that supports Learning Health System cycles and leverages computable biomedical knowledge to achieve the quintuple aim. This interactive panel will provide attendees with valuable insights and hopefully help identify opportunities to advance their efforts in ways that further accelerate progress toward a shared LHS future vision.

Interactive Panel Programmatic Theme: Clinical Informatics
Tracks: Policy Keywords: Global Health; Legal, Ethical, Social and Regulatory Issues; Usability
Working Group Endorsements: Ethical, Legal, and Social Issues; Clinical Information Systems

Learning Objectives:

- Define opportunities to reduce clinician burnout around the globe
- Learn global policy differences which prevent, reduce, or eliminate root causes of clinician burnout
- Debate panelists’ suggestions for policy and process modification to eliminate root causes of burnout

Abstract

Clinician burnout is a growing problem in the United States and to a much greater extent than in other countries around the world. The Covid pandemic has increased the rate of clinician burnout to the point where there are mounting concerns of clinician shortages in the very near future\textsuperscript{1} and at enormous cost.\textsuperscript{2} In this context, it is increasingly clear that urgent efforts are needed to reverse this dangerous trend. This panel will focus on root causes of clinician burnout, especially on how features of healthcare policies that impact health informatics implementation in regions outside the US seem to reduce or avoid clinician burnout and may model how to reverse the current trends if adopted in the US and in other countries where clinician burnout is prevalent.

Panel Description

Clinician burnout was first described in the United States only 25 years ago.\textsuperscript{3} Its prevalence in the last 10 years has expanded markedly, coincident with adoption and wide dissemination of Electronic Health Records (EHRs). The physical and emotional toll of the Covid pandemic has exacerbated the high baseline level of burnout. Considering the current trajectory of the rate of burnout, it seems likely we will start to see clinician shortages in the not-to-distant future.

There have been many studies, publications, and presentations discussing burnout. Generally, these efforts have focused on how to mitigate the symptoms of burnout rather than eliminate the underlying causes. For example, meditation has been proposed to allow clinicians to calm and refocus, but this does nothing to remove the underlying cause. Although there are studies showing different documentation practices across the globe,\textsuperscript{4} we are not aware of any investigations or discussions that have looked at the impact of international policy variances that might impact the varying rate of burnout in different countries. This panel is the first to our knowledge to consider how the United States and other countries with high rates of burnout might consider implementing major policy changes to reduce rates of burnout to the level seen in most countries, including many where clinician burnout appears to be rare.

Larry Ozeran, MD, FAMIA, will introduce the panel and moderate the discussion. He will guide the audience on a journey from the United States to Canada and Australia to see how differences in health policies lead to differences in informatics solutions that might provide clues to reducing clinician burnout. He will then briefly describe the difference between symptom mitigation and the elimination of root causes of clinician burnout as well as the danger of failing to eliminate the root cases.\textsuperscript{3} With this context he will challenge the audience with questions like:

- If the U.S. reduced the requirement for clinical documentation to match Canada or Australia, how might that change our existing informatics solutions and potentially reduce the rising rate of clinician burnout?
- Can we improve informatics tools and implementation without changing informatics policies?
- How might informatics standardization simplify informatics tools to reduce the transition from one informatics tool to another?
**Jon Patrick**, PhD, MAMIA, will discuss clinician burnout as a function of Clinical Systems Architecture and Interfaces. A study of EHR software in 2008-2010 pointed to major limitations in large scale systems and hardened best-of-breed systems. It identified critical needs for clinical users’ satisfaction with an EHR system: 1. Immediate adaptability, 2. User control of the system design, 3. Native Interoperability, 4. In-built analytics. Early experimental work showed viable technical solutions to these requirements which lead to a commercialization initiative which has resulted in a number of clients. The largest system built with this technology has a been full oncology patient EHR with Tumour Board Management for 11 discrete tumour streams and incorporating direct delivery of data from systems for: Surgery, Pathology (including NLP content extraction), Patient administration, Chemotherapy, Radiology and Radiotherapy. There is no evidence of a serious need for workarounds as only 138 change requests have been serviced at an average time delay of 11 days over 18 months of maintenance. In a clinician conducted assessment at another site it was shown learnability was very high. These cases indicate that clinician control of the design of the EMR results in high levels of satisfaction and so reduces the agents of burnout.

**Yalini Senathirajah**, PhD, will discuss burnout in international perspectives. Other countries may have less of a problem, due to different roles of EHR documentation in the US, where it is inextricably tied to billing and legal liability purposes. She will summarize the association of EHRs and physician burdens and burnout across Anglophone Canada, Europe, and Asia, different top-down and bottom-up approaches and their impact, including modification of US-based software for different countries, vendor control, and designs. She will discuss sociotechnical aspects of EHR development and use, contrasted with consumer app development, and how this makes a difference in EHR usability, possible mechanisms for change, and psychological aspects of EHR use unrelated to usability. Recent European and Asian flexible system initiatives including NHS hybrid model(s) are discussed, and she will cover design and architectural features which reduce cognitive and navigational burdens.

- What pathways exist to test and implement potential solutions arising from clues we find in international work?
- What barriers exist?

**William Foster**, MD, PhD, FRCSC, FAMIA will discuss Canadian physician burnout affecting approximately 30% of physicians, and why implementation of EHRs and electronic tools for clinical practice are substantially lower than in the USA. 11 – 35% of physicians e-prescribe, yet 80 – 92% have digital access to laboratory results. In most provinces, a top-down approach is common: Québec offers free access to Dossier Santé Québec, a database with a secure web-based interface to access patient imaging and laboratory results, and currently filled medications. The majority of outpatient specialists in Québec primarily use paper charts, often with a PACS system, although there is some effort to transition to EHRs (there are few EHRs designed for the French language and the Régie de l’assurance maladie du Québec insurance system). Notes are typically brief. Surveys suggest burnout is less prominent in Canada than in the USA. An increased focus on providing physicians with free informatics tools that provide validated data (from pharmacies, imaging centers, laboratories, perhaps by the use of state-wide registries) without additional effort on the part of the physician may provide direct benefit to physicians and reduce physician burnout. Dr. Foster will discuss other sources of data that can be useful for front-line providers, and ask what informatics approaches might mitigate physician burnout.

- Is it possible to provide free informatics tools that offer physicians validated data?
- Can we find reliable, clinically relevant data without physician review prior to entry into the medical record?

**Richard Schreiber**, MD, FACP, FAMIA will discuss the profound deterioration in clinician satisfaction in the United States during the past 30 years. Many ascribe this to the introduction of the EHR resulting in abrupt retirement of some clinicians, but other factors contribute. Dr. Schreiber will elaborate on these questions:

- Can we improve usability, and eliminate workflows and tasks to reduce documentation burden?
- What policy and regulatory changes can effect real change in documentation burden?
- What is the impact of two apparently contradictory documentation needs: how to capture sufficient medical information (and yet not cause note bloat) while providing sufficient association of that information for billing?
- What lessons learned has the Covid pandemic provided that may actually reduce burnout?
- How can we bring the pleasure of clinical work back to the bedside to reduce clinician burnout?

**Participants (All panelists have agreed to participate)**

Dr. Ozeran has spent more than 20 years in information technology and software development, clinical medicine, healthcare leadership, and health policy. His efforts have ranged from the development and interpretation of public policy to helping startups develop market strategy to supporting healthcare organizations. Dr. Ozeran has responded to proposed federal regulations, written to many elected officials, and testified before committees of the California Senate and Assembly. He was an invited speaker before the Congressional Budget Office. He has twice served on the AMIA Public Policy Committee. He is focused on strategic initiatives, policy development, and innovation supporting healthcare entities, government agencies, and startup companies.
Dr. Patrick In 2005 Dr. Patrick won Australia’s national Eureka Science prize for his work in natural language processing. Subsequently he has conducted extensive research on the use of language technology in Intensive Care, Pathology and Radiology departments, and in information systems research in emergency medicine and oncology. In 2012 he left the University of Sydney, where he held both the Chairs of Information System and Language Technology, to pursue his interests in commercializing his Health IT and NLP ideas. He is the CEO for the companies Health Language Analytics (HLA) and its USA subsidiary Health Language Analytics Global, and Innovative Clinical Information Management Systems (iCIMS). His NLP companies hold contracts for the 3 California Cancer Registries and the Centers for Disease Control, and the University of California and hospitals and authorities in Australia. His clinical systems company has built over 30 different applications particularly in the arena of cancer care and tumour board solutions. Most recently the work of the two companies at the Sydney Adventist Hospital has been highlighted at https://www.pulseimagazine.com.au/australian-ehealth/4980-the-san-rolls-out-icims-cancer-information-management-system-for-mds.

Dr. Senathirajah conducts AHRQ-funded studies of EHR design and usability, including studies of interruptions, cognitive load imposed by different EHR UI designs, and a novel ‘composable’ approach which permits the nonprogrammer clinician end-user to design and control their own interfaces by drag/drop, assembling relevant data on the same screens and marking, visualizing and sharing it in different ways. The aim is to reduce display fragmentation and clinical cognitive, navigational, and time burdens. She is Associate Professor in the department of biomedical informatics at University of Pittsburgh School of Medicine.

Dr. Foster is an American-trained Ophthalmologist and physician-scientist with experience practicing in the US and in Canada. He earned his undergraduate degree in Physics from Caltech, a Master’s and PhD in Physics from Harvard University, and his MD from Duke. He is a Diplomate of the American Board of Ophthalmology and the American Board of Preventive Medicine in Clinical Informatics as well as a Fellow of the Royal College of Surgeons of Canada. He is a Fellow of both the Association for Research in Vision and Ophthalmology and AMIA. He has extensive experience with implementation and clinical decision support with electronic medical records and, for example, is a Physician Builder with numerous Epic certifications.

Dr. Schreiber is Associate Chief Medical Informatics Officer, Penn State Health Holy Spirit Medical Center, Camp Hill, PA; Professor of Medicine, Geisinger Commonwealth School of Medicine; and Chair of the Clinical Information Systems Working Group. His research focuses on clinical decision support, alert fatigue and alert burden reduction, transitions from one EHR to another, drug-drug interaction alerting, documentation improvement, problem list curation, ethical issues in informatics, and laboratory nomenclature. Recent publications include risks of harm of mHealth applications, and a perspective on reduction of clinician burnout.

Adaptable Patient-facing and Clinical Decision Support Systems: The Next Frontier

Mustafa Ozkaynak, PhD¹ (Co-organizer), Karen D. Lopez, PhD, MPH, RN² (Co-organizer), Adam Wright, PhD³, Andrew Boyd, MD⁴, Blackford Middleton, MD, MPH, MSc⁵ (Moderator)

¹University of Colorado | Anschutz Medical Campus, Aurora, CO, USA; ²University of Iowa, Iowa City, IA, USA; ³Vanderbilt University Medical Center, Nashville, TN, USA; ⁴University of Illinois at Chicago, Chicago, IL, USA; ⁵Apervita Inc., Chicago, IL, USA

Abstract
Clinical decision support (CDS) systems can demonstrate their full potential if they are context-sensitive and can tailor their interaction with the user. Adaptable CDS aims to achieve this goal by accounting for various context and user characteristics and therefore avoid the many undesired outcomes of current CDS systems. To this end, the panel will begin with a discussion by each panelist of their experience with adaptable CDS in various health care settings with decision support that targets both clinicians and patients. This will be followed with an interactive session, in which the audience and panelists will prioritize related challenges (generic, or clinical setting specific) in development of adaptable CDS. Finally, we will discuss known effective and potentially new strategies to address these challenges.

Intended Audience
Attendees of any level who are interested in: 1) the next generation of clinical decision support (CDS) that aims to reduce alert fatigue and cognitive workload and 2) improving the efficacy of these systems. This interdisciplinary panel considers CDS broadly to include both adaptable patient- and clinician-facing decision support (CDS) systems. The panelist will present these next generation CDS systems, which are adaptable to user or context characteristics, from the perspectives of industry, practice, and research. Attendees will benefit from this session by understanding: 1) the adaptive mechanisms that make technology successful in various industries, 2) novel approaches to study adaptability, and 3) ways to integrate the current research into the design, implementation, and evaluation of CDS.

Introduction of the Topic
CDS should evolve rapidly, given the exponential growth in health data and evidence, and the growing capacities to store and analyze data.¹ Future CDS can address this necessity by being adaptable. Adaptable CDS is defined as CDS with the ability to change its interaction with the user, based on programmed sensitivities to various issues and characteristics, in order to provide optimal decision support. Adaptability to such macro factors (e.g. new evidence, changes in policies) and micro factors (e.g. user or situational characteristics) is a necessary capability for CDS to provide the best support to clinicians who are making decisions that directly affect patient outcomes.

An important criticism of CDS is that it is not sensitive to the user or the context.²⁻⁵ Alarm fatigue is the most well-known issue of decontextualized CDS. However, dealing with alarms may cause additional problems, such as excessive cognitive workload. Adaptivity can make CDS context-sensitive by accounting for various macro or micro level factors, and present clinicians with opportunities to improve care through individualized interaction with CDS technology and patient-centeredness.¹ For example, CDS can adapt to user characteristics, such as the user’s experience or fatigue level, or context characteristics (e.g. busyness of clinics, up-to-date evidence).

Although adaptable CDS is novel in health care, adaptable technologies have been studied in other domains such as defense systems and transportation. Existing frameworks and approaches can provide a head start in designing adaptable CDS.

Aim of Discussion
This session will highlight the opportunities that adaptable CDS technologies can bring to clinicians and patients in clinical practice, self-management, and wellness in daily living. The panel will discuss the challenges and facilitators of the design, implementation, and evaluation of adaptable CDS. We will engage in an exchange of ideas and experiences from both the expert panel and the audience. The panel will focus on novel features (i.e. adaptability) that
can be a standard feature for the next generation of CDS. This panel will link interested individuals with one another, and mutually learn about cutting-edge work in this area.

Timeliness of the Topic

CDS systems show promise in improving patient and organizational outcomes. Their full potential can be realized only when they become sensitive to the relevant characteristics of users and the context in which CDS is used and decisions are made. Because of its interactive nature, the panel will serve as a forum in which members of the audience and panelists can collaboratively advance the dialogue of informatics in this novel area. The sharing of experiences stimulated by this panel will serve as a foundation for generating and prioritizing future design and research initiatives in CDS at various health care delivery settings.

Contribution of Each Panelist

Mustafa Ozkaynak: Dr. Ozkaynak will discuss adaptive (or adaptable) automation literature that can provide insights into developing next generation of CDS. He will also discuss being adaptive to clinicians’ fatigue, a significant barrier to the clinician successfully adapting to CDS. Relevant literature will be reviewed, as well as findings from a study that aimed to develop CDS as a part of antimicrobial stewardship program in emergency departments.

Adaptive automation, an emerging area within human factors engineering, is an approach to technology design where tasks are dynamically allocated between user and technology. One main system parameter of adaptive automation is the level of automation, which depends on the amount and type of work allocated to user and computer.6

Decades of adaptive automation literature suggest that CDS systems that can adapt to contemporaneous variations in clinician’s fatigue have the potential to intercept fatigue-induced human errors and preclude potential adverse events.5 9 Adaptive modifications to CDS for fatigue have many benefits including: (1) lowering trigger rates, thus reducing alert fatigue; (2) providing an interaction opportunity that matches the user’s current capability; (3) compensating for suboptimal working conditions; and (4) reducing information overload to increase the effectiveness of decision-making. Despite the potential benefits of adaptable CDS, it must be designed and implemented deliberately in order to avoid the possible negative effects of having multiple behaviors of the same CDS during the same shift.

Our recent study,3 highlights the significance of fatigue in EDs in making antibiotic decisions. Adaptability can be a feasible and effective solution to incorporate clinician and organizational factors into CDS design and implementation.

Karen Dunn Lopez: Dr. Dunn Lopez will share insights from her multidisciplinary NIH-funded research team that applied data mining algorithms from nursing care documentation data in electronic health records (EHR) from four hospital systems.10 The analysis provided the foundation for alerts that were transformed into multiple CDS formats, which were then tested using simulation with 60 practicing nurses.11 The findings suggested differences in comprehension and efficiency of use among the participants. We hypothesize that differences may be associated with cognitive characteristics (graph literacy and numeracy) and format preference.12,13 We tested this hypothesis in our follow-up randomized controlled trial using simulation methods with a fully powered national sample of nurses. We tested our adaptable CDS web app remotely from nurses’ homes using video conferencing software. Our methods provide a feasible foundation for widespread national testing of adaptable CDS before use in practice.

Adam Wright: Dr. Wright will share synthesized findings from multiple projects that provided insights about challenges of and effective strategies for gathering and incorporating user (e.g., clinicians) feedback and performance (e.g., specificity and sensitivity) – data that can lead to CDS that is adaptive to situation and local context. He will specifically highlight design and implementation implications of these insights.
Andrew Boyd: Dr. Boyd will discuss insights learned through a multi-year study of tailoring patient’s discharge instructions of patients with heart failure. This tailoring and simplification is important as patients receive lengthy documents at the time of hospital discharge that include complex terms and, occasionally, conflicting information provided by physicians and nurses. This has become more routine with the OpenNotes initiative and is particularly challenging for patients with heart failure in settings that serve patients in the low socioeconomic group. These patients have unique challenges in comprehending the information, which intends to support effective self-management at home and help them avoid hospitalization. Our multidisciplinary NIH-funded research team addressed these challenges through the design of a novel mHealth for post-hospitalization heart failure self-management. Their design used natural language generation to merge physician and nursing care summaries into one information source, which was tailored to patients’ context and motivation, including their health literacy and engagement level.14

Interactive Session

After the introductory presentations, the panel and audience will engage in a facilitator-moderated discussion of (1) important design, implementation, and evaluation considerations for adaptable CDS; (2) information needs to make CDS more adaptable; (3) potential unintended consequences of adaptable CDS and mitigation strategies; and (4) ways that the AMIA community can advance the field of adaptive CDS. Prioritized lists of issues and strategies will be developed for research, practice, and design. All panelists have agreed to take part on this panel.

To share or not to share: Exploring the ethical implications of sharing personal health data with patients and informal caregivers

Meghan Reading Turchioe, PhD, MPH, RN; Sabrina Mangal, PhD, RN; Marianne Sharko, MD, MS; Natalie Benda, PhD; Ruth Masterson Creber, PhD, MSc, RN

Weill Cornell Medicine, Dept. of Population Health Sciences, Div. of Health Informatics, New York, NY

Introduction

National conversations are taking place about ethical practices of ownership, sharing, and privacy of electronic personal health data as it proliferates in healthcare. To date, a major focus of these conversations has been data sharing between healthcare organizations or companies. There has been significantly less attention paid to ethical practices surrounding organizations returning personal health data back to patients or informal caregivers. While there are at least legal standards concerning patients’ personal health information that compel healthcare organizations and researchers to take precautions, such as the Health Insurance Portability and Accountability Act (HIPAA), there are no explicit ethical obligations for them to return personal health data to patients or their informal caregivers. This creates moral ambiguity regarding the return of personal health data; withholding the data may cause harm, but returning it without adequate consideration of nuances or comprehension could also cause harm.

One example includes the collection and return of patient-reported outcomes (PROs), defined as health outcomes directly reported by the patient, back to patients. PROs are widely used in clinical trials and increasingly collected by healthcare organizations nationally for use in clinical care. In cancer care, use of PROs by health professionals has been demonstrated to improve survivorship in several clinical trials, and thus is becoming part of routine clinical practice. Despite the acknowledged value of PROs, ethical obligations surrounding whether PRO data should be returned to patients are in nascent stages. In general, patients report that viewing their PROs is highly informative because they provide an indicator of current health status (for example, symptoms, functioning, and quality of life). When tracked over time, PROs provide insight into changes in health status, and can also empower patients. However, PROs are rarely returned to participants. At the same time, there are concerns about the potential to cause harm when PROs are not returned with adequate explanation, context, or guidance for patients to correctly interpret the data and decide whether and how to act based upon the data.

Another example is parental access to pediatric health portal accounts. There is concern for adequate privacy protection related to sensitive health information released through patient portals. With increased use of OpenNotes and other forms of health data accessed through patient portals, inadvertent breaches of privacy are possible. This is concerning for vulnerable patient populations, such as adolescents whose parents may have access to patient portal information. Considerations regarding the type of information to release in a patient portal must take into account potential harm to patients and their families. Clinically, adolescents are likely to have new and potentially sensitive medical needs, such as sexual and reproductive healthcare and mental health issues. Mental health visits increase during adolescence and can include screening surveys for reported mental health symptoms, such as depression and anxiety. Studies have found that adolescents need privacy and confidentiality when deciding whether or not to receive medical care and how much sensitive information to share with their providers. Inconsistent privacy protection can erode trust in healthcare providers. Until professional standards are developed and technology reliably protects patient privacy, the risk of inadvertent privacy breaches remains.

Additional ethical questions arise when considering other types of informal caregivers beyond parents. For example, informal caregivers play an important role for cancer patients, reportedly spending an average of 32.8 hours on care-related tasks per week. Patient portals and portal secure messaging provides a means for patients and their informal caregivers to communicate with healthcare professionals. One problem, however, is that portal secure messages coming from a patient account, as opposed to a formally designated proxy account, may actually be written by someone other than the patient. Promoting the appropriate use of proxy patient portal accounts will help understand the needs of informal caregivers, differentiate patient and caregiver needs, and ensure the patient has agency in granting proxy access.

In this panel, we will present primary data from multiple studies exploring these ethical questions from the perspective of multiple key stakeholders, including patients, informal caregivers (including parents), and healthcare professionals. These include qualitative interviews with stakeholders and surveys with a large, representative sample of U.S. adults as part of an NIH bioethics supplement grant (R00NR016275-05S1). In addition, we will discuss opportunities to bring diverse perspectives into the public discourse on policies and governance of personal health data, ownership, privacy, and use.
Each ethical question will be explored through the lens of an ethical framework developed by MITRE, “An Ethical Framework for the Use of Consumer-Generated Data in Healthcare.” The framework is intended to guide healthcare organizations and professionals to consider salient ethical concepts when creating policies surrounding personal health data access. In this panel, we will discuss each of the three example scenarios described above in the context of core values which must be protected according to the framework, including distributive justice, individual self-determination, privacy, and trustworthiness. We will also explore policies for each scenario that adhere to guiding ethical principles, including fairness, individual and population health, empowerment, and transparency.

**General Description of Panel and Objectives**

Ethical quandaries surrounding the return of personal health data to patients and informal caregivers merit serious consideration given the potential for both sharing and withholding data to cause harm. In this panel, we will explore and synthesize the ethical principles and values that surround the return of personal health information from the perspectives of multiple stakeholders within the clinical enterprise who regularly engage with electronic personal health data. In addition to presenting primary data from multiple studies with key stakeholders, we will also discuss potential policies that may best uphold the core values and guiding ethical principles within the rapidly changing digital health landscape. By the end of this panel, participants will be able to:

- Identify ethical principles and values relevant to the collection, use, and sharing of personal health data.
- Discuss potential benefits and harms of returning personal health data to patients and informal caregivers.
- Apply the MITRE framework to generate ethical guidelines for the return of personal health data to patients and informal caregivers in specific contexts.

**Intended audience**

As digital tools are increasingly used to generate and share personal health data across academic and industry research, questions of appropriate recipients of the data, including patients themselves, are highly pertinent. Therefore, this topic is relevant to informatics researchers, administrators, and clinicians in industry, academia, and healthcare, particularly those who are generating policies and guidelines surrounding personal health data access.

**Interactivity**

This panel will incorporate multiple features to facilitate engagement and interaction with the audience, including live audience polling using Poll Everywhere and a moderated discussion. Differing viewpoints will be encouraged to stimulate rich dialogue surrounding each of the example scenarios. Example questions include:

- How should researchers and healthcare organizations weigh the potential benefits against the potential harms of sharing data with various recipients (i.e., patients, different types of informal caregivers)?
- How can the MITRE framework be operationalized to create policies that protect patients from harm?

Example policies will be constructed through dialogue from the audience.

**The Panel**

**Dr. Meghan Reading Turchioe** is a nursing informatics researcher whose work involves developing and implementing consumer health technology to improve health outcomes and quality of life. Specifically, she studies ways to develop and implement consumer technologies including mobile applications, wearables, and telehealth to support optimal patient self-management, shared decision-making, and prevention for chronic conditions. Dr. Reading Turchioe will describe the legal and ethical landscape surrounding access to personal health data and introduce the MITRE framework, including salient core values and guiding principles to be considered.

**Dr. Sabrina Mangal's** research focuses on patient engagement and communication strategies (e.g., visualizations) to
enhance patients’ comprehension of their health information. She is closely involved in studies that explore the potential for enhanced engagement in care. Dr. Mangal will discuss the bioethical implications of researchers returning collected health information to participants, and public levels of trust in research based on sharing collected health information to multiple stakeholders.

Dr. Marianne Sharko is a pediatrician who received her master’s degree in Health Informatics from the Population Health Sciences Department at Weill Cornell Medicine and has completed a Preventive Medicine Residency. She is currently working in a pediatric obesity clinic and conducting research through the Empire Clinical Research Investigator Program. Her research interests include protection of patient privacy in the electronic health record and patient portals, particularly for adolescent populations. Dr. Sharko will discuss the unique patient privacy needs of the adolescent patients in relation to the patient portal and parental proxy access.

Dr. Natalie (Nat) Benda is an expert in human factors engineering/systems safety, and her work involves advancing health equity and inclusivity through technology-based interventions. She will introduce a project about using natural language processing to automatically detect patient portal secure messages in a cancer population sent from the patient account by someone other than the patient (e.g. an informal caregiver), a phenomena referred to as “hidden proxies”. In this work, the team is also analyzing demographic differences in patient accounts containing a larger proportion of hidden proxy messages. Dr. Benda will present these results and discuss implications for proxy data sharing in an oncology setting.

Dr Ruth Masterson Creber leads an interdisciplinary program of research focusing on using technology and remote monitoring data to improve patient centered outcomes among individuals with cardiovascular disease. Dr. Masterson Creber is the principal investigator of NIH-funded grants that support the data collection and return of patient reported outcomes (R00NR016275, R00NR016275-05S1, R01HL152021) and a PCORI grant evaluating a clinical informatics intervention, “Using Mobile Integrated Health and Telehealth to Support Transitions of Care among Heart Failure Patient.”

Panel Organizer Statement: All participants have agreed to participate in this panel.

Conflicts of Interest: Dr. Reading Turchioe is affiliated with Iris OB Health Inc. and has equity ownership. 

Acknowledgements: The described research was supported by the National Institute of Nursing Research (4R00NR016275-05S1) and Memorial Sloan Kettering Cancer Center’s Population Sciences Research Program (PI; L Diamond and P Stetson). Dr. Sharko is supported by the NYS Department of Health Empire Clinical Research Investigator Program. Perspectives on Developing and Implementing Shareable, Interoperable Clinical Decision Support for Chronic Pain: The CDS4CPM Project

Joshua E. Richardson PhD, MS, MLIS¹ (Organizer); Cheng-Kai Kao, MD²; Laura Haak Marcial, PhD¹; Bryn Rhodes³; Asli Weitkamp, PhD⁴

¹RTI International, Research Triangle Park, NC; ²University of Chicago, Chicago, IL; ³Alphora, Orem, UT; ⁴Vanderbilt University Medical Center, Nashville, TN

Abstract

Open-source efforts that utilize emerging standards for clinical decision support (CDS) may enable healthcare organizations to share and implement evidence from external stakeholders including guideline clearinghouses and researchers. This panel provides perspectives from an Agency for Healthcare Research and Quality-sponsored project, CDS for Chronic Pain Management (CDS4CPM), that are working with publicly-available standards-based, interoperable CDS for chronic pain management and shared decision-making in real-world settings. The panelists will provide their unique perspectives and experiences as developers and implementers of these CDS knowledge artifacts and detail how this work can inform future efforts to develop and implement similar CDS interventions. The CDS4CPM speakers will highlight the technical and organizational challenges they encountered over the course of the project and provide their insights for audience members interested in the challenges and opportunities for leveraging new open-source CDS tools and standards, particularly in chronic pain management.

Significance

Chronic pain affects as many as one in ten Americans and significantly disrupts “work, social, and/or self-care activities.”¹ Furthermore, the related use of opioids is linked to co-morbidities and mortality that some have described as “twin crises” in healthcare,² and the annual costs of chronic pain exceed those from heart disease, diabetes, or cancer ($560 billion to $630 billion).³ The COVID-19 pandemic further complicates chronic pain and opioid management.⁴ The significant rates of morbidity, mortality, increased costs and adverse effects on quality of life make chronic pain a significant problem in healthcare and is therefore an important area for informatics research. Given this context, public access to standards-based and shareable clinical decision support (CDS) in the future may help providers and healthcare organizations deliver timely and evidence-based patient-centered care.

Clinical decision support development tools and strategies are undergoing rapid changes due to the emergence of shareable interoperable solutions like those deposited in the Agency for Healthcare and Research Quality (AHRQ)-sponsored CDS Connect Repository of available CDS artifacts. These artifacts leverage Health Level 7 (HL7) standards for CDS including Clinical Practice Guidelines on FHIR (CPGonFHIR), CDS Hooks, Clinical Quality Language (CQL), and SMART on FHIR. AHRQ contracted RTI International (RTI) to address two broad aims: 1) to advance evidence into practice through CDS; and 2) to make CDS more shareable, interoperable, and publicly-available. RTI in turn partnered with two academic medical centers, Vanderbilt University Medical Center (VUMC) and the University of Chicago Medicine (UCM), a software development company (Alphora), and consultants to develop and implement patient-facing and provider-facing CDS artifacts intended to promote shared decision-making around chronic pain management. The team named the project CDS for Chronic Pain Management or CDS4CPM.

After a year of development, the team implemented all components of the CDS4CPM system. This includes a patient-facing CDS artifact called MyPAIN (My Pain Assessment and Information Needs) as a SMART on FHIR application that launches from a patient portal (MyChart, Epic). MyPAIN is used to collect patient reported data including pain location and type, PROMIS measures on pain intensity and interference with daily functioning, and patient goals and values. MyPAIN also provides education materials related to chronic pain management. The data collected via MyPAIN are then stored in the electronic health record (EHR) and retrieved by a provider-facing SMART on FHIR application, PainManager, which is available within the EHR. PainManager displays MyPAIN data as well as relevant diagnoses, medications (including PDMP data when available), and urine drug screens. PainManager offers both passive and active CDS alerts based on the CDC Opioid Guideline.⁵ PainManager also provides individual medication
level morphine medication equivalent (MME) and total MME/day calculations using an embedded calculator, also based on the CDC Opioid Guideline.

During development and implementation, project members routinely addressed issues that were not only technological in nature, but also challenges related to integration into the local environment, including navigating internal development processes, directing staff, and engaging patients and providers. Examples of these included concurrent testing of the CQL-based MME calculator (technical); determining a means to reconcile and access data from a state PDMP based on policy and legal limits (organizational); and weighing strategies for CDS maintenance to support the CDS beyond the project period (financial). Developing and implementing standards-based, interoperable, and publicly available CDS is socio-technically complex, not simply “plug and play” for even sophisticated implementation sites. Panel members will discuss these and other challenges along with solutions encountered over the course of the CDS4CPM project, with each panelist sharing their unique perspective and lessons learned.

Learning Objectives

1. Describe technical challenges and opportunities for healthcare organizations developing a single system with publicly-available, standards-based, and interoperable CDS that addresses chronic pain management.
2. Identify organizational strategies that future organizations may encounter—such as staffing and collaborating—when jointly implementing a single system with publicly-available, standards-based, and interoperable CDS.
3. Develop internal and external organizational strategies that account for socio-technical issues of collaborative development and implementation of a single system with publicly-available, standards-based, and interoperable CDS.

Individual Speaker Contributions

Joshua Richardson, PhD, MS, MLIS – Dr. Richardson is a health informatician at RTI International who will serve as the panel moderator and introduce the panel participants. In addition, he will describe the aims of the project to develop, implement, and evaluate the lessons learned for disseminating publicly-accessible, standards-based knowledge artifacts for chronic pain management within primary care clinics. Dr. Richardson will describe the partnering structure with the developer, Alphora, two academic medical centers, VUMC and UCM, and consultants.

Laura Haak Marcial, PhD – Dr. Marcial is a health informatician at RTI International who will discuss specific design choices, technical challenges and opportunities for enhancements associated with patient- and clinician-facing interoperable CDS for chronic pain.

Bryn Rhodes – Bryn Rhodes will discuss development and implementation of the standards-based CDS artifacts, MyPAIN, PainManager, and the related CDS4CPM implementation guide. He will provide an overview of the architectural approach, a review of the standards and content that were selected and used, as well as gaps identified during the project, and some novel approaches to addressing those gaps within the implementation.
Asli Weitkamp, PhD – Dr. Weitkamp is an Associate Professor in the Department of Biomedical Informatics and the Director of Knowledge Engineering at Vanderbilt University Medical Center. She is the site co-Principal Investigator leading the implementation and integration of the CDS for chronic pain management. She will share the experiences, challenges, and lessons learned about integrating standards based CDS into the EHR. She will discuss the strategies for supporting architectural solutions to facilitate data integration between the EHR and interoperable CDS.

Cheng-Kai Kao, MD – Dr. Kao is the Associate Chief Medical Information Officer at University of Chicago Medicine and its site co-Principal Investigator. He will share the experiences, challenges, and lessons learned about implementing a newly developed CDS solution into their EHR, the strategies they used to overcome barriers to adoption, and the considerations and next steps after the pilot phase of the project.

Expected Discussion and Discussion Questions
We expect the audience will want to engage the panelists in discussions on their approaches to leveraging recent open-source standards for developing and implementing patient- and provider-facing CDS. We expect the audience will benefit from learning how our organizations had to adapt staffing and internal processes to operationalize the CDS into clinical workflows. We anticipate these topics to lead to areas for future research and development that could better scale publicly available, standards-based, and interoperable CDS, considerations around implementing approaches to standards-based CDS, and approaches to patient-facing CDS systems. The discussion questions include:

1. How can future projects balance the availability and use of standards-based and proprietary APIs for publicly-available, standards-based, and interoperable CDS?
2. What advances in semantic vocabularies, value sets, and patient-reported outcome measures could benefit the future use of publicly-available, standards-based, and interoperable CDS?
3. How can organizations plan, staff, and budget for working with this kind of CDS?

Urgent Topics for Intended Audiences
This panel addresses pressing issues around developing, implementing, and managing the challenges they encountered with managing the sociotechnical and management challenges publicly-available, standards-based, and interoperable CDS into clinical workflows that address both patients’ and providers’ needs.

- **CMIOs and CNIOs**: those responsible for implementing CDS in healthcare organizations;
- **EHR Implementers**: implementation staff responsible for implementation and effective use of EHR tools, and system optimization, including patient-facing tools;
- **CDS Systems Developers**: development staff building clinical decision support tools and services for providers and patients;

Attestation
The panel moderator has assurances from all participants that they will be available to participate at AMIA 2021.

Abstract

During the COVID-19 pandemic, social distancing requirements prompted health systems, clinicians, and patients to rapidly switch to telehealth (video and telephone visits) as alternatives to in-person visits.¹ This shift was further supported by policy changes—for example, CMS offered payment parity across visit type.² Early evidence on telehealth use has demonstrated disparities in use, especially as it relates to video visits, among racial/ethnic minorities as well as limited English proficient, low income and low literacy patients (Figure).³ These disparities are driven by factors including a lack of technology access (broadband and device), limited technology literacy, and system level barriers. Thus, there is a need to understand and share best practices for equitable implementation of telehealth. Our panel presents diverse experiences and best practices for telehealth equity.

Learning Objectives

After attending our panel, participants will be able to:

1. Understand the current multilevel drivers of telehealth disparities, including technology access, technology literacy, and workflow considerations.
2. Formulate a diverse set of approaches to improve telehealth equity, including technology screening and digital health navigators.

*Excludes ambiguous encounters.

***p < .001.

Figure 1. Telemedicine Visit Type by Patient Characteristics at Mass General Brigham³
Importance of Topic
The confluence of telehealth as a new care tool, telehealth access disparities, and worse COVID-19 outcomes among underserved communities positions telehealth equity as a critical component of health equity.

General Description
Our panel will present multilevel approaches to telehealth equity from diverse perspectives, including researchers, clinicians, and administrators.

<table>
<thead>
<tr>
<th>Panelist</th>
<th>Presentation Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Panel moderator: Jessica S Ancker</td>
<td>Dr. Ancker has studied a number of issues in health literacy and technology adoption, including ways to reduce socioeconomic disparities in patient portal adoption. She is an associate professor at Vanderbilt University Medical Center in the Department of Biomedical Informatics. Dr. Ancker currently leads a PCORI grant to study the impact of the telehealth transition in primary care prompted by the COVID-19 pandemic.</td>
</tr>
<tr>
<td>Amy Sheon</td>
<td>Dr. Sheon will review several approaches to telehealth equity including: Policy measures being pursued by The Telehealth Equity Coalition; Digital health equity metrics developed for health care systems; Mapping to reveal digital redlining; Implementing universal patient screening for digital health readiness; Establishing community referral partnerships with digital inclusion organizations; and using Digital Health Navigators for screening, referral, and coaching to address individual patient needs for devices, connectivity and skills.</td>
</tr>
<tr>
<td>Courtney Lyles</td>
<td>Dr. Lyles will cover ongoing approaches and best practices for telehealth implementation from safety net delivery systems in California, including a) broad approaches outlined in our telehealth for equity toolkit and b) more specific findings related to language access for patients with limited English proficiency and workflows for team-based primary care.</td>
</tr>
<tr>
<td>Sarah Nosal</td>
<td>Dr. Nosal will walk through the rapid roll out of telehealth in the very early pandemic in a network of Federally Qualified Health Centers located in Brooklyn, Manhattan, Bronx, and Mid-Hudson region. She will discuss transitioning to telehealth in the earliest pandemic hit zip codes in our country in an organization that had had no large-scale telehealth ambitions in its near future. She will highlight choices made to assure patient access and equity in care and transitions made to make telehealth sustainable.</td>
</tr>
<tr>
<td>Jorge A. Rodriguez</td>
<td>Dr. Rodriguez will provide a clinical perspective into the facilitators and barriers for implementing equitable telehealth in primary care and in care transitions following hospital discharge. He will also discuss how privacy, and trust influence telehealth among vulnerable populations.</td>
</tr>
</tbody>
</table>
Discussion Questions
1. What are optimal telehealth outcomes and use cases that we should look for? (e.g., generally video visits are preferred but there are some circumstances where audio and asynchronous might be optimal)
2. How do we know what telehealth use patterns are? Where are data gaps?
3. Which populations are less likely to use video visits as compared to audio or in person?
4. What are factors associated with lower telehealth use, particularly video visits?
5. How can telehealth address disparities for specific diseases?
6. Beyond technology access, how does technology literacy contribute to telehealth disparities?
7. How do different institutions approach telehealth equity?
8. How can healthcare systems screen patients for their technology needs?
9. What are digital health navigators and how can they address telehealth equity?
10. What resources are available to patients who lack the basic technology needs?
11. What are especially considerations for implementing telehealth with patients with limited English proficiency?
12. What are specific privacy and security considerations for implementing telehealth among vulnerable populations?
13. How can public policy influence telehealth disparities?

Statement of Participation
All participants have agreed to take part on the panel.

How the COVID-19 Pandemic Accelerated AI Technology Development and Adoption in Healthcare: Lessons Learned

Panel Organizers:
- Michal Rosen-Zvi, PhD, IBM Research, Haifa, HA, Israel & Vising Professor, Faculty of Medicine, Hebrew University
- Anil Jain, MD, FACP, Independent healthcare IT advisor, part-time clinician, Department of Internal Medicine, Cleveland Clinic, Cleveland, Ohio
- Eileen Koski, M.Phil, FAMIA, Center for Computational Health, IBM Research, Yorktown Heights, NY

Panel Participants:
- Michal Rosen-Zvi, PhD, IBM Research, Haifa, HA, Israel & Vising Professor, Faculty of Medicine, Hebrew University (Moderator)
- Anil Jain, MD, FACP, Independent healthcare IT advisor, part-time clinician, Department of Internal Medicine, Cleveland Clinic, Cleveland, Ohio
- Aris Persidis, PhD, President/Co-Founder, Biovista: Chairperson/Co-Founder, X-Pandemia; Board of Directors: Biovista, MBFT Therapeutics, X-Pandemia, Charlottesville, Virginia
- Michal Guindy, M.D. MPA, Head of Imaging, Assuta Medical Centers, Tel-Aviv, Israel
- Mihaela van der Schaar, PhD, John Humphrey Plummer Professor of Machine Learning, Artificial Intelligence and Medicine, University of Cambridge

Abstract

AI is transforming many aspects of society, but adoption has been slow in healthcare. The COVID-19 pandemic presented a wide array of challenges and an urgent need for rapid response, which accelerated the development and adoption of AI in the medical domain. This has led to the creation of new tools and methods as well as elevated the need for partnerships between healthcare providers and AI researchers across academia and industry. It has also accelerated interest within the AI research community in applying AI technologies to tackle the unique challenges posed by the medical domain. As a result, the creation of large novel datasets and new technologies has proceeded at an unprecedented pace. This session will focus on lessons learned from the accelerated development and deployment of AI technologies in healthcare in response to some of the urgent needs and challenges and posed by the pandemic which may form the basis of a “new normal” for AI in the medical domain.

Learning Objectives

The specific learning objectives are:
- Review the lifecycle of AI development and adoption in the medical domain
- Identify how regulatory and ethical challenges to AI projects have been affected by the COVID-19 pandemic, including long-term implications
- Discuss how implementation, usability and adoption of medical AI have been prioritized during the pandemic, particularly given heightened clinician burden
- Examine factors that the medical AI community must confront around fairness, bias, privacy and health equity in leveraging AI to improve care both during the COVID-19 pandemic and beyond

General Panel Description
This panel will bring together experts working in different areas of healthcare who will discuss their point of view on the impact of pandemic on the development of AI technologies.

Panelist Presentation Descriptions:

- **Anil Jain** will discuss how the global pandemic has placed increased demands on the clinical community to simultaneously accelerate knowledge discovery, improve clinical outcomes and leverage existing and novel data sets through advanced technologies such as ML/AI while straddling the need to support overburdened clinicians and researchers, develop and maintain AI-savvy talent, and operate within economic and regulatory constraints. He will discuss the possible roles of large companies, small companies, provider organizations, and life sciences in collaborating towards a shared goal through shared risk. As a former member of the US Health Information Technology Advisory Committee formed by the 21st Century Cures Act, he will discuss the role of policymakers to accelerate innovation and promote meaningful adoption of medical AI as well as the role of adjacent technologies, such as Electronic Health Records, in supporting the medical AI community.

- **Aris Persidis** will provide an overview of AI-driven drug repositioning for the Covid-19 pandemic and beyond. The pandemic revealed immediate treatment needs which galvanized the entire industry. Plasmapheresis was the front runner during the wait for vaccines. Then came the vaccines, which must continue to evolve to keep pace with variants, similar to the annual development cycle for influenza vaccines. At the same time, the lack of effective drugs to treat the active infection and its complications (the latter now formally called PASC) became a glaring gap. Drug repositioning emerged as the starting point of choice, as the most efficient way to identify or develop a new drug by leveraging existing ones. AI became a cornerstone of next-gen efforts to reposition existing compounds, instead of starting from scratch, and is becoming a cornerstone in efforts for drug development for PASC and preparedness for future pandemics.

- **Michal Guindy** will review the exponential growth in the number of projects to develop AI in Medical Imaging (MI) for COVID-19 as reflected by the extraordinary number of papers shared in 2020 on the topic. She will discuss the shift in openness to collaboration and the increased number of interdisciplinary and often multi-national collaborations of medical professionals with computer vision researchers. She will present results of an analysis regarding the focus of AI in MI for COVID-19 compared to traditional MI and what characterizes mature studies. Finally, she will present an analysis of patients’ behavior shift during the pandemic and its implication for health systems.

- **Mihaela van der Schaar** will discuss her interactions with governments regarding adoption of proven machine learning methods and use of existing data to help healthcare systems respond to the pandemic, conduct research and statistical analysis regarding the nature of the disease and its spread, and explore the potential impact of machine learning on clinical trials. She will also discuss how evidence is generated regarding the variability of the impact of COVID-19 across ethnicities, which is particularly pronounced within certain countries. Finally she will share results of a study of ethnicity as a COVID-19 risk factor in England.

**Importance of the Topic**

The pace at which AI has transformed the medical world has been slow compared to other domains. The generation of AI technologies often requires long cycles of negotiating data access agreements, harmonizing and cleansing data, developing advanced algorithms and designing and implementing holistic solutions. The sensitivity of healthcare data and associated regulations, as well as the unique infrastructure and incentive systems in the healthcare industry, often further complicate the process. The COVID-19 pandemic presented unique pressure on the AI development process to accelerate delivery of solutions. Vast amounts of healthcare data were quickly generated in care systems as part of the standard monitoring of the increasingly large number of people who have been affected by COVID-19. Healthcare workers on the front lines of the pandemic have experienced burnout, which in turn presented pressure on quick generation of AI based solutions that could help in diagnosis, contact tracing, treatment decisions and monitoring. The novelty of the disease meant that new drugs and vaccines were urgently needed, as well as
accelerated approval of the new COVID-19 indication for existing drugs that proved useful. Time was of the essence, so AI technologies that could accelerate the process of addressing all of these challenges were urgently needed. Moreover, from a public-health perspective, governments have been struggling to find an optimal set of nonpharmaceutical interventions (NPIs) that can help contain or stop the spread of the disease with the least possible harm. Many attempts have been made, and again, rich information has been generated that can be harvested manually or with AI technologies that can also analyze the data to inform approval and policy decisions. Finally, due to the risk of contagion, COVID-19 related confinement and stay at home orders, remote care for both related and unrelated medical conditions, have become a valuable mode of operandum in many settings. This rapid adoption of remote care has presented further urgent need of AI technologies to both evaluate, support and optimize delivery of such services.

The session will benefit from the perspective of almost two years of global experience with the pandemic.

Discussion Questions

While all panel participants agree that advanced AI technologies have the potential to transform healthcare and bring better care at sustainable cost, they have different viewpoints regarding the impact of the pandemic on the acceleration of AI development and adoption.

1. Based on your experience and observations, has the pandemic enabled overcoming regulatory, contractual or other non-technological barriers and accelerated the development of AI technologies? If yes, do you believe these changes are here to stay?
2. Can you share concrete examples of how the pressure of the pandemic has led to investment in AI efforts that were timely and useful in practice? Additionally, do you have examples of how the same pressure may have led to less effective efforts or investments in the development of AI technologies?
3. How has the COVID-19 pandemic affected your own involvement in the development of AI technologies? What are your primary lessons learned from your experiences during the pandemic?

Participation

The panel organizers confirm that all participants have agreed to take part in the panel.
Health Information Exchanges and Public Health Data: Lessons from COVID  
Moderator: Donald W. Rucker, MD  
Panel Participants: Jaime Bland, DNP, RN-BC (Cync Health), Lisa Bari, MBA, MPH (SHIEC), Daniel Chavez, MBA (formerly San Diego Health Connect, HealthTech Solutions) and David Horrocks, MBA, MPH (CRISP)

Abstract

The COVID pandemic has focused attention on what public health data we collect and how we collect and potentially share that data. Historically public health agencies have relied on reporting, typically mandated, of pre-defined data fields specifically tailored to previously known questions about the specific illness (COVID) or to syndromic surveillance of pre-defined symptoms. Today with widespread electronic medical record data and health information exchanges (HIEs) exchanging that data at national scale, we have the opportunity to move from mandated reporting to exchange and re-use of data already captured clinically. This panel discussion features HIE experts who have exchanged public health data at scale throughout the United States.

Panelist Topics

The panel will discuss the role of HIEs in public health data, specifically discussing the learnings from many COVID uses cases. The panel will provide the audience with insights to understand how widespread HIE toolsets can allow us to rethink public health data reporting. Two of the panelists currently manage 5 state HIEs (Jaime Bland and David Horrocks). One of the panelists (Jamie Bland from Cync Health (Nebraska and Iowa’s HIE) will describe how these privacy protecting techniques were used to precisely stratify COVID risk factors. Three of the panelists (Jaime Bland, David Horrocks, Lisa Bari) are working on national efforts to connect HIEs and state-based immunization information systems (IIS). One of the panelists (Dan Chavez) did extensive work connecting the San Diego HIE and CIE (Community Information Exchange) with the San Diego Health and Human Services Agency connecting for Social Determinants of Health. The moderator (Donald Rucker) served as National Coordinator of Health Information Technology and will set the stage by describing Office of the National Coordinator funding of the Star HIE program to better link public health agencies, immunization information systems and HIEs.

Topic Relevance to AMIA Members

The COVID pandemic has highlighted the both the need and the opportunity to rethink public health data collection. Reporting, often mandated, has been the centerpiece of public health data collection for 150 years – arguably starting with John Snow’s identification of the Broad Street water pump has a source of a cholera outbreak. Today multiple local and state public health agencies as well as the Centers for Disease Control and Prevention (CDC) have required reporting for a variety of diseases, lab results, and syndromic symptoms. With the COVID pandemic the Department of Health and Human Services (HHS) including the Center for Medicare and Medicaid Services (CMS) added additional reporting requirements for COVID test results, hospital resource uses such as ICUs and ventilators. These mandated reporting requirements included information on race and ethnicity, which were often missing. Additional reporting systems are currently being introduced to track COVID vaccinations.

This overarching reliance on reporting raises two large questions. The first question is whether this approach provides us the data we need to intelligently understand both the current and likely future pandemics. The second question is whether piecewise unidirectional reporting to public health agencies is the best way to rapidly capture information about and respond to a pandemic in a clinical world where we capture vast amounts of medical data as part of the process of care and have extensive coverage by rich, bi-directional exchange networks already in place.

Answering the first question of what data do we need for a pandemic can start by looking at what is captured today and then considering what is needed. Today state and local health departments collect patient-identified information on specific diseases and lab test results. De-identified versions of these data are sent to the CDC and now to HHS as well. While this information is stored in a variety of databases, none of these databases replicate the
functionality of electronic medical records though that may be an implicit assumption by policy makers. In particular, public health databases obviously can only, at best, store the information that was required to be reported. This means that richer details on illness such as a patient’s comorbidities and social determinants such as race and ethnicity are likely to be missing or incomplete.

Maybe most importantly understanding of a disease requires understanding how that disease can change over time. While de-identified population counts can provide an overall sense of disease trajectory, they cannot answer questions such as what is the range of individual patient trajectories, for example from symptoms to disease treatment and outcome, or from a positive test to a negative test to development of markers of immunity. Transitions in care from home to emergency room to intensive care to nursing home or other pathways that may benefit from specific policy interventions are difficult to track with point-in-time reporting.

The need for individually identifiable information is also present with a vaccination program. It is not enough to collect reports from vaccination centers on how many patients were vaccinated and with what type of vaccine. Critical downstream functions such as nuanced measurement of vaccine complications require a numerator and a denominator. While the FDA’s Vaccine Adverse Event Reporting System (VAERS) captures submitted case reports and will likely capture most obvious complications that are either unique or closely related to the administration of the vaccine, such as system will be unlikely to identify that a vaccine, imaginably, increased asthma events in patients with underlying lung disease or increased abdominal symptoms in patients with inflammatory bowel disease (1). Individual information is also necessary to fully ensure equity in the vaccination distribution process. Such insights require systems that track patients over all of their care, all of their providers, and over time. No state, local or federal public health reporting or data platform can consistently provide such information today.

Successful adoption of informatics solutions requires attention to operational detail. Public health reporting, especially mandated reports, raises many operational issues. The structured data fields captured have to be pre-specified and if additional clinical or other questions arise over time, the reporting has to be redesigned. Almost by definition, mandated reports are after the fact and often they are not integrated into the clinical care process so they require potentially massive amounts of additional resources in order to be implemented (2). When reports are not part of the process of care, data quality is suspect as they do not have the many “eyeballs” looking at clinical data and making sure that the data is accurate. Such reports represent points in time and points of geography so correlation is difficult even if patients are identified and could potentially be followed. As with COVID, the impact of a pandemic can change rapidly – retrospective reporting based on questions built to answer concerns raised by prior clinical outbreaks is inherently unlikely to adequately anticipate differing scenarios arising with future pandemics.

The second question raised is whether piecemeal unidirectional reporting (e.g. electronic case reporting) to public health agencies is the current optimal way to rapidly capture information about and respond to a pandemic in a clinical world where we capture vast amounts of medical data as part of the process of care. Almost all US hospitals and physicians now have electronic medical records. While the CDC syndromic surveillance system does capture selected presentations with a focus on respiratory viruses from over 6,000 sites this data flow still represents a small part of the overall electronic medical data generated in the United States (3). Clinical data is present in electronic medical records but largely absent in the data available to public health agencies.

What are the ways we can enrich the information public health agencies use to protect the public? While there is additional COVID Cares Act funding for the CDC improve and enhance its reporting infrastructure, the use of Health Information Exchanges (HIEs) by many state and local public health agencies offers a partially alternate and a partially complementary way to greatly enrich the real-time availability of broadly-based practice data.

Health Information Exchanges are typically state-wide or large regional organizations designed to allow clinical data sharing among all providers in that geography. Many were started as a response to the Health Information Technology for Economic and Clinical Health (HITECH) Act, enacted as part of the American Recovery and Reinvestment Act of 2009 (ARRA), funding during the Obama Biden Administration. There are approximately 100 HIEs in the United States and they cover approximately 92% of the US population (4). These exchanges include not just doctors and hospitals who have options to join EHR vendor sponsored exchanges or private sector exchanges.
which often focus on serving at-risk (economic risk) Accountable Care Organizations but other providers such as nursing homes, home health agencies and in some cases mental health providers such as group homes and shelters (5).

HIEs have full geographic master patient index functionality so they can aggregate patient data no matter the site of service sending that data. Being able to follow patients and thus diseases over time requires that these challenging to implement and manage patient identification activities be robust. This allows HIEs to serve as the geographic source for truth for demographics need to help with social determinants of health. Today HIEs routinely exchange clinical document summaries, lab results and ADT feeds (admit, discharge and transfer messages) as well as providing analytic tools around population health services and quality measures. By tracking patients over time and geography an HIE can provide insights not available through simple reporting. For example, a reference lab will have a positive COVID test but their staff and software are not well-equipped to accurately capture a patient’s race, ethnicity, comorbidities or medications.

State and local HIEs have a number of valuable attributes that position them to serve as the last-mile for public health data. They are all non-profits with public governance avoiding the likelihood of inadvertently creating another toll-taker disproportionately raising health care costs. Their geography often matches that of public health agencies. They have rich experience in cleaning data, de-duplicating data and normalizing data. Because they cross care boundaries, HIE data has many folks viewing that data which provides ongoing quality control and audit. The panel will also discuss the role of state and local HIEs and their relations to various EHR vendor-based exchange activities.

HIEs are wellpositioned as a source of public health data for state, federal, and local public health agencies. They are also well-positioned to implement clinical data sharing privacy provisions and mitigate the risks of that data being used against patients. The non-profit public governance of most HIEs melds well with the governmental nature of public health agencies and they may serve as public health data utilities in a way similar to other public utilities which are heavily regulated. Modern machine learning data analytic techniques allow privacy protecting transformations known as federated learning, split learning or privacy protected learning. One can imagine use of these software tools with diverse data stores at each of the state and local HIEs providing extraordinarily rich and real-time information so public health agencies have a better prospective ability to detect pandemics however they start.

Primary Care Informatics Working Group (PCIWG) Panel:
Demonstrating the Value of a Complex System Problem Solver

Matthew Sakumoto, MD¹, Tiffany I. Leung, MD, MPH, FACP, FAMIA², Ryan Jelinek, DO³, Stephen Morgan, MD, MS, FAAP⁴, Deepti Pandita, MD³

¹University of California, San Francisco, San Francisco, CA; ²Maastricht University, Maastricht, The Netherlands; ³Hennepin Healthcare, Minneapolis, MN; ⁴Pediatrics Associates of Greater Salem, Beverly, MA

What might the attendee be able to do after being in your session?

The intended audience is applied clinical informatics professionals, health system administrators in both academic and community settings, and students who are considering a career in applied clinical informatics.

The attendee will be able to:

- Present and justify the value of the role of a primary care clinical informaticist to their employer
- Identify key variables of importance to the health system and the community it serves
- Quantitatively and qualitatively describe improved communication, outcomes, and impact in their organization

Description of the Problem or Gap

This is a submission under the Academic Informatics theme describing the challenges and remedies to workforce development in the Primary Care Clinical Informatics space.

In 2020, 97% of clinical practices and health systems struggled with negative financial effects due to the COVID-19 pandemic¹. However, the health systems that had prioritized complementary leadership from primary care and clinical informatics prior to the pandemic actually flourished². They had information systems and standards of practice in place for population health management and patient outreach to drive innovations in both COVID-19 response and continuity of non-COVID care. Primary care informatics is valuable for the efficiency and efficacy of healthcare delivery systems and the wellbeing of the community of patients they serve. Primary care informatics enables insight and understanding of clinical workflows from diverse perspectives from developer to end-user. Uniquely, the primary care physician is trained to practice with a whole-person view of the patient within the context of a whole system of care and well-being.

In this panel sponsored by the AMIA Primary Care Informatics Working Group (PCIWG) we aim to demonstrate the specific value of combining primary care clinical skills with applied clinical informatics knowledge and best practices.

Methods

This panel will use a clinical case study to describe key shared principles of primary care and clinical informatics and the impact of a primary care clinical informaticist at the level of the patient and the healthcare system.

Our discussion will center around the New Primary Care Paradigm, a joint statement by leading primary care professional organizations identifying seven shared principles of primary care, where care is Person/Family-centered, Continuous, Comprehensive and Equitable, Team-based and collaborative, Coordinated and Integrated, Accessible, and High-value³. Three of these seven principles of primary care are especially illustrative of the core principles of Primary Care Clinical Informatics: 1) Coordinated and Integrated, 2) Team-based and collaborative, and 3) Comprehensive and Equitable.

Results and Panel Description

Moderator will present the overall problem statement and a summary slide of the three domains to be described across the different speakers' roles.

Moderator: Matthew Sakumoto - Practicing virtual primary care internist and recent graduate of the Clinical Informatics Fellowship. He has primary care and clinical informatics experience in multiple settings including
academic health centers, community hospitals, and industry start-ups.

Panel expertise includes:

1. **Deepti Pandita** - Chief Medical Information Officer (CMIO) and Program Director of the Clinical Informatics Fellowship and practicing internist at Hennepin Health in Minneapolis, Minnesota. She is a C-suite executive clinician with background and experience in Care Delivery, Innovation, Population Health, Data and Analytics and Informatics. Her passion is in using technology to bridge health disparities especially in Medicaid populations in order to transform care and create healthy communities. She will describe how her perspective as an internist in various roles across internal medicine informs her role as the CMIO facilitating Coordinated and Integrated care across her health system.

2. **Tiffany I. Leung** - Assistant Professor at Maastricht University, The Netherlands. As an internist and Clinical Informatics diplomat, she has a background in clinical practice in multiple US academic practice settings, currently in Dutch clinical practice, as well as public and population health, and clinical informatics. Her PhD work (ongoing) focuses on understanding and mitigating job distress among physicians especially when healthcare systems undergo redesign. She will share experiences in international health systems to describe Team-based and Collaborative care in PCI.

3. **Ryan Jelinek** - Current informatics fellow and practicing internist. He will discuss how his experiences with caring for patients in both the ambulatory and acute care settings at a safety net hospital inspire his design and incorporation of comprehensive and equitable care into his clinical informatics initiatives. His current work has focused largely on the equitable provision of telehealth and thinking about how access to care can be improved with better technology and workflow process design.

4. **Stephen Morgan** - Immediate past-chair of the Primary Care Informatics Working Group and practicing pediatrician. He will describe specific career pathways, skill sets, and the value and return on investment a primary care clinical informaticist can bring to an organization of any size, from small practice to large integrated health system.

All participants have agreed to take part on the panel.

The panel will conclude with an open discussion section around the specific questions listed below, as well as audience-submitted questions (by utilizing the conference room microphone if in person, or chat function if virtual):

- As a primary care clinical informaticist what area have you had the largest impact and return on investment (ROI)? (Examples can include financial savings due to increased efficiency and time, improved usability, decreased burnout, and increased satisfaction and retention.)
- How has your primary care background improved provider and patient engagement and satisfaction?
- What is your definition of team-based care and what is different about managing team dynamics in the clinical space compared to the clinical informatics space?
- What primary care principles do you bring to designing and implementing shared savings programs or value based care models?

**Discussion of Results**

The panel will share individual experiences and formulate best practices in describing the business value of the primary care clinical informaticist. To reflect the goals of the Academic Informatics theme, we will also share training experiences from the Program Director and Learner perspectives on data-driven educational programs. We plan to facilitate audience discussion around identification of any missing insights, and how AMIA-PCIWG can utilize this information to further support physician informaticians in their role. Facilitated discussion with the audience may also include developing a survey and repository of sample “job descriptions” and business cases detailing Primary Care Clinical Informatics impact and employment opportunities.

**Conclusion**

We provide a panel perspective on how to support Primary Care physician informaticists in highlighting their unique role and values in healthcare organizations, start-ups and industry. We hope to utilize these insights to encourage others to share their experiences and gather a collection of value statements, descriptors, and successes.

**Attendee’s Take-away Tool**

The attendees should have a good concept of the unique value of a primary care clinical informaticist and specific examples of organizational impact. Through the panelists’ experiences we will demonstrate:
Coordinated and Integrated care will lead to new and innovative primary care delivery models
Team-based and collaborative care can improve provider and patient satisfaction
Comprehensive and Equitable care can improve access and patient outcomes, and ultimately add value to the health system

References

Abstract

Primary Care Informatics (PCI) is essential to the efficacy of healthcare delivery systems and the wellbeing of the patients’ community. Uniquely, the primary care physician is trained to practice with a whole-person patient view in the context of systems-based care and these principles translate into valuable PCI insights.

The speakers will present a clinical case study to describe three shared principles of primary care and clinical informatics and the impact of PCI at the level of the patient and the healthcare system; including themes of clinical care that is 1) Coordinated and Integrated, 2) Team-based and collaborative, and 3) Comprehensive and Equitable.

The objectives of this panel are to: 1) Present and justify the value of the role of a primary care clinical informaticist to their employer 2) Identify key variables of importance to the health system and the community it serves, and 3) Quantitatively and qualitatively describe improved communication, outcomes, and impact in their organization.
Accelerating the Use of Standardized APIs to Support Real-World Data and Real-World Evidence for Health Care and Research

Anita Samarth1, Kevin Chaney, MGS2, Gideon (Scott) Gordon, PhD3, Vera Mucaj, PhD4, Andrew Kress5
1Clinovations GovHealth, Washington, DC; 2Office of the National Coordinator for Health Information Technology, Washington, DC; 3Food and Drug Administration, Washington, DC; 4Datavant, San Francisco, CA; 5HealthVerity, Philadelphia, PA

Abstract

The 21st Century Cures Act (Cures Act), enacted in 2016, promotes and funds efforts in research, precision medicine, drug and medical device development, and addresses issues related to the opioid crisis and mental health service delivery in the United States. The Cures Act also supports adoption and use of real-world data (RWD) to support drug development processes and healthcare decisions by developing guidelines for use of real-world evidence (RWE) to make regulatory decisions, post-market requirements, and new indications for approved drugs. Additionally, the Office of the National Coordinator for Health IT (ONC) Cures Act Final Rule promotes adoption and use of standardized application programming interfaces (APIs) such as the Health Level Seven (HL7®) Fast Health Interoperability Resource (FHIR®) APIs for data exchange between health IT systems and health care applications (apps). This emerging ecosystem of APIs and apps allows developers and data aggregators to expand their product offerings to support life sciences and research communities as RWD and RWE become more prolific. Panelists will bring government, standards, research, and industry perspectives regarding successes, barriers, and challenges of using standardized APIs for the collection and exchange of RWD and RWE to support clinical research, precision medicine, drug development, and other uses.

Introduction

In recent years, there has been an emergence of real-world data (RWD) use to support drug development processes, research, and clinical decision making, enabled and accelerated by increased access to, and sharing of, health data for clinical and research purposes. These trends were further accelerated in 2016, with the 21st Century Cures Act (Cures Act),1 which promoted the acceleration of research into preventing and curing serious illnesses through precision medicine initiatives; accelerates drug and medical device development; attempts to address the opioid crisis, and tries to improve mental health service delivery. The law also contained a number of provisions that promoted greater interoperability and adoption of electronic health records (EHRs) and support for human services programs.

Generally, RWD is observational data related to patient health status and/or the delivery of health care routinely collected from a variety of sources outside regulated clinical trials. Data sources may include EHRs, medical claims and billing activities, product and disease registries, patient-generated data (including in home-use settings) and data gathered from sources that can inform on health status, such as mobile devices.2

The Cures Act additionally provides guidance on the use of real-world evidence (RWE), which states it is “the clinical evidence regarding the usage and potential benefits/risks of a medical product derived from the analysis of RWD.” RWE represents the analytical data that details the use, potential benefits, or risks of a drug obtained from non-traditional clinical trials such as randomized controlled trials and observational studies (prospective and/or retrospective).3 With the use of RWE, the Food and Drug Administration (FDA) can obtain insights on how to best design and operate clinical trials/studies in healthcare settings to resolve unanswered questions and improve treatments.

Concurrently, the Office of the National Coordinator for Health Information Technology (ONC) Cures Act Final Rule (Cures Act Final Rule),4 released in March 2020, seeks to accelerate a shift towards greater access and data exchange by enabling consumers to store, aggregate, use, and share electronic health information (EHI) using standardized application programming interfaces (APIs) and apps of their choice by establishing access to EHI “without special effort” and the ability to exchange EHI with third-parties, including researchers. The Cures Act Final Rule established

128
the Health Level Seven (HL7®) Fast Health Interoperability Resource (FHIR®) standards to achieve this interoperability and data exchange to meet these goals.

While it is possible to extract RWD from EHR data using standardized APIs, gathering RWD from most other data sources is not possible using current standards. In addition, EHR data are insufficient to answer the questions asked by researchers conducting complex analyses trying to leverage clinical data with other RWD to develop RWE in comparison to other research common data models such as: FDA Sentinel Initiative,6 Informatics for Integrating Biology and the Bedside (i2b2),7 Observational Medical Outcomes Partnership (OMOP)8, and Patient-Centered Outcomes Research Network (PCORnet).9 Approaches to gathering sufficient RWD through the use of APIs will continue to emerge as the standards evolve and industry is incentivized to use these standards-based technologies as to bridge the digital divide between health IT systems.

Panel Objectives and Presenters

The aim of this panel is to provide insights from both government and industry perspectives on the use of APIs and third-party apps for the purposes of collecting and sharing RWD and RWE to support clinical decision making and research. The panelists will share findings from federally funded efforts to investigate facilitators and barriers to using APIs to advance RWD and RWE. Panelists representing data integrators will discuss their experiences supporting government, provider, pharmaceutical, and life sciences organizations in the use of real-world data and real-world evidence. The panelists will describe both current examples and future use cases using RWD and RWE to promote a robust research ecosystem that integrates data from a variety of sources, including electronic health records (EHRs).

Mr. Kevin Chaney, MGS (moderator), a Senior Program Manager in ONC’s Scientific Advancement Branch, will provide an overview of ONC’s priorities and their relation to the promotion and use of standardized APIs for scientific discovery, lessons learned and currently funded work in the API and interoperability areas. Mr. Chaney will discuss findings from ONC efforts to review the landscape of API use in the field, specifically to support scientific discovery. He will discuss ONC efforts to develop tools and resources to support improved transparency for providers, patients, researchers, and health IT developers and integrators.

Ms. Anita Samarth (panelist), the CEO of Clinovations GovHealth, will introduce and moderate the session. Ms. Samarth has implemented health IT at over 200 provider organizations and will highlight findings from provider organizations, researchers, and app developers implementing and using APIs to access data contained within EHRs.

Gideon (Scott) Gordon, PhD (panelist), a Senior Health Informatics Officer at FDA for the Office of Strategic Programs in the Center for Drug Evaluation and Research, will discuss FDA activities to standardize data for clinical research, submissions to FDA, and post-market surveillance. A significant aspect of Dr. Gordon’s work includes a focus on RWD derived from health IT and other non-traditional sources for use as an adjunct to data from traditional clinical trials and current pharmacovigilance methods.

Vera Mucaj, PhD (panelist), the Head of Trials and Chief Scientist at Datavant, will discuss their mission to connect health care data from a variety of sources to be used for academic research, pharmaceutical research, and clinical care. Dr. Mucaj’s current role includes a focus on clinical trials and using real-world data connected to trial data to generate real-world evidence in a privacy preserving manner, and to make it useful for retrospective cohort analysis, post-marketing studies, hybrid studies, and complex data analytics.

Mr. Andrew Kress (panelist), CEO of HealthVerity, will discuss current activities to provide a seamless, high-governance, privacy-compliant way to connect and exchange complete real-world data about people across the healthcare and consumer data ecosystem, enabling next-gen analytics and applications. He brings perspectives from HealthVerity’s platform that provides linked, de-identified data for real-world evidence, pharmaceutical companies, payers, clinical trial optimization, and population health.

Panel Discussion Questions

• Describe your experience using real-world data or real-world evidence to support clinical decision making and research efforts. How are you seeing novel approaches to using this data to advance health care and research?
• What do you see as the biggest incentives or barriers to using standardized APIs for the collection and sharing of real-world data and real-world evidence? What types of challenges or barriers are the most difficult to overcome?
• What technical, policy, and/or financial needs or gaps have been identified through your work that limit the adoption of standards-based APIs for the collection and use of real-world data and real-world evidence?
• What educational tools and resources are available or needed to support technology companies as they continue to develop products to support the advancement of real-world data and API use for clinical care and research?

Panel Learning Objectives

• Participants will learn the specific technology, policy, and privacy considerations and industry drivers for the promotion of standardized APIs for the use of RWD and RWE, for promoting data access and sharing for research.
• Participants will have an improved understanding of the emerging use cases for using standardized APIs for the collection and aggregation of RWD and RWE for clinical research and health care.
• Participants will engage with panelists in the discussion and share feedback and experiences advancing the collection of RWD and RWE to support traditional use cases such as clinical trials, as well as research studies and clinical decision making.

Conclusion

Some forms of RWD exists in small data sets, which provides for more rapid, yet less robust research. These data sets do not require extensive data curation and mapping. Conversely, there are larger data sets, such as data collected during clinical trials, that are robust but time-consuming to curate and obtain. Often, such data sets cannot be merged in ways that preserve patient privacy preferences. Some data aggregators have developed the infrastructure and open, scalable technologies to host the data and link to any additional RWD through a robust governance structure that controls access to data sets. In the future, the use of standardized APIs such as FHIR® could improve the ability to collect and disseminate RWD for research purposes, and make such data accessible to research organizations that may not have the resources to acquire it from data aggregators and integrators. The rapidly evolving and expanding RWD and RWE market is blurring the lines between health IT and data products that serve traditional grant-funded academic research and industry-led activities (e.g., clinical trials, pharmaceutical and medical device funded research). While expanded use of multiple data sets found in EHRs used in conjunction with other data for large research studies can be linked and matched to create robust RWD data sets, acceptance of this emerging practice requires understanding and addressing resistance and barriers to use of RWD sources.

Statement of Participation

Each of the panelists and the moderator have confirmed that they will participate if this submission is accepted, at the assigned timeslot during the Annual Symposium.

Advancing Interoperability: Analysis of EHR Interoperability Measurement Capabilities

Anita Samarth¹, Amit Trivedi, MS², Steven Lane MD, MPH, FAAFP³, Vaishali Patel, MPH, PhD⁴
¹Clinovations Health + Government, Washington, DC; ²Healthcare Information and Management Systems Society, Chicago, IL; ³Sutter Health, Sacramento, CA; ⁴Office of the National Coordinator for Health Information Technology, Washington, DC

Abstract

Increasing interoperability and use of exchanged data is a national priority established by the Medicare Access and CHIP Reauthorization Act (MACRA) of 2015. Currently, progress is measured primarily through national surveys of hospitals and office-based physicians; however, these data sources do not contain a level of granularity to compare interoperability trends across health information technology (IT) developers and providers using their products. In 2020, the Office of the National Coordinator for Health Information Technology (ONC) launched an initiative to understand how healthcare stakeholders measure the ability to exchange and use external information to improve health outcomes and delivery. This initiative’s findings will provide insights on leveraging electronic health record (EHR) data to measure interoperability. The panel will present findings, including leading practices and types of data used by EHR developers and their customers to measure interoperability. The panel will discuss conclusions about known levels of interoperable information exchange that can be drawn from available measures and reporting capabilities. An important objective of the panel is to engage the informatics community to spur discussion on potential measures of value and utility that provide understanding of progress to advance interoperability.

Introduction

MACRA established a national priority to drive widespread interoperability and to report exchange and use of clinical information to facilitate coordinated care and improve patient outcomes.¹ Subsequently, the 21st Century Cures Act of 2016 (Cures Act) requires the Department of Health and Human Services (HHS) and Office of the National Coordinator for Health Information Technology (ONC) to improve the interoperability of health information.² To date, primary data sources for measurement of interoperable data exchange are limited to national surveys of hospital and office-based physicians.³⁶ While these sources offer general insights on exchange and use of health information, ONC seeks national measures feasible to collect from health IT products that send, receive, query, incorporate, and use information from external products and organizations. In addition, while measures derived from health IT may reduce reporting burden on providers, a deeper understanding of interoperability measurement is necessary prior to drawing conclusions about national levels of interoperable data exchange.⁷⁸ For example, clinical quality measures are relatively mature and are developed, tested, and vetted through national consensus processes and EHR generated measures exist for assessing provider burden⁹; however, detailed interoperability measure specifications are nascent and not available in a format that allows consistent and comparable reporting across different health IT products.¹⁰ Further, making conclusions about the value and utility of exchange is challenging, due to the inability of measures that track volume to also convey context.⁸ Together, these factors constrain the ability of clinicians, health care delivery administrators, researchers, and policy makers to understand the level and impact of health information exchange and support their business and policy decisions.

Understanding Interoperability through Interoperability Measurement

ONC initiated a multi-year endeavor to advance interoperability measurement by developing an in-depth understanding of measures created for health IT users and developers. The project involved an analysis of the current state landscape of interoperability measurement capabilities within EHRs and offers recommendations on strategies and specific tactics that consider real-world experience and value to providers. The project approach consisted of an environmental scan of current state of interoperability measurement, including existing methods used by EHR developers, and an iterative interview approach with various key stakeholders, including health IT users and developers.

The panel will present: 1) an overview of the factors that drove national efforts to understand interoperability measures derived from data within and exchanged with health IT products; 2) findings and insights learned from health IT users and developers about the aspects of interoperability that are currently tracked or measured; 3) lessons learned to implement for health IT developers and users both to support better interoperability, and 4) an overview of possible measurement strategies and insights to support future interoperability tracking and measurement.
Panel Objectives and Presenters

The aims of this panel are: (1) to share findings from ONC’s supported project to identify EHR generated measures of interoperability and (2) to invite participants to provide feedback that can advance the national approaches to measuring interoperability. To engage participants, the presenters will frame the discussion with prepared questions for open discussion amongst health IT users, developers, and other interoperability measurement stakeholders in the audience.

Dr. Vaishali Patel (moderator) leads ONC’s Data Analysis Branch. She is responsible for measuring and reporting on national progress related to interoperability and use of health IT. Through her experiences at ONC and Weill Cornell Medical College, where she evaluated NY State’s health IT and health care delivery transformation initiatives, she will discuss ONC’s role and experiences in obtaining measurement data in support of advancing health IT and interoperability in health care.

Anita Samarth (panelist) is CEO of Clinovations Government + Health with more than 25 years of implementing health IT in the health system, hospital, and ambulatory practice settings at over 200 provider organizations. She serves as the technical project director on a multi-year project for ONC investigating interoperability measurement and will discuss project findings and ongoing efforts to identify and define interoperability measures of value.

Amit Trivedi (panelist) is the Director of Informatics & Health IT Standards at HIMSS with more than 20 years of experience in the certification of health IT products and the development of test criteria and methodology, specializing in interoperability and technical testing of health IT products. He will speak to the elements of health IT standards and interoperability strategy and measurement and discuss insights from EHR Association (EHRA), HIMSS Davies awards winners, and other HIMSS HIE and Interoperability Committee and Community efforts.

Dr. Steven Lane (panelist) is the Clinical Informatics Director for Privacy, Information Security & Interoperability at Sutter Health. As a practicing primary care physician and informaticist, he has been a leader in eliminating barriers to information sharing, optimizing the utility of data exchanged, and leveraging health IT tools available to track numerous interoperability aspects related to his practice. Dr. Lane will discuss his experiences using health IT reporting solutions, and present considerations for uses and limitations of measures derived from health IT data to inform clinical and business decisions.

Panel Discussion Questions

The moderator will address the following types of questions to the panelists and encourage the audience to share their input and experience.

1. What EHR capabilities are available to measure interoperability? How do capabilities differ across different EHR products and reporting solutions?
2. What measures are appropriate to measure at the health IT developer level vs. customer level? Describe the level of insights and conclusions that can be derived from developer level vs. customer level measures.
3. What are the most common transactions, standards, and data that are exchanged between different EHR products? What factors affect whether a particular method is used (e.g., Direct vs. national networks like Carequality and Commonwell)?
4. Where can interoperability investments continue to improve health IT user and developer measurement of exchange? How can tracking and reporting be designed to reduce burden on end-users while still providing accurate information?
5. How should the project’s findings about data tracked by health IT developers and users support ONC’s interoperability measurement strategy?

Panel Learning Objectives

1. Participants will learn about the common interoperability measures that health IT developers use or provide for their customers to assess exchange activity, and the factors that support or present challenges to measurement.
2. Participants will understand how interoperability measure structure and definition can support measurement of inter-and intra-organizational data exchange and measure the types of data that are exchanged.
3. Participants will share perspectives on health IT developer and customer capabilities and challenges related to interoperability measurement in real-world settings and learn how individual customizations and configurations present challenges to interoperability measure comparability.
4. Participants will critique and discuss the advancing interoperability measurement ecosystem, including interoperability measures in use by health IT users and developers.
5. Participants will learn how an understanding, and a measure of how organizations use measurement and use external data can provide valuable data for clinical decision support and care coordination.

Conclusion

The first year of this multi-year initiative supports the goal of understanding the current state of interoperability measurement by health IT developers and users. Health IT national initiatives and federal efforts will be able to leverage the data collected on current interoperability measurement methods and investments to leverage current measurement efforts undertaken by health IT developers alongside national surveys to provide meaningful information for clinicians, health care administrators, policy makers, researchers, and other stakeholders. By identifying the practices and data used by developers to measure interoperability, this project will yield deep insight into the state of interoperability that is currently not gleaned through surveys and provide stakeholders with an understanding of the interoperability capabilities of health IT systems as they work in tandem to improve health outcomes.

Statement of Participation

Each of the panelists and the moderator have confirmed that they will participate if this submission is accepted, at the assigned timeslot during the Annual Symposium.

References

What will the attendee be able to do after being in your session?
1. Summarize the latest advancements in AI and machine learning models in terms of ensuring safety, reliability, sensitivity, and precision
2. Understand the components that go into securing provider adoption and ensuring utilization of AI tools in the care delivery space
3. Identify and illustrate the limitations of AI/machine learning for health delivery from a governance and regulatory perspective, and create an evaluation rubric built from best practices of evaluating these types of tools, in order to ensure accuracy, actionability, and usability

Description of the Problem or Gap
The increasing focus of AI on the frontier of clinical applications has led to the accumulation of evidence for clinical decision support across a wide range of specialties such as radiology, oncology, ophthalmology, and critical care. FDA has published action plans for regulating AI/ML-Based Software as a Medical Device (SaMD) and approved more than 160 medical AI products. Meanwhile, due to the sensitivity of clinical AI in producing unintended consequences such as incorrect diagnoses, unnecessary treatments, and racial disparities, there is also a growing concern on how to produce safe, reliable, and trustworthy AI for adaptive clinical decision support (adaptive CDS) systems.

Panel Topics
The overarching goal of this panel is to bring together the thought leaders in the field who have experience in both theory and practice to pinpoint the challenges in creating precise, sensitive, and usable AI tools in the care delivery space, drawing on their experience both in the lab and in practice.

The panel will be entirely discussion-based. The panelist will draw from their own real-world case studies to share lessons learned, including recent evaluations of tools that are implemented in health systems right now, creating best practices for model creation, deployment, provider use, evaluation and ongoing governance and regulation. The invited moderator and discussants are all leading experts who will collectively discuss the pros and cons leveraging studies and live-experience building, deploying, and evaluating CDS tools.

Questions to be answered
- With health data being messy, what strategies does one need to use to measure and tackle bias, ensure reliability and safety, and deliver high precision and sensitivity?
- Once the models are created, how do the insights need to be packaged and delivered to providers to ensure adoption and continued engagement/use?
- After deployment, how should one think about evaluation? Without regulatory bodies requiring certain practices, the evaluation process can look different for each tool, so what are the necessary evaluation steps (rubric) that should be followed?
- What are the safety hazards facing these types of tools? How should regulation and governance of these tools look, and what are the best practices for monitoring and governance?
- Do we have any consensus with regards to the important questions to be solved next and the important steps to take to get to the next level of understanding?
Who Should Attend?
The panel is crafted to provide insights for healthcare professionals and informaticists from all areas of practice interested in real-world evidence for real-time insights in healthcare delivery. Potential attendees include: CMOs, CQO, CMIOs, CIOs, clinical informatics fellows, clinicians (superusers), researchers/faculty, administrators, vendors, health IT professionals, and other AMIA participants.

Organizer and Speaker Qualifications
The organizers and discussants of this panel are healthcare system leaders and experts within care delivery transformation, implementation science, patient safety, informatics, and machine learning/AI. The panel proposal is also based on the gaps identified from a series of events previously organized in AMIA CIC Conference 2021 and AMIA annual symposium 2015-2020 and with the overlapping targeted participants in Applied Data Science for Healthcare Workshop from Association of Computing Machinery (ACM) SIGKDD International Conference of Knowledge Discovery and Data Mining (KDD 2018-2020).

Dr. Eric Topol is the Gary & Mary West Endowed Chair of Innovative Medicine, Scripps Research and the Director and Founder of Scripps Research Translational Institute. His research is on individualized medicine, using the digital technologies to understand each person at the biologic, physiologic granular level to determine appropriate therapies and prevention. An example is the use of pharmacogenomics and his research on clopidogrel (Plavix). By determining the reasons for why such a large proportion of people do not respond to this medication, we can use alternative treatment strategies to prevent blood clots.

Dr. Suchi Saria, PhD is the John C. Malone Associate Professor of computer science, statistics, and health policy, the Director of the Machine Learning and Healthcare Lab, and the founding Research Director of the Malone Center for Engineering in Healthcare at Johns Hopkins. She is also the founder of Bayesian Health. Her research has pioneered the development of next generation diagnostic and treatment planning tools that use statistical learning methods to individualize care. Her work has received recognition in numerous forms including Rambus Fellow, NSF Computing Innovation Fellow, IEEE Intelligent Systems to Artificial Intelligence’s “10 to Watch”, the DARPA Young Faculty Awardee, MIT Technology Review’s ‘35 Innovators under 35’, National Academy of Engineering’s Frontiers of Engineering, the Sloan Research Fellow, National Academy of Medicine’s Emerging Leaders in Health and Medicine, the World Economic Forum Young Global Leader, and the National Science Foundation’s Top Four Contribution to Congress. She is on the editorial board of JMLR and the board of several companies using ML for healthcare.

Dr. Ziad Obermeyer, MD, PhD is the Blue Cross of California Distinguished Associate Professor of Health Policy and Management at the UC Berkeley School of Public Health. He is a physician and researcher who works at the intersection of machine learning, medicine, and health policy. He previously was an Assistant Professor at Harvard Medical School, where he received the NIH Early Independence Award for exceptional junior scientists. He continues to practice emergency medicine in underserved parts of the US. Prior to his career in medicine, he worked as a consultant to pharmaceutical and global health clients at McKinsey & Co. in New Jersey, Geneva, and Tokyo.

Dr. Karandeep Singh, MD, MMSc is Assistant Professor in the Departments of Learning Health Sciences and Internal Medicine at University of Michigan. He is a physician, researcher, and educator interested in studying learning health systems, making new discoveries about disease, and improving patient care through technology. His research areas include natural language processing of clinical notes, risk prediction using high-dimensional data, and mobile health. He is also an assistant professor of Medicine in the Division of Nephrology at the University of Michigan Medical School and has previously served as chief resident, and a nephrology fellowship at Brigham and Women’s Hospital in Boston. He is board certified in internal medicine, nephrology, and clinical informatics.

Dr. Marzyeh Ghassemi is an Assistant Professor at the University of Toronto in Computer Science and Medicine, and a Vector Institute faculty member holding a Canadian CIFAR AI Chair and Canada Research Chair. She is the founder of the Machine Learning for Health group which targets "Healthy ML," with a focus on creating applying machine learning to understand and improve health. She will join MIT's IMES/EECS in July 2021. Professor Ghassemi has a well-established academic track record across
Dr. Pei-Yun Sabrina Hsueh is a health AI leader who has spent more than 10 years in industry building CDS tools between her time at IBM Watson, Viome, and Bayesian Health. Dr. Hsueh is the Past-Chair of the AMIA Consumer and Pervasive Health Informatics Work Group, current co-chair of AMIA Women in AMIA Leadership and Awards Subcommitte, and a Board Member on ACM Practitioners Board. She previously served as the Chair of IBM Research Health Informatics Professional Community. She has authored 20 patents and 50 scientific publications and books in AI/ML for Medicine and Personal Health Informatics and edited for various journals including JAMIA OPEN.

Statement of Participation
Each invited presenter/organizer has confirmed via email that they agree to take part in the proposed panel, and the views expressed in this panel do not represent their institutions and the financial interest.

Re-imagining Academic-Private Sector Collaboration to Enhance Digital Health Equity

Urmimala Sarkar, MD, MPH1, Ashwin Patel, MD, PhD2, Everett Crosland, MSC, JD3, David W. Bates, MD, MSc4,5,6, Courtney R. Lyles, PhD1
1University of California, San Francisco, San Francisco, CA; 2InquisitHealth, River Edge, NJ; 3AppliedVR, Los Angeles, CA; 4Brigham and Women’s Hospital, Boston, MA; 5Harvard Medical School, Boston, MA, 6Mass General Brigham, Somerville, MA

Abstract

This panel will provide academic researchers, health informatics professionals, vendor representatives, and clinicians with pragmatic recommendations to develop and sustain cross-sector partnerships to improve digital health equity. The panel includes a primary care physician and health services researcher based in a safety-net health care setting, two digital health entrepreneurs, and a moderator with expertise at the intersection of academia and health informatics. The panelists will describe two research projects that investigate and adapt the fit of health technology for historically marginalized and minoritized populations, including why and how they initiated the projects, what they learned, and how their success may be replicated elsewhere. After participating, attendees should be better able to understand current gaps in consumer health informatics for vulnerable populations, recognize how cross-sector partnerships may be able to address some of these gaps, and formulate recommendations for developing such partnerships in pursuit of equitable digital health innovation.

Introduction/Overview

This panel will provide an overview of digital health disparities and offer pragmatic approaches to addressing them with cross-sector partnerships between academia and the private sector.

Health technology developed in the private sector is critically important to deliver health care, especially during the COVID-19 pandemic.1-3 However, despite high interest,4,5 marginalized and minoritized patients are least likely to access digital tools6,7 due to barriers related to broadband, wifi, and device access as well as usability and accessibility (e.g. literacy, inclusivity, language).8,9 One promising approach to this gap between patient needs/interest and technology is to re-imagine public-private partnerships. Previous research describes challenges of university-industry collaboration and misalignment across stakeholder groups,10,11 making it important to share learnings from successful experiences.

Two academic researchers with expertise in health communications, implementation science, digital, and health equity (Dr. Lyles and Dr. Sarkar) launched an academic incubator, UCSF S.O.L.V.E. Health Tech, in May 2019.12 They invited applications from digital health companies interested in adapting or evaluating their product with a focus on health equity, and selected two companies to partner in a 12-18 month incubation cycle. Dr. Patel and Mr. Crosland represent the two companies that partnered with S.O.L.V.E. Health Tech during this inaugural cycle. As a result of this work, the team generated two peer-reviewed publications,13,14 garnered additional venture capital funding, and initiated two follow-up projects. During this panel, Dr. Lyles and Dr Sarkar will provide insight into the collaboration from the perspective of academics and Dr. Patel and Mr. Crosland will share their perspectives as digital health leaders. Dr. Bates will moderate.

We expect academic researchers, health information technology professionals, vendor representatives, and clinicians will benefit from this panel.

Panel Presentations

1. Courtney Lyles, PhD, Associate Professor of Medicine, University of California, San Francisco, “Background on gaps and opportunities for existing digital approaches to improve health equity” (10 min + 5 min for Q&A = 15 min) Dr. Lyles will provide an overview of existing digital approaches in
healthcare. She will describe how they fall short in meeting needs for patients – particularly those from historically excluded groups such as racial/ethnic minorities, older adults, and those with limited English proficiency and limited health literacy.

2. Urmimala Sarkar, MD, MPH, Professor of Medicine, University of California, San Francisco, “Re-imagining private-public partnerships with an academic incubator” (10 min + 10 min for Q&A = 20 min) Dr. Sarkar will describe the formation of an academic incubator designed to address the gaps that Dr. Lyles introduced. She will provide details on how she and Dr. Lyles created the incubator, what they expected, challenges they encountered (including those related to legal issues such as intellectual property), how they adapted in response to the COVID-19 pandemic, and discuss results.

3. Everett Crosland, MSC, JD, Chief Commercial Officer, AppliedVR, “Academic partnerships for digital health approaches” (5 min + 5 min for Q&A = 10 min) Mr. Crosland is Chief Commercial Officer of a company offering therapeutic virtual reality for patients with serious health conditions in the hospital, ambulatory, and home settings. Mr. Crosland will describe the breadth of academic partnerships AppliedVR has engaged in, their rationale for engaging with S.O.L.V.E. Health Tech in light of their prior randomized clinical trials, and the risks/rewards of the partnership.

4. Ashwin Patel, MD, PhD, Co-Founder and CEO, InquisitHealth, “How clinicians in industry can engage with academic partners” (5 min + 5 min for Q&A = 10 min) Dr. Patel is the Chief Executive Officer and co-founder of a remote, technology-enabled peer mentoring company that delivers chronic disease management longitudinally and one-on-one to patients, through telephonic and smartphone outreach in both in English and Spanish. Dr. Patel will delineate learnings and best practices for partnering with academics, including suggestions for advancing this work with resource-limited delivery system partners during the COVID-19 pandemic, from his unique perspective as a clinician-entrepreneur.

5. Moderated discussion with digital health company partners, “Lessons learned from partnering with an academic incubator to improve digital health equity” (moderated by David W. Bates, MD, MSc, Professor of Medicine, Harvard Medical School, Chief of the Division of General Internal Medicine and Primary Care, Brigham and Women’s Hospital) (20 min + 15 min for Q&A = 35 min) Dr. Bates is Medical Director of Clinical and Quality Analysis, Information Systems at Partners Healthcare System, Inc. and a national leader in patient safety, informatics, and digital health equity. He will moderate a discussion between Dr. Patel and Mr. Crosland regarding their experiences working with an academic incubator to adapt and evaluate their digital health products with a focus on health equity. The panelists will provide examples of cross-sector partnerships from the company perspective, challenges they encountered, facilitators, and recommendations for other vendors.

Audience Discussion Questions

1. How can academic-private sector partnerships like these improve health equity? What can other stakeholders (e.g. health systems, clinicians, information technology professionals, and policy makers) do to support this work?

2. What are the biggest barriers and facilitators to establishing partnerships among academic research teams and digital health companies? How do these barriers and facilitators change based on setting and company stage?

3. What are best practices for deciding who to partner with when establishing academic-private sector collaborations?

4. What are examples of pressing topics that academic-private sector partners can study together?

Statement Confirming Participation

As organizer of this panel, I, Urmimala Sarkar, confirm that all panelists have agreed to take part.

Broadband Internet Access as a Social Determinant of Health
With Impacts on Health Disparities During COVID-19

Marianne Sharko, MD, MS1, Natalie (Nat) Benda, PhD1, Tiffany Veinot, PhD, MLS2,
Cynthia Sieck, PhD MPH3, Jessica S. Ancker, PhD, MPH4

1. Weill Cornell Medicine, New York, NY; 2. University of Michigan, Ann Arbor, MI; 3. The Ohio State University College of Medicine, Columbus OH; 4. Vanderbilt University Medical Center, Nashville TN

Abstract Disparities in broadband internet access is an important public health issue. Broadband internet access (BIA) affects “the health of people and communities where they live, learn, work and play,” and thereby should qualify as a social determinant health as defined by the American Medical Association. During the COVID-19 pandemic, lack of universal internet access has contributed to the widening gap in health disparities with vulnerable populations disproportionately experiencing the effects of insufficient BIA. In this panel, we will demonstrate how poor internet access influences health disparities, particularly through limited access to healthcare and health-related information. This presentation will highlight the need to identify internet access as a social determinant of health. After participating in this session, attendees should be able to identify the effects of limited BIA access on health disparities and inequities and discuss policies for addressing the disparity.

Keywords: Social determinants of health, broadband internet access, health disparities, telehealth

Introduction The unprecedented COVID-19 pandemic has widened health disparities; this has resulted in as yet unappreciated impacts—particularly on vulnerable populations. As Americans have become reliant on the internet for most aspects of our lives, limitations in access can influence multiple domains of social determinants of health, including economic stability, education, food security, social support and physical environment.1,2 Inconsistent or low-quality internet access also contributes to inequitable healthcare and access to health-related information, which widens existing health disparities. (Figure 1) Vulnerable populations, such as those from low income neighborhoods, older adults, and racial and ethnic minorities, have already experienced deep-seated inequities in health care which have been compounded by gaps in information and healthcare access.3,4 There are trends in disparate infections rates. For example, in Milwaukee County, WI, 81% of the deaths reported from COVID-19 in were Black residents, despite a Black population of 26%.5 Blame for this disparity is often placed on underlying comorbid conditions such as obesity and hypertension; however, there are structural factors that are also contributory. Differences in resources accessible to people who have better broadband internet access enable them to work from home and more effectively access healthcare and information. During the pandemic, those without in-home internet access had a limited ability to gain information about office closures, schedule appointments, and ultimately access care. Those we may have been able to access a healthcare provider via telephone-only missed the ability to have the health professionals’ complete visual examinations, that are possible to some extent via video-based visits. Issues are also not limited to those without an in-home internet connection, but others who had unstable internet service, or had to contend with family members working or schooling from home, also faced barriers to accessing video-visits. Lastly, vital public health information has changed rapidly during the pandemic, and predominantly exists online. COVID-19 vaccine administration has further demonstrated inequities for those without stable broadband internet access, as many states are showing Whites
have been vaccinated at a much higher rate than African Americans who have borne the brunt of COVID-19 related disparities.\(^{(7)}\)

In 2017, the American Medical Informatics Association urged the Federal Communication Commission to consider BIA as a SDOH.\(^{(8)}\) This would identify the need to provide universal access to internet access in order to work towards an equitable healthcare system. In recognition of this issue, the Federal Communications Commission recently approved the $3.2 billion Emergency Broadband Benefit Program during the pandemic. This program provides support for broadband services to help connect low-income households during the COVID-19 pandemic.\(^{(9)}\)

This panel will explore how limitations in internet access contribute to inequalities in access to healthcare and health information. Our panel members will provide an overview of social determinants of health and will use their research to demonstrate how limitations in BIA can affect health disparities by limiting access to healthcare and health information. We will conclude by discussing policy implications for ensuring that public programs include BIA beyond the COVID-19 pandemic.

**Discussion questions**
- What would be the benefits or drawbacks of defining broadband internet access as a social determinant of health?
- How can we improve broadband internet access and where do we focus these improvements for maximum impact?
- How can we identify populations in need of improved broadband internet access?
- What policy mechanisms exist to improve broadband internet access?

**The Panel**

Each panelist will share research that seeks to provide information on the importance of recognizing limited BIA as a social determinant of health.

**Dr. Natalie (Nat) Benda (moderator)** is an expert in human factors engineering/systems safety, and her work involves advancing health equity and inclusivity through technology-based interventions. She will serve as the moderator. Following the panelists’ presentations, the moderator will facilitate discussion by first posing one to two questions to the panel regarding policy or other mechanisms for addressing BIA disparities. The audience will then be invited to ask additional questions and engage in a discussion surrounding the role of informatics in promoting BIA and ensuring it is provided as a public resource.

**Dr. Jessica Ancker** has conducted extensive research on health literacy and numeracy as social determinants of health and on the use of health information technology by diverse patient populations. She is leading a comparative effectiveness study funded by PCORI to examine the impact of the COVID pandemic on telemedicine uptake and impact. She will provide an overview of public health research on the impact of social determinants of health. She will introduce the concept of limited broadband internet access as a social determinant of health and provide a context for the need to ensure equitable access to this resource in order to reduce health disparities. Her overview of broadband internet access issues will be supplemented with evidence from her ongoing PCORI study related to the utilization of telemedicine during the pandemic.

**Dr. Marianne Sharko** is a pediatrician who received her master’s degree in Health Informatics from the Population Health Sciences Department at Weill Cornell Medicine and has completed a Preventive Medicine Residency. She is currently working in a pediatric obesity clinic and conducting research through the Empire Clinical Research Investigator Program (ECRIP). Her research interests include the intersection of obesity and social determinants of health and how this synergy contributes to health disparities. Dr. Sharko is currently conducting an interview study discussing the pandemic experience of families in a low-income population on public health insurance. She will share their words and experiences regarding BIA limitations and how it has affected their lives. She will identify challenges of insufficient BIA and sources of support to improve BIA or to compensate for insufficient access.

**Dr. Cynthia J. Sieck** is an Associate Professor in Family and Community Medicine in The Ohio State University College of Medicine and in the Center for the Advancement of Team Science, Analytics, and Systems Thinking (Catalyst). Her research focuses on patient engagement in health care, particularly through the use of health information technology (HIT), and disparities in health care access and outcomes. With a background in Health Behavior and Health Education, she studies how patients can increase their level of engagement to fully participate in their own health care, and how healthcare systems can best support patients in these efforts. She will discuss efforts to identify populations in need of improved broadband internet access and community collaborations that support digital skill and literacy training to ultimately improve access to health services and health information.
Dr. Tiffany Veinot is Associate Dean for Faculty at the University of Michigan (UM)’s School of Information. She is also Professor at the Schools of Information and Public Health at UM. Her research focuses on “community health informatics,” or the use of information systems and services to improve the health of marginalized populations and reduce health disparities. She will discuss findings from an NSF-funded project focused on telehealth access at a federally qualified health center with six clinical sites in Metropolitan Detroit. Detroit is 78.6% African American, and Detroit households also have lower rates of in-home broadband internet (59.3%) when compared to the US (80.4%). While placing the findings in the context of structural racism and digital redlining, Veinot will discuss analyses of technical problems during video visits with FQHC patients, including high numbers of visits interrupted or restarted—or switched to telephone—due to technical challenges. She will also outline results of a pilot intervention in which trained master’s students helped patients get set up for telehealth, including challenges and problems encountered in doing so. Finally, she will outline ongoing efforts to quantify and reduce the complexity of telehealth processes and systems in order to reduce barriers to access for FQHC patients.

Learning Objectives
After participating in the session, the attendant should be able to:

- Describe how limited BIA contributes to widening health disparities
- Appreciate the need to identify BIA as a social determinant of health
- Advocate for strategies to widen BIA and reduce barriers to access for vulnerable patient populations

Panel Organizer Statement
All participants have agreed to participate in this panel.

Conflicts of Interest
The participants have no conflicts of interest to disclose.

Acknowledgements
Jessica Ancker and Natalie Benda are supported by PCORI COVID-2020C2-10791 (Ancker and Kaushal, co-PIs). Marianne Sharko is supported by the NYS Department of Health Empire Clinical Research Investigator Program. Tiffany Veinot is supported by NSF RAPID-COVID-19-#2031662 and a Google Health Unrestricted Gift.

Informatics Career Journeys Among Academic, Government and Industrial Roles

Moderator:
Jane L. Snowdon, PhD

Proposed Panelists:
Patricia Flatley Brennan, RN, PhD
Judy Murphy, RN
Marion Ball, EdD
Yull Arriaga, MD

Proposed Panelist Affiliations:
a IBM Watson Health, Cambridge, MA
b National Library of Medicine, Bethesda, MD
c Freelance, Lake Elmo, MN
d University of Texas at Arlington, Arlington, TX
e Bristol Myers Squibb, Lawrenceville, NJ

Abstract: The healthcare industry is transforming along four dimensions: societal, economic, individuals, and organizations. First, scarce resources and rising demand are driving a relentless focus on cost reduction and quality with improved and equitable access. Second, patients and families are empowered with digital tools such as smart devices, wearables, telemedicine, and remote monitoring that are driving new expectations in standards of care and ownership of health interventions and outcomes. Third, business and operating models are driving consolidation and disruption, new entrants, and an evolving regulatory environment.

Having healthcare informatics experience in various sectors (e.g. academic, industry, and government) can provide a broader perspective about the challenges of and opportunities for developing and applying informatics and innovative technologies to facilitate healthcare transformation and collaboration leading to advances in science. In this panel, we present the experiences of several individuals with successful informatics careers that involved transitions from academia to government, government to industry, industry to academia, and academia to industry. The panelists will share their lessons on how to be successful in a dynamic environment, support for research, growth opportunities, skills development, and how their time in one sector influenced their career choice.

Moderator and Proposed Panelist Information:
- Jane L. Snowdon, PhD, FAMIA is Deputy Chief Science Officer, Scientific Operations, Center for AI, Research and Evaluation, IBM Watson Health
- Patricia Flatley Brennan, RN, PhD, FAIMBE, FACMI, FAAN is Director of the National Library of Medicine
- Judy Murphy, RN, FACMI, FHIIMSS, FAAN is a Nurse Executive and Health IT Leader who served as ONC Deputy National Coordinator for Programs and Policy
What might the attendee be able to do after being in your session?
Attendees at this session will be better able to navigate informatics career transitions between academic, industry, and government sectors. Panelists will share insights into how to be agile, adaptive, and successful in dynamic healthcare sectors and environments.

Description:
The 90 minute panel will be organized as follows:

- Dr. Snowdon will introduce the topic, the panelists, and their organizations (15 minutes)
- The panelists will discuss each of the prepared topic questions below (45 minutes)
- Dr. Snowdon will facilitate questions from the audience (30 minutes)

- What factors influenced your decision to go into the [academia, government, or industry] sector as an initial career choice?
- What were the most important factors you considered when evaluating a career transition to your next opportunity?
- How have you employed informatics and technology to address the challenges and opportunities presented by the three, global disruptive forces above for your sector?
- How have your multi-sector experiences helped to facilitate collaborations leading to advancements in science?
- Which skills do you recommend acquiring to become agile and adaptive, and to keep pace with change in your sector?
- How have your experiences and skills development prepared you and influenced you to make a career transition from one sector to a different sector?

Participation statement:
All proposed panelists are aware of this panel submission and have agreed to participate in the panel if the proposal is accepted.
Home Healthcare to Primary Care Data Interoperability Challenges and Opportunities

Paulina S. Sockolow, DrPH, MS, MBA1, Kathryn H. Bowles, PhD, RN, FAAN, FACMI2,3, Maxim Topaz, PhD, RN, 3,4, Edgar Chou, MD, MBA, FACP5
1Drexel University, Philadelphia, PA; 2University of Pennsylvania School of Nursing, Philadelphia, PA, 3Center for Home Care Policy & Research, Visiting Nurse Service of New York, NY, 4 School of Nursing and Data Science Institute, Columbia University, New York, NY, 5Thomas Jefferson University, Philadelphia, PA

Abstract

Medicare patients are expected to have a primary care office visit within 2 weeks of hospital discharge. Over 1 million of these patients receive home healthcare (HHC) services. Despite HHC electronically collecting a wealth of patient assessment data, primary care receives a fax with little data asynchronous to the visit. Informatics has opportunities to address the interoperability challenge to improve patient safety and outcomes. This panel discusses challenges and opportunities in information continuity for primary care to have the right HHC information at the right time. Panelists will also discuss applying predictive analytics approaches with HHC data to identify rehospitalization risk factors, which if communicated to primary care could trigger preventive interventions. Session learning objectives are: describe visit and HHC information; identify HHC to primary care interoperability barriers; discuss how HHC data can inform primary care of patient risk factors; and describe risk prediction models using HHC data.

Keywords: communication, home health care nursing, home health nursing, primary health care, continuity of patient care/standards, transition of care, nursing informatics, documentation.

Introduction

This panel of informatics experts will discuss the need to improve the interoperability and sharing of patient data from home healthcare (HHC) to primary care. Panelists will describe the relevance of HHC data to the patient-centered primary care team, presenting as exemplars the rich HHC data used to develop valuable prediction models. Panelists will discuss the challenges of unleashing patient data trapped in HHC electronic health record systems (EHR) and delivering it to the primary care team. The intended audience is primary care providers, nurses, EHR vendors, and informatics researchers. The objectives are to: 1. illuminate a gap in information continuity from HHC to primary care; 2. highlight an opportunity for the patient-centered primary care team to have the right information at the right time to improve patient safety and outcomes; and 3. encourage informatics research in HHC and primary care interoperability.

This topic is especially timely and important as the Centers for Medicare and Medicaid (CMS) encourages healthcare organizations to move towards value-based care where hospitalizations and readmissions are key quality and cost drivers. To prevent hospital readmissions and to care for the growing chronically-ill population, the United States increasingly uses HHC. More than 3.4 million homebound Medicare beneficiaries, mainly chronically ill, older adults are admitted to HHC services annually. Of these, one-third transition to HHC from a hospital.[1] Evidence based recommendations to reduce rehospitalization indicate the primary care team should evaluate HHC patients within two weeks of hospital to HHC transition.[2] Outpatient follow-up within one week, in combination with timely HHC nursing visits, has been shown to reduce rehospitalization in high risk heart failure [3] and sepsis [4] populations. Correspondingly, CMS Transitional Care Management requires a patient office visit within 14 days of hospital discharge, the Transition of Care (TOC) visit.[5]

For the TOC visit, the primary care team receives a minimal amount of non-electronic HHC patient data. However, HHC clinicians collect a rich set of structured data about the clinical, functional, and service needs of the patient during the first (admission) home visit. Guided by the CMS required Outcome and Assessment Information Set (OASIS),[6] HHC clinicians assess nearly 100 items including medications, patient safety, wounds, and cognitive and functional capabilities. Unfortunately, only a tiny subset of the structured OASIS data and narrative clinical notes are faxed to the primary care physician in the request to sign-off on HHC orders necessary for reimbursement. The faxed form (known as form ‘485’), contains a paucity of structured data, a preponderance of narrative text, and is not received in synchrony to the patient’s outpatient follow-up visit. Due to information silos and lack of implemented interoperability standards, there is a serious communication deficit along the HHC and primary care transition in care continuum.
Unleashing data from the HHC EHR is critical to capitalize on predictive analytics that may identify hospitalization risk factors, which if communicated to the primary care team could trigger preventive interventions. Also, the brief 15-20-minute TOC visit limits the amount and quality of information primary care providers can gather as they address acute and chronic illnesses, and hospitalization risk factors, making communication from HHC all the more valuable.

Primary care and HHC information siloes are reinforced by a lack of implementation of interoperability standards between the disparate HHC and primary care EHRs. Communication of OASIS data not on the 485 is not fully supported by existing interoperability standards. For example, the U.S. Core Data for Interoperability (USCDI) Version 2 [7] does not include medication self-administration capability. HHC is explicitly excluded from Advancing Care Information (formerly Meaningful Use) and implicitly excluded from USCDI due to health information exchange participation requirements. Information communication discontinuity creates potential missed clinical opportunities (not having information in the right place at the right time) which can impact patient outcomes. Implementation of an interoperability standard that supports communication of specific OASIS data and risk indicators to the primary care team for the TOC visit is necessary to address the fragmented delivery of care across the health care continuum.

**Panel Moderator: What Are the Interoperability Challenges in the Current Health Care System?**

**Paulina S. Sockolow DrPH MS MBA** will open the panel with a short overview of the primary care TOC visit, patient information collected in HHC, and HHC patient information communicated to primary care. She will discuss interoperability between HHC and primary care EHRs, and challenges of the USCDI interoperability standard.

Dr. Sockolow, Associate Professor at Drexel University, just completed an observational study of information availability and decision-making during the HHC admission.

**HHC Data for the Primary Care Team’s Transition of Care Visit: Challenges in Interoperability**

**Edgar Chou MD** will identify HHC data available for the TOC visit and gaps in data availability relevant to patient-centered, value-based care. He will detail the intersection of OASIS data, TOC data, and the USCDI. Dr. Chou will discuss HHC data that would be informative for the TOC visit including OASIS data (e.g., cognitive function, medication self-administration capability) and risk indicators (i.e., hospitalization, falls). He will specify this data’s presence or absence in the USCDI and offer research recommendations on USCDI HHC data inclusion.

Dr. Chou, Clinical Associate Professor at Thomas Jefferson University, is a primary care physician and an informatician. His research interests including leveraging information technology to improve the quality and efficiency of care and health care disparities.

**Structured HHC OASIS data: An Opportunity to Communicate Fall Risk**

**Kathryn H. Bowles PhD RN FAAN FACMI** will provide detail about the rich, structured, and standardized HHC data captured in the OASIS. She will describe the use of OASIS data in a machine learning analysis to predict fall risk, a cause for hospital admission, from her recently completed study.[8]

Dr. Bowles is Professor and van Ameringen Chair in Nursing Excellence at the University of Pennsylvania School of Nursing. She is the Vice President and Director of the Center for Home Care Policy & Research at the Visiting Nurse Service of New York. Dr. Bowles’ programs of research are in transitional care, decision support, HHC, and the EHR.

**Narrative HHC data: An Opportunity to Communicate Hospitalization Risk**

**Maxim Topaz PhD RN** will describe the HHC clinical notes data. He will show how this data can be used in predictive modeling with examples from his NLP studies to identify hospitalization risk factors in clinical notes.[9-11]

Dr. Topaz is an Associate Professor at Columbia University School of Nursing, Columbia Data Science Institute, and Research Scientist, Center for Home Care Policy & Research at the Visiting Nurse Service of New York. He conducts research in health informatics, focusing on natural language processing (NLP) and clinical decision support in HHC.

**Learning Objectives**

After participating in this session, attendees will be able to:

- Describe TOC information and HHC information
- Identify HHC to TOC interoperability barriers
- Discuss how HHC data can inform the primary care team and HHC nurses of patient risk factors
- Describe a couple of informatics approaches to develop risk prediction models with HHC data
Panel Organizer Statement

All participants have agreed to participate in this panel. The AMIA Primary Care Informatics Working Group and the Nursing Informatics Working Group endorse this panel.

Conflict of Interest

The panelists have no conflicts of interest to disclose. The HHC research of Dr.s Topaz, Sockolow, and Bowles is funded by the National Institute of Nursing Research (NINR) (R01NR018831 PI: Topaz). Dr. Bowles is also funded by the National Institute of Aging (R01 AG056607; P30 AG064105), the Agency for Health Care Quality and Research (AHRQ) (R01HS026599), NINR (R01 NR018196), National Institute on Minority Health and Health Disparities (R01 NR019315), and the Betty Irene Moore Foundation. Dr. Topaz and Bowles are also funded by AHRQ (R01HS027742).

Discussion Questions

- Are primary care teams aware or knowledgeable of the OASIS and HHC hospitalization risk factors information? If aware, would they like to know the OASIS information; the hospitalization risk factors information? If not, how to address this deficit?
- What OASIS data elements would primary care teams incorporate in the TCM visit (e.g., Activities of Daily Living, social determinants of health)?
- What changes to inclusion of data elements in the USCDI interoperability standard would support data sharing between HHC and primary care EHRs?
- What changes to HHC and primary care EHRs are needed to adopt the revised interoperability standard?

Applying State of the Art Language Models to Enable Better Clinical Natural Language Processing

Bryan D. Steitz, PhD¹; Emily Alsentzer, MS²; Hoo Chang Shin, PhD³; Byron C. Wallace, PhD⁴; Adam Wright, PhD¹

¹Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN
²Massachusetts Institute of Technology, Cambridge, MA
³NVIDIA Corporation
⁴Northeastern University, Boston, MA

Abstract

The natural language processing (NLP) domain has seen important advancements in recent years. Transformer-based contextual word embedding models, such as BERT, have demonstrated significant improvement in NLP performance across a range of tasks. Similarly, the growing scope of data has enabled large language models that support efficient transfer learning. The Bidirectional Encoder Representations for Transformers (BERT) model has demonstrated promise in the clinical domain, but research on the degree of model training and configuration necessary for clinical tasks is in its infancy. This panel will discuss several projects that highlight state-of-the-art training and development of bidirectional language models across clinical and biomedical contexts. The panel will discuss differences between models and vocabularies trained on various specialty texts, including scientific literature and clinical documents. The audience will engage in discussion about opportunities for future model development and privacy concerns when sharing clinical vocabularies and model parameters derived from potentially sensitive data.

Learning Objectives

After participating in this session, the learner should be able to:

- Describe how contextualized word embedding models can improve NLP performance
- Understand and contrast different “pre-training” strategies, and which might be best for clinical texts
- Weigh the trade-offs and benefits of different pooling strategies to derive aggregate representations from BERT-based vectors induced over chunks of input
- Compare and contrast bidirectional transformer models based on the dataset on which they were developed and trained
- Evaluate practical opportunities for transfer learning

Panel Description

Developing meaningful, rich word representations is integral to creating accurate natural language processing (NLP) models. Word embedding approaches, such as Word2Vec, have shown promise in improving NLP performance since their introduction in the early 2010s. These traditional approaches take a context-independent view of text, which limits their ability to capture semantic meanings. Recent advancements have developed large context-dependent word embedding models using large text corpora, such as Bidirectional Encoder Representations from Transformers (BERT), which have demonstrated significant improvements to NLP tasks. Despite the promise of these models, the degree to which generic architectures and weights can be adapted to specific application domains (such as healthcare) is an active area of research.
Since the inception of bidirectional transformers, developers and researchers have created numerous task- and domain-specific models using two approaches: pre-training and fine-tuning. Pre-training “in-domain” entails training a model on domain-specific text (e.g., clinical notes from EHR) to learn to induce contextualized word embeddings. Domain-specific models have demonstrated improved performance, but the training task comes at significant computational cost. In contrast to pre-training, fine-tuning tasks allow researchers to apply transfer learning using existing pre-trained models. In fine-tuning, one typically adds modules (e.g., a single linear layer) on top of an existing architecture to add domain-specific context to the model with significantly less computational cost and a smaller corpus of data than required for pre-training. Understanding the tradeoff of pre-training and fine-tuning that are necessary for domain-specific tasks is an active area of research. Further, many of the pre-trained models have maintained generalized vocabulary, which was created using a non-domain-specific corpus. The degree to which creating new vocabularies for domain-specific models is currently unknown. These areas of research are rich for novel discovery and represent significant opportunities to improve clinical and biomedical NLP tasks.

For this panel, we selected a set of research projects that feature cutting edge use and development of bidirectional transformer models in the clinical and biomedical contexts. The panelists will detail the challenges that they are solving, their approach advancing the state-of-the-art, and key results. The presentations by each panelist will be followed by a moderator-led interactive discussion around developing task-specific architectures, transfer learning, model dissemination, and future work in model development for clinical contexts. The panelists represent different institutions and have diverse background and training.

**Bryan Steitz, PhD** (panelist and organizer) is a postdoctoral research fellow in the Department of Biomedical Informatics at Vanderbilt University Medical Center. Dr. Steitz will present about his work to apply bidirectional transformers to understand clinical workflow tasks. Dr. Steitz’s research interest focuses on using NLP to understand the context of clinical messages to reduce alerts and improve information seeking in the EHR. His work has discovered and classified the content of messages across clinicians and staff treating breast cancer patients. He identified high degree of triage work for clinicians when communicating about logistical issues, which suggests an opportunity to improve message routing.

**Emily Alsentzer** (panelist) is a PhD student in the Health Science and Technology program at Harvard Medical School and MIT. She received a B.S. in computer science and M.S. in biomedical informatics at Stanford University. Her research involves developing NLP and graph neural network methods for healthcare with applications to summarization and rare disease diagnosis. She will discuss her work to develop clinicalBERT, a publicly available BERT model adapted for the clinical domain and outline promising directions and challenges for leveraging clinical language models.

**Hoo Chang Shin, PhD** (panelist) is a senior research scientist in conversational AI at NVIDIA. Dr. Shin is an expert in applying machine learning and deep learning approaches to contextualize unstructured medical data. His work in NLP has focused on understanding the training and transferability considerations of large language models. As a panelist, he will discuss his work on BioMegatron – one of the largest published language models, which was trained on a corpus of general and domain-specific text. He will also discuss the trade-off between model training time and model size.

**Byron C. Wallace, PhD** (panelist) is an Assistant Professor at Northeastern University. Dr. Wallace is an expert in developing NLP methodologies, with a particular interest in model interpretability, trustworthiness of model outputs, and active learning. As a panelist, Dr. Wallace will present about his recent work to understand the privacy implications of training large language models over clinical notes with an emphasis on how to safely distribute these models. He will also discuss trade-offs and takeaways observed in working with BERT-based models to process biomedical literature.

**Adam Wright, PhD** (moderator) is a Professor of Biomedical Informatics at Vanderbilt University Medical Center and the Director of the Vanderbilt Clinical Informatics Center. Dr. Wright is an expert in clinical informatics and has extensive experience applying language models to process clinical documents.
in support of a variety of clinical applications. As the moderator, Dr. Wright will kick off the panel, introduce panelists, and provide a high-level overview of the BERT architecture. He will frame the discussion associate the panelists’ presentations within the current state of BERT language model research. He will also facilitate participatory discussion between the panelists and audience.

**Importance of this panel**

The growing scope of data, coupled with significant advancements in contextual embedding architectures, yields significant promise to the informatics community for improving NLP performance. The AMIA community is a leader in the application and development of NLP to clinical contexts. It is important to share current results and approaches as well as engage in thoughtful discussion about future directions and opportunities to further improve these models. The anticipated audience for this panel will likely cover a broad spectrum of the AMIA community who are building or applying NLP models to clinical and biomedical contexts, including academic and industry researchers, healthcare leadership, and biomedical informatics trainees.

**Discussion Questions**

1. How much data is necessary to retrain from scratch?
2. To what extent does growing model size affect the need for more specific contextual models?
3. To what extent can models trained on data containing patient identifiers be shared? Is there any research that looks into reconstructing clinical text using these models?
4. How can we evaluate large language models in the clinical context?
5. Are there confidentiality issues introduced by sharing large language models?
6. What are the ethical issues related to the use of large language models? (E.g. environmental impacts and bias).

**Statement of Agreement to Participate**

All participants have agreed to attend the 2021 AMIA Annual Symposium and participate in this panel.

**Acknowledgement**

Work presented by Bryan Steitz and Adam Wright was supported by grant 5R01AG062499 from the National Institute of Aging.

Career Development Issues for Women in Biomedical Informatics within Professional Organizations

Donghua Tao, PhD, MA, MS¹, Duo (Helen) Wei, PhD², Rubina F. Rizvi, MD, PhD³, Deepti Pandita MD, FACP, FAMIA¹⁴, Bushra Alghamdi MS, PhD candidate⁵, Polina Kukhareva, PhD, MPH⁶, Margarita Sordo, MSc, PhD, FAMIA⁷, William Hersh, MD, FACMI, FAMIA, FACP⁸, Omolola Ogunyemi, PhD, FACMI ⁹,¹⁰, Kelly Taylor, BS¹¹, Gretchen Purcell Jackson, MD, PhD, FACS, FACMI, FAMIA³,¹²

¹Saint Louis University, St. Louis, MO; ²Stockton University, Galloway, NJ; ³IBM Watson Health, Cambridge, MA; ⁴Hennepin Health Care, Minneapolis, MN; ⁵Case Western Reserve University, School of Medicine, Cleveland, OH; ⁶University of Utah, Salt Lake City, UT; ⁷Brigham and Women’s Hospital, Harvard Medical School, Boston, MA; ⁸Oregon Health & Science University, Portland, OR; ⁹Charles R. Drew University of Medicine and Science; ¹⁰University of California, Los Angeles; ¹¹AMIA, Rockville, MD; ¹²Vanderbilt University Medical Center, Nashville, TN

Abstract

In 2020, the Women in AMIA(WIA) Networking, Mentoring, and Lifecycle Committee administered a survey to: 1) identify resources/needs to help support women in informatics and to connect them to the appropriate resources; and 2) further the opportunities and attract more women into the informatics field. The survey results revealed important career development issues for women and roles of professional organizations in nurturing a culture of diversity and inclusivity, providing professional skills training, building networking and connections, and improving communications within and between organizations and members. After this panel, the audience should be able to:

- Understand the career development challenges and issues for women in the biomedical informatics field.
- Exchange ideas and suggest solutions targeting female professionals in biomedical informatics for supporting their career development.

Panel Description

One of the overarching themes in the 2020-2025 American Medical Informatics Association (AMIA) strategic plan states that “AMIA will harness the diversity inherent in the informatics profession and the initiatives we champion, and will bring it to life within AMIA.”¹¹ Aligned with this perspective, in 2020 the WIA Networking, Mentoring, and Lifecycle Subcommittee administered a survey to current AMIA members, both male and female, in different career stages and work settings, to: 1) identify resources/needs to help support women in informatics and to connect them to the appropriate resources; and 2) further the opportunities and attract more women into the informatics field. The survey results revealed important career development issues for women and roles of professional organizations in cultivating a culture of diversity and inclusivity, providing professional skills training, building networking and connections, improving communications between organizations and members, and across groups within professional organizations. Organized by the same committee, the proposed panel presents the survey findings, and seeks to exchange ideas and suggest solutions targeting female professionals in biomedical informatics for supporting their career development.

Moderator: Deepti Pandita, MD, FACP, FAMIA, is the Chief Health Information Officer at Hennepin Healthcare in Minneapolis, MN. Dr. Pandita is Board Certified in Internal Medicine and Clinical Informatics. She is also Program Director of the Clinical Informatics Fellowship at Hennepin Healthcare. At a national level, Dr. Pandita is active in AMIA Primary care, WAMIA, CICOP and CDS committees and the American College of Physicians (ACP) leading several committees including the ACP Medical Informatics and Telehealth Committee.

Panelist #1: Gretchen Purcell Jackson, MD, PhD, FACS, FACMI, FAMIA, AMIA Board Chair-Elect 2021, IBM Watson Health. Dr. Jackson is Vice President, Chief Health and Science Officer at IBM Watson Health and Associate Professor of Surgery, Pediatrics, and Biomedical Informatics at the Vanderbilt University Medical Center. She is an internationally recognized informatician and accomplished clinical surgeon with over 25 years of...
contributions to informatics research, innovations in health information technologies, and surgical science. Dr. Jackson serves on several journal editorial boards, including Journal of Biomedical Informatics, International Journal of Medical Informatics, and an associate editor of Applied Clinical Informatics and JAMIA Open. Her current research focuses on evaluating clinical decision support systems and empowering patients and families through health information technologies. As the AMIA Board Chair, Dr. Jackson will share her ideas on how a professional organization can support her members’ career development, especially for the female members.

Panelist #2: Omolola Ogunyemi, PhD, FACMI, Director, Center for Biomedical Informatics (CBI), Professor in the Department of Preventive and Social Medicine, Charles R. Drew University of Medicine and Science and co-Chair of the UCLA CTSI’s biomedical informatics program. Dr. Ogunyemi’s research interests include computerized medical decision support, reasoning under uncertainty, 3D graphics and visualization, and machine learning. She has been awarded several NIH grants focusing on informatics solutions for medically underserved communities. Dr. Ogunyemi is an editorial board member of the Journal of Biomedical Informatics. She served as a member of AMIA’s Doctoral Dissertation Award Committee (2017-2020), is an elected Fellow of ACMI and a Member-at-Large of the ACMI Executive Committee. As the current Chair of the WIA Steering Committee, she will share her experience of becoming a leader by collaborating with professionals to contribute to professional organizations.

Panelist #3: William Hersh, MD, FACMI, FAMIA, FACP is Professor and Chair of the Department of Medical Informatics & Clinical Epidemiology in the School of Medicine at Oregon Health & Science University (OHSU). Dr. Hersh is a leader and innovator in biomedical informatics both in education and research. He serves as Director of the OHSU Biomedical Informatics Graduate Program. Dr. Hersh's research focuses on information retrieval and he has authored over 200 scientific papers. Dr. Hersh has won numerous awards for his innovations, including the 2008 AMIA Donald A.B. Lindberg Award for Innovation in Informatics; the Modern Healthcare Top 25 Clinical Informaticists (three times); and the HIMSS Physician Leadership Award. He was elected President of the International Academy of Health Sciences Informatics in 2020. As a senior informatics expert, Dr. Hersh will discuss the presented topics from a male’s perspective, including as a department chair mentoring junior women faculty in their career development.

Panelist #4: Kelly Taylor, Program Manager, Member Services and Engagement, AMIA. Ms. Taylor manages the AMIA Connect platform and she is the membership department’s liaison to all working groups, the WIA steering committee and subcommittees. She manages AMIA’s First Look Program. Ms. Taylor will share her experience in communications within and among professional organizations.

The panel will cover the following topics:
1. Cultivating a culture of Diversity, Equity & Inclusion (DE&I). DE&I related efforts have a long history in the USA. This important topic has gained much more spark and attention in the year 2020, not only in the US but also worldwide. The existing gaps in DE&I efforts and suboptimal outcomes have spanned across various disciplines and professions, and the field of informatics is not an exception. Upholding DE&I core values, AMIA with more than 5000 members from diverse backgrounds has been striving and taking actions to help alleviate the existing gaps in this important area. The panel will discuss how the informatics community, especially a professional organization such as AMIA can foster and nurture a culture of DE&I by advising and guiding, and help executing strategic goals and objectives centered around DE&I activities.
2. Professional development to improve professional qualities and interpersonal skills. The survey results showed that communication, critical thinking, leadership and interpersonal skills are four top skills for career development, especially for female informaticists. Although both female leadership and recognition have been improving in general, a recent publication on gender representation in U.S. biomedical informatics leadership and recognition found that “as in other STEM fields, leadership and recognition in biomedical informatics is lower for women.” These findings inform data-driven strategies to foster diversity and inclusion. The panelists will discuss possibilities for various professional development formats, including providing a second term of WIA Leadership Program, workshops or regular webinars in professional skills trainings and so on.
3. Networking and connection building. Engaging in networking behavior is considered an important career management strategy. Majority of jobs are filled through networking, which means this activity ultimately
benefits us in the long term. However, such study indicates that women’s networks are less powerful than men’s and women are less able to utilize the networks they have due to various reasons, e.g. lack of confidence, missing out on networking opportunities due to childcare responsibilities. For women in informatics, it is crucial to discuss how to build and strategically maintain a network in the biomedical informatics career settings.

4. Effective communications and active publicity from professional organizations. In an era of excessive marketing and consumer avoidance, no other topic could be more interesting than engagement. The value of publicity is dependent on the outcome it produces through different types of media channels. The survey distributed by the committee found that about 50% of respondents never heard of or participated in events organized by the committee. This is a dilemma faced by many non-for-profit organizations, and a strategy to incorporate members' consistent feedback and increase their involvement is compelling to the success of activity publicity in a professional organization. The panel will discuss channels and strategies enhance the communications within and across organizations and groups.

**Significance of the Topic and Anticipated Audience**

The topic of this panel is timely, urgent, needed, or attention-grabbing given the need to:

- Develop a better understanding of career development issues at different stages of women’s lives and careers in biomedical informatics.
- Identify concerns, and develop programs and solutions to provide a supporting culture and environment to foster the career advancement of health informatics professionals, especially women.

This session will be of interest to biomedical informatics professionals at any career stages, especially women, who are interested in learning and preparing for career development issues they may encounter. In addition, professional organizations, such as AMIA, working with their members as a community, may develop policies and programs to provide additional supports to execute strategic plans and fulfill the needs of their members.

**Expected Discussions**

After introductory presentations, the moderator will ask questions and solicit questions from the audience to prompt discussions among the panelists. Potential questions include:

- What resources are currently available to female informaticians that our audience may not be aware of?
- How can we bridge the gap between the resource availability and unawareness or inaccessibility?
- What is a path forward to create Equity and Inclusiveness for women in Informatics, especially addressing current gaps around the representation of women of color?
- What can be done in general to promote career development for women in the informatics field?

**Participation Statement**

All proposed panelists and the moderator are aware of this panel submission, and have agreed to participate in the panel if the proposal is accepted (as of 3/10/2021).

Public Health Informatics in a Global Pandemic: In the COVID response trenches

Jessica D. Tenenbaum, PhD1,2, Theresa R. Cullen, MD3,8, Neil Sarkar, PhD, MLIS4,5, Philip R.O. Payne, PhD6, Brian E. Dixon, PhD7,8

1Duke University, Durham, NC; 2North Carolina Department of Health and Human Services; 3Pima County Department of Public Health; 4Rhode Island Quality Institute, Providence RI; 5Brown University, Providence, RI; 6Washington University in St. Louis School of Medicine; 7Indiana University Fairbanks School of Public Health, Indianapolis, IN; 8Regenstrief Institute, Indianapolis, IN

Abstract

The COVID-19 pandemic unfolded rapidly around the globe over the course of 2020 - 2021. As the pandemic has progressed, public health agencies and healthcare provider organizations (HPOs) have sought to gather, manage, analyze, and share data and information to track disease spread, establish response plans, and keep the public informed. These responses require informatics methods and tools, such as data integration and harmonization, analytical modeling, data visualization, and a variety of decision support modalities. However, many stakeholders struggled to respond due to inefficiencies, antiquated infrastructure, and poor communications systems. In this panel we will discuss public health informatics related to COVID-19 from different vantage points: state government, regional health information exchange, county government, and HPO partnerships with local and state officials. We will discuss lessons learned, best practices, and what the world and the field should be investing in now to make sure we’re better prepared for the next public health emergency, global or otherwise.

Introduction

Public health informatics, one of the major branches of the field of biomedical informatics, is a discipline in which methodologies are developed and systematically applied to leverage digital health data to support public health practice, research, and learning. Informatics leaders in public health organizations and HPOs that are engaged in public or population health initiatives support policy decision-making with data and information on community health and well-being, including non-medical data on social and environmental determinants. Informatics professionals in public health organizations and HPOs leverage information systems to support the development, implementation, and evaluation of population level interventions that aim to improve the health and well-being of communities. In the context of a pandemic like COVID-19, these interventions include widespread testing, case investigation, contact tracing, exposure notification, isolation support services, hospital capacity planning, and most recently, vaccination campaigns.

Topic importance and timeliness

Beginning in 2020, and continuing into 2021, the COVID-19 pandemic challenged public health systems and HPOs around the world. Data and information were critical to public health organizations’ and HPO’s efforts at tracking disease spread (e.g., screening for new cases), deploying public health workers and care providers to affected areas, and implementing policies (e.g., lockdowns, social distancing, masking). Yet many public health organizations struggled to effectively and efficiently capture, store, manage, analyze, and use data and information when tracking COVID-19 and responding to its presence. HPOs engaged in public and population health initiatives in response to COVID-19 have experienced analogous challenges. These public health informatics struggles, successes, and lessons learned from COVID-19 are important to highlight during the 2021 AMIA Annual Symposium. The pandemic has served to shine a spotlight on the historic underinvestment and consequential shortcomings of public health informatics infrastructure nationally, as well as clinical informatics capabilities needed to deliver and coordinate care across and between traditional organizational boundaries. This has resulted in the renewed recognition of need for increased investment in public health digital infrastructure, the important synergies between public health organizations and HPOs, and the need for infrastructure that can support or enable such data-driven collaboration. Examination and discussion of the challenges and opportunities faced will help guide allocation of newfound resources in this space coming from a number of local, state, federal, and private initiatives.

In contrast with other sessions on the 2021 agenda that may highlight innovations and lessons from the perspective of clinical organizations in their efforts to effectively treat individuals severely impacted by the SARS-CoV-2 virus, this panel will provide knowledge and lessons from the public health perspective.
Speakers:

**Dr. Brian E. Dixon – IU Fairbanks School of Public Health and Regenstrief Institute - Moderator**

Dr. Dixon’s research focuses on applying informatics methods and tools to improve population health in clinical as well as public health organizations. His work leverages clinical and administrative data in electronic health records to measure population health, better understand the determinants of health, examine information flow in the health system, and improve outcomes in individuals and populations. In 2020, Dr. Dixon led a team of informaticians, data analysts, and computer scientists to create an interactive, statewide dashboard on COVID-19 cases, hospitalizations, and mortality for the State of Indiana. The dashboard was used by state and local public health leaders to identify trends, examine sub-populations (especially minority populations), and plan strategies for testing as well as vaccination. Last year he also published the 3rd Edition of the *Public Health Informatics and Information Systems* book in the Springer International Health Informatics series.

Dr. Dixon will introduce the topic of the panel and the panelists. He will then moderate audience questions and discussion after the panelists each present a brief summary of their work during the pandemic.

**Dr. Jessica D. Tenenbaum- NC DHHS; Duke University**

Dr. Tenenbaum has served as Chief Data Officer for North Carolina’s Department of Health and Human Services since 2019 when the NCDHHS Data Office was created. She is also an Assistant Professor of Translational Biomedical Informatics at Duke University. Under Dr. Tenenbaum’s leadership, the NCDHHS Data Office focuses on data democratization, governance, and quality improvement, infrastructure modernization, and analytic innovation. The intent is to facilitate data-driven policy and a “learning DHHS” analogous to the Learning Health System.

In this panel, Dr. Tenenbaum will describe numerous data challenges that COVID-19 has posed for NC DHHS where existing systems were not built to handle the types and volumes of data needs that have arisen in the COVID-19 context. She will describe the early days of the pandemic, where testing volumes were gathered via email. She will also describe the transition of collecting data regarding hospital surge capacity from a process involving manual surveys and pivot charts in Excel to automated HL7 feeds imported into a cloud-based data warehouse, which then feed a public-facing Tableau dashboard. She will describe North Carolina’s ever-expanding public facing COVID-19 data dashboard, including emphasis on downloadable data and demographic stratification. She will highlight both victories and limitations of efforts to better integrate clinical data from NC HealthConnex, North Carolina’s Health Information Exchange (HIE) with public health surveillance data, and of predictive modeling to anticipate demand on hospital capacity. Finally, Dr. Tenenbaum will highlight how data visualization helped inform on-the-ground tactics to improve equity in the push to vaccinate, ensuring allocation and administration of vaccines to portions of the population that have been hardest hit by this cruel pandemic.

**Dr. Neil Sarkar- Rhode Island Quality Institute (RIQI) and Brown University**

Dr. Sarkar is the President and Chief Executive Officer of the Rhode Island Quality Institute (RIQI), which serves as Rhode Island’s Regional Health Information Organization. He is also an Associate Professor of Medical Science and Associate Professor of Health Services, Policy & Practice at Brown University. Prior to his current role at RIQI, he was the founding director of the Brown Center for Biomedical Informatics. Dr. Sarkar’s work is focused on the development of a systemic framework that bridges digital health data to support patients, providers, and payers in achieving the vision of a continuously learning health system.

Dr. Sarkar will share his perspective as a Regional Health Information Organization (RHIO) in supporting both public health and provider community needs. He will describe a RHIO’s role from the early days of the COVID-19 pandemic, and how informatics approaches were developed in near real-time to address myriad information needs, including access to SARS-CoV-2 test results done across multiple laboratory sites and rapid point of care testing, working with community organizations to identify barriers to testing in underserved and high-risk populations in Rhode Island, modeling of health data to support targeted vaccination efforts, developing and implementing approaches to identify putative adverse events in high risk populations that were not included in vaccine clinical trials, and supporting the monitoring of short-term and long-term health impacts of COVID-19 and vaccination. A unifying theme in Dr. Sarkar’s presentation will be an exposition of informatics approaches that can be used to support the pragmatic design and development of sustainable infrastructure for supporting public health needs, which extend beyond pandemic response.

**Dr. Philip Payne, Washington University in St. Louis School of Medicine**

Dr. Payne is the Associate Dean for Health Information and Data Science and Chief Data Scientist at the Washington University School of Medicine. In addition, he is the Janet and Bernard Becker Professor and founding Director of the school’s Institute for Informatics (I2). Dr. Payne is the author of over 200 publications. His current research portfolio focuses on: 1) machine
learning and cognitive computing approaches to the discovery and analysis of bio-molecular and clinical phenotypes; 2) interventional approaches to the use of electronic health records and clinical decision support systems; and 3) the design and evaluation of open-science platforms that enable collaborative and cumulative approaches to scientific discovery.

Since March of 2020, Dr. Payne has led the joint COVID-19 analytics workgroup convened by Washington University and its partners at BJC Healthcare. This workgroup has served to not only support the operational needs of Washington University Physicians and BJC Healthcare in meeting the challenges posed by COVID-19, but has also served as the primary data, information, and knowledge “engine” for the St. Louis Metropolitan Pandemic Task Force, a coalition of elected officials, public health organizations, and HPOs that collectively serve the 3.4M citizens of the St. Louis MSA. Via this unique and collaborative structure, Dr. Payne’s team has rapidly implemented and supported: 1) a regional data sharing network that enables hospital capacity planning and epidemiological surveillance of COVID-19 cases; 2) comprehensive case management, contact tracing, and exposure notification solutions that have facilitated the monitoring and containment activities of five different public health organizations serving the region as well as major employers and universities; 3) data management and reporting platforms that allow for the delivery of an inexpensive and rapid-cycle saliva-based COVID-19 testing assay developed by Washington University for use by multiple regional partners; and 4) pre-registration, tracking, and scheduling technologies that support public vaccination campaigns spanning high-throughput HPOs and public health organizations. In all of the aforementioned cases, the work of Dr. Payne’s team has served to demonstrate the unique opportunities afforded by substantive partnerships between HPOs and public health organizations to offset infrastructure issues and ultimately respond to the public health needs of the region, thus identifying new opportunities to build a public health informatics “fabric” that can both scale and be sustained in the long-term.

Dr. Theresa Cullen- Pima County AZ Department of Public Health; Regenstrief Institute

Dr. Cullen is currently the Public Health Director at Pima County, Arizona, a county of over 1 million people that encompasses urban and rural communities as well as two American Indian reservations. In this role, she has overseen the Pima County COVID-19 response, including testing, case investigation, contact tracing and the accelerated immunization plan. Pima County surpassed over 120K cases of COVID 19 in the first 12 months of the pandemic, and also delivered over 300K immunizations in January and February 2021.

Dr. Cullen will talk about the epidemiological cascade and data needs from a County perspective. In addition, she will share insights about the vaccine delivery system, and the impact of limited public health infrastructure on health equity at a county level. Pima County is committed to health justice and equity, and successfully supported novel technologies as well as interventions to accelerate a healthy community during the COVID epidemic. However, there continue to be multiple public health informatics opportunities that will need to be addressed in the future, including the need for rapid reconciliation of patient identification, near real time longitudinal sharing of infectious disease test results and demographics with local as well as state based public health agencies for early sentinel awareness as well as intervention, the minimum data set for rapid registration and longitudinal tracking at mobile vaccination sites, and ongoing efforts to achieve equity throughout the epidemiological, therapeutic and immunization cascade.

Questions to be addressed:

- What were the major obstacles in the COVID-19 pandemic response from a data/informatics perspective?
- What data/informatics lessons were learned by public health agencies and collaborating HPOs as their response efforts unfolded?
- What were the greatest successes or opportunities for innovation and impact?
- What technological/infrastructure/data challenges remain to be addressed post-pandemic?
- What unique cross-sector partnerships are needed to address these technological/infrastructure/data challenges moving forward?

Conclusion

This collection of panelists represents a diverse set of perspectives and approaches to this timely topic. The topic could not be timelier and addresses the public health end of the informatics spectrum that has been top of mind throughout the pandemic, not only for our field but for the world.
Leveraging PGHD in Clinical Workflows: Opportunities and Challenges for Use in Patient Care

Victoria L Tiase PhD, RN-BC, FAAN, FAMIA1,2; Robin R Austin PhD, DNP, DC, RN-BC, FAMIA3; Christie L Martin MN, MPH, RN, PHN, LHIT-HP3; Young Ji Lee PhD, RN4;

1Department of Information Technology, New York-Presbyterian Hospital, New York, NY; 2College of Nursing, University of Utah, Salt Lake City, UT; 3School of Nursing, University of Minnesota, Minneapolis, MN; 4University of Pittsburgh, Pittsburgh, PA

Abstract
Given the emphasis on digital health solutions and the increasing number of mobile health applications, patient-generated health data (PGHD) are abundant. However, without the availability of PGHD at the point of care, some of their utility may be lost. If presented to clinicians at the point of care, PGHD have the potential to improve patient outcomes by providing new insights into the patient’s longitudinal status and decreasing nursing documentation burden. This interactive panel of nursing informatics leaders will discuss key findings from several studies aimed at leveraging PGHD within clinical workflows. Session participants will have the opportunity to discuss successes and challenges, suggest a road map for additional research, and envision PGHD use cases across the continuum of care.

General Description
Patient generated health data (PGHD) are data created, recorded, or gathered by or from patients (or family members or other caregivers) using smartphones, sensors, or other medical devices.1 PGHD can be incorporated into clinical practice at the point of care and may facilitate communication between clinicians and patients. Longitudinal data, for example, provide insights into patients’ health behaviors and outcomes. In tandem with their patients, clinicians are well suited to interpret these data and find patient-centered solutions to improve overall health and well-being. Specifically, using their assessment skills, nurses are instrumental in advancing care practices that utilize PGHD.

Although PGHD can provide value to the patient’s overall health status, there are very few examples of their use within the clinical setting. In 2019, a systematic review explored the impact of PGHD in clinical settings and found just 21 studies, including limited integration of PGHD into electronic records.2 A scoping review, published in 2020, reported only 19 studies that described the characteristics of PGHD integration to electronic health records (EHRs) and found that efforts are needed to optimize the incorporation of PGHD into clinical workflows.3 Furthermore, there is concern that adding more information to an EHR that contains a large amount of outdated regulatory requirements may contribute to provider burnout.4 Additional concerns surrounding the use of PGHD in clinical practice include time to review data, scope of practice, liability for data that is received, and appropriate interpretation and clinical action based on the data. PGHD may potentially be lost, excluded, or hidden due to a lack of standards and are often incorporated in the EHR as unstructured data.

Incorporating PGHD into workflows, both technically and operationally will require careful consideration of information needs that support clinical decision making. Data standards, including standardized terminologies (i.e., SNOMED CT and others), can provide structure to the data facilitating interoperability, thereby enabling patients to share their voice within the EHR. This interactive panel includes a variety of PGHD integration topics based on the panel participants’ collective work. The panel aims to engage a wide variety of participants (clinicians, researchers, CMIOs, CNIOs, etc.). Panelists will discuss approaches to the design and implementation of mobile health applications as well as care interventions that encourage the collection, use, and sharing of PGHD.
Discussion Topics

Panel members will present their recent findings, personal perspectives, institutional experience, and plans to engage audience members in a robust discussion to elicit participants’ opinions, experiences, and practices with PGHD use.

The following topics will be addressed:

• The role of the nurse in supporting patients and families with their PGHD ○ Highlighting novel COVID-19 use cases
• The impact of PGHD on patient outcomes ○ Including opportunities for new care models and community outreach
• Interoperability and standards for PGHD ○ Research related to visualization and summarization
• Types of PGHD that may be of interest to clinicians ○ Examples using pain scale data, environmental data, social media

Along with eliciting questions from the audience, we will use the following questions to guide the discussion:

1. What challenges have you experienced integrating PGHD into clinical practice?
2. Describe successful PGHD use cases that you have found to be beneficial?
3. What specific types of PGHD are best suited to be shared by patients (families) and clinicians?
4. What areas of PGHD research require further exploration?

Panel Members

Victoria L Tiase, PhD, RN-BC, FAAN, FAMIA is a nurse, informatician, and Director of Research Science at NewYork-Presbyterian Hospital. She supports a range of clinical information technology projects related to patient engagement and is passionate about the integration of patient generated health data into clinical workflows. She serves on the steering committee for the Alliance for Nursing Informatics and is a board member of AMIA, NODE.Enh, and the CARIN Alliance. Recently, she was appointed to the National Academy of Medicine Committee on the Future of Nursing 2030. In addition, Dr. Tiase is an Assistant Professor in the Division of Health Informatics at Weill Cornell Medicine. She completed her BSN at the University of Virginia, MSN at Columbia University, and PhD from the University of Utah with a focus on the integration of PGHD into clinical workflows to impact care and reduce documentation burden. Dr. Tiase, also serving as moderator, will present her work on provider preferences for the graphical display of pediatric-asthma PGHD to support decisions and information needs in the outpatient setting. She will also discuss the need for future research that examines the interactive nature of PGHD and EHR data.

Robin R Austin, PhD, DNP, DC, RN-BC, FAMIA is an Assistant Professor at the University of Minnesota, School of Nursing. Dr. Austin has over 20 years of clinical healthcare experience and has translated this experience to focus on patient-centered research. Dr. Austin has earned a Doctorate in Nursing Practice (DNP) and PhD in Nursing, both specializing in Nursing Informatics. Dr. Austin integrates her clinical background with informatics methods to represent the patients’ perspectives across the healthcare continuum. Through her research, Dr. Austin seeks to empower individuals through the use of technology and include their voice in person-centered care. Dr. Austin will present her research examining PGHD from a web-based application, entitled MyStrengths+MyHealth, from a virtual community outreach initiative examining individual and community strengths, challenges, and needs during COVID-19.

Christie L Martin, MN, MPH, RN, PHN, LHIT-HP is a medical-surgical nurse at Abbott Northwestern Hospital in Minneapolis and a Research Assistant for the Child and Family Health Co-
Operative Unit at the University of Minnesota, School of Nursing. Ms. Martin is a doctoral candidate at the University of Minnesota School of Nursing. Her research focuses on child and adolescent health promotion and informatics with an emphasis in behavior change and mobile health technologies. She completed a Master of Nursing and a certificate in Leadership in Health Information Technology for Health Professionals from the University of Minnesota, School of Nursing and has a Master of Public Health from the University of Minnesota, School of Public Health. Ms. Martin is the outgoing co-chair of the Nursing Knowledge Big Data Science mHealth for Nursing working group and the VP of Membership of the AMIA Consumer and Pervasive Health Informatics Working Group. **Ms. Martin will present findings of a systematic review investigating the efficacy and components of pain-related mHealth apps and speak specifically to the sharing of PGHD between consumers and providers of eligible studies.**

**Young Ji Lee PhD, RN,** is an Assistant Professor at the University of Pittsburgh School of Nursing and Department of Biomedical Informatics. Dr. Lee has focused on structuring and delivering health information through an informatics-based approach for diverse groups and underserved populations. She has completed several projects on PGHD collected from online cancer forums to understand the unmet needs of cancer patients and caregivers. Currently, Dr. Lee is a PI of the NIH-funded study to build and implement a personalized information access system with a hybrid recommender engine that adapts to different patient needs: HELPeR—Health E-Librarian with Personalized Recommendations. Currently, she is serving on the program committee for the AMIA 2021 Informatics Summit and AMIA 2021 Clinical Informatics Conference. Dr. Lee was elected as a member-at-large of the AMIA Nursing Informatics Working Group. She is also a member of the ANI Emerging Leaders Program which aims to understand facilitators and barriers of PGHD implementation in clinical settings. **Dr. Lee will discuss nurses’ perceived challenges of PGHD implementation in the clinical settings. She will also present how researchers and clinicians can utilize PGHD collected from social media to understand patients’ needs and perspectives.**

Lessons in Health Equity from the CMS AI Health Outcomes Challenge

David K. Vawdrey PhD, FACMI¹, Dave DeCaprio², Carol McCall FSA, MPH³, Yaron Kinar PhD³, Aneesh Chopra, MPP⁴

¹Steele Institute for Health Innovation, Geisinger, Danville, PA
²Closedloop.ai, Austin, TX
³Medial Earlysign, Tel Aviv, Israel
⁴CareJourney, Arlington, VA

Abstract

In April 2021, CMS announced the winner and runner-up of the CMS Artificial Intelligence Health Outcomes Challenge, the largest-ever prize competition for innovators to demonstrate how AI solutions can predict patient health events. The two-year competition was described as “an exciting example of how public/private partnerships can drive innovation.” This panel will explore how the winner and runner-up in the AI Challenge approached health equity by measuring and mitigating algorithmic bias. The panelists will discuss the current and future state of algorithmic bias in applications using healthcare claims data, debating topics such as: 1) how to effectively identify the sources of bias in AI algorithms—including data quality and representativeness, 2) the difference between bias and fairness, 3) the value of scoring systems for quantifying bias, and 4) practical implications of applying predictive models in healthcare compared to other settings. Ample time will be provided for audience questions and discussion.

General Description

The CMS Artificial Intelligence Health Outcomes Challenge launched in 2019 with more than 300 entrants representing the world’s leading technology, healthcare, and pharmaceutical innovators. Entrants competed to create explainable AI solutions that clinicians could trust to predict health outcomes, target scarce resources, and keep their patients healthy. Sponsored by CMS’s Center for Medicare and Medicaid Innovation (CMS Innovation Center) in collaboration with the American Academy of Family Physicians and Arnold Ventures, the AI Challenge was designed to accelerate development of AI solutions for predicting patient health outcomes for Medicare beneficiaries for potential use by the Innovation Center. With prizes totaling $1.6M, the AI Challenge is the largest healthcare AI competition to date. The winner, announced in April 2021, was ClosedLoop.ai (Austin, TX), with Geisinger (Danville, PA) in partnership with Medial Earlysign (Tel Aviv, Israel) as runner-up.

Health equity was at the heart of CMS AI Challenge. In addition to industry-standard measures of algorithmic accuracy (e.g., area under the ROC curve, calibration, and precision) and data visualization (to explain predictive models’ output to clinicians and patients in an understandable, useful, and trustworthy way), the AI Challenge judged finalists on their ability to address the issue of implicit algorithmic bias in their submissions. ClosedLoop.ai and Geisinger/Medial Earlysign proposed creative approaches to mitigating potential bias.

This panel will educate healthcare providers and informatics professionals about the challenges associated with algorithmic bias in predictive models based on healthcare claims data. The panel participants represent the winner and runner-up in the CMS AI Challenge, and they have extensive experience developing and implementing health information technology in a just and equitable manner. Panelists will synthesize their perspectives on the biomedical literature and future developments in this area. They will explore the following discussion topics and engage in stimulating dialog based on questions from the audience.

Discussion Topics

How to effectively identify the sources of bias in AI algorithms

Representativeness and data quality are two issues to consider in terms of their impact on algorithmic bias. When discussing representativeness, a question that algorithm implementers may ask is, “To what extent did the data used to train the algorithm come from a population that is representative of the intended recipients?” In the CMS AI Challenge, through a data use agreement, teams were provided with a 5% sample of the CMS Limited Data Set (LDS) Files, containing beneficiary level health information (such as claims) stripped of specified direct identifiers [1]. The Table compares age, race/ethnicity, and sex from the CMS LDS sample with data from the entire

160
U.S. population obtained from the U.S. Census Bureau. Beneficiaries in the LDS data are much older on average than the U.S. population, include more females, and considerably underrepresent racial and ethnic minorities.

Even if a training data set is “representative” of the intended delivery population, data quality remains an issue. Polubriaginof and colleagues reported that among the 160 million combined patients from two large observational health data sets (one public and one private), race or ethnicity was unknown for 25% [2]. In the CMS Limited Data Set, for example, race and ethnicity are conflated into one construct; “Two or more races” is not an option, and options for Sex are limited to “Female” or “Male.” Other important social determinants of health (e.g., primary language, education attainment, household income, veteran status, sexual orientation) are often completely missing, especially in data sets with healthcare claims.

**Bias vs. fairness**

AI platforms should systematically assess for bias in model design, data, and sampling, and they should use measures such as Michael’s Correlation Coefficient that are insensitive to differences in disease prevalence between groups. Additionally, it’s important to understand the concept of fairness in relation to bias. Assessing fairness can involve questions such as, “to what extent does the output of the algorithm differ for various groups in a manner that is not clinically justifiable and/or is ethically tenuous?” [3].

In the AI Challenge, ClosedLoop.ai developed a new metric for measuring fairness called Group Benefit Equality (GBE). Standard fairness metrics (e.g., Disparate Impact) are not well suited to healthcare situations. They ignore false-negative errors, which can leave individuals who would benefit from an intervention unable to get it, or they use arbitrary benchmark thresholds that fail to adjust for instances where the alarm rate for the reference group is too low. The GBE metric addresses these shortcomings. It is also easily explained, has transparent procedures, and uses clearly defined thresholds to assess when models are biased [4]. The Geisinger/Earlysign team applied the simple fairness criterion suggested by Hardt et al. [5] which helps evaluate the equality of opportunities for various subgroups. It is important to understand the root cause of algorithmic bias, which may arise from inherent differences between subgroups in demographic characteristics (e.g., age or sex distribution). Unfortunately, mitigation strategies often involve a tradeoff between fairness and model performance—which should lead to a lively discussion amongst panelists and audience members.

**The value of “scoring systems” for quantifying bias**

The underlying data used to train many healthcare AI models—including the CMS data using in the AI Challenge—reflects historical biases and inequities in access and utilization. The increasing reliance on algorithms to do things like target interventions, reward performance, and distribute resources has put the notion of quantifying algorithmic bias and fairness in the spotlight. This is particularly important in settings where AI models could be used to help prioritize the allocation of limited resources—for example, to decide which Medicare beneficiaries a care manager should reach out to, based on the beneficiaries’ algorithmically-determined risk of an unplanned hospital admission.

Models that systematically underpredict risk for a particular group can lead to that group being unfairly denied resources. For example, the recent Algorithmic Bias Playbook developed by Obermeyer and colleagues based on their previous work [6,7] describes how algorithm implementers should be cautious of conflating healthcare costs (i.e., utilization) with healthcare needs. Even though cost and health needs are correlated, two patients with the same level of need might have considerably different costs if one receives less care. The authors poset that we should not necessarily blame algorithms when their predictions “reinforce and perpetuate systemic racism,” for example, when an algorithm that was trained to predict healthcare costs (which are historically higher for white vs. Black Americans) is improperly applied to as a proxy for healthcare needs (and Black individuals receive less care as a result). Such findings must be considered when evaluating predictive models for bias based on race, ethnicity, sex, age, disability status, and other characteristics.

[1] The value of “scoring systems” for quantifying bias. The underlying data used to train many healthcare AI models—including the CMS data using in the AI Challenge—reflects historical biases and inequities in access and utilization. The increasing reliance on algorithms to do things like target interventions, reward performance, and distribute resources has put the notion of quantifying algorithmic bias and fairness in the spotlight. This is particularly important in settings where AI models could be used to help prioritize the allocation of limited resources—for example, to decide which Medicare beneficiaries a care manager should reach out to, based on the beneficiaries’ algorithmically-determined risk of an unplanned hospital admission.

Models that systematically underpredict risk for a particular group can lead to that group being unfairly denied resources. For example, the recent Algorithmic Bias Playbook developed by Obermeyer and colleagues based on their previous work [6,7] describes how algorithm implementers should be cautious of conflating healthcare costs (i.e., utilization) with healthcare needs. Even though cost and health needs are correlated, two patients with the same level of need might have considerably different costs if one receives less care. The authors poset that we should not necessarily blame algorithms when their predictions “reinforce and perpetuate systemic racism,” for example, when an algorithm that was trained to predict healthcare costs (which are historically higher for white vs. Black Americans) is improperly applied to as a proxy for healthcare needs (and Black individuals receive less care as a result). Such findings must be considered when evaluating predictive models for bias based on race, ethnicity, sex, age, disability status, and other characteristics.
Practical implications of applying predictive models in healthcare compared to other settings

One well-known application of predictive algorithms outside of healthcare is the Netflix Recommender System [8]. Similar systems exist to connect individuals (e.g., via Facebook or LinkedIn), to target advertising, or to suggest products to prospective buyers. Predictive models in healthcare may have much in common with these applications, but there are also important differences. As Halamka and Cerrato recently explained, when Netflix “recommends a new movie on the basis of a person’s previous movie choices, the viewer may find the suggestion helpful, annoying, or even amusing — but not life-threatening. When algorithms are used to assist in the diagnosis of eye disease, melanoma, or sepsis, the stakes are obviously much higher because misleading advice can have far more serious consequences” [9].

Besides the life-threatening stakes that exist in healthcare versus other industries, implementing predictive models in the healthcare setting is complicated by ethical questions related to beneficence, by the rapidly evolving regulatory environment and by questions involving healthcare payment models. One idea that touches on these topics is Eaneff and colleagues’ proposal that healthcare organizations adopt Algorithmic Stewardship for AI and machine learning technologies [10].

Panel Members  (All members have agreed to participate on the panel)

David K. Vawdrey, PhD, FACMI is Chief Data & Informatics Officer for Geisinger. His research interests include using health information technology to improve value, patient engagement, and safety.

Dave DeCaprio is Chief Technology Officer and co-founder at ClosedLoop.ai. He has two decades of experience in healthcare and life sciences AI and led the ClosedLoop.ai team in the CMS AI Challenge.

Carol McCall FSA, MPH is Chief Health Analytics Officer at ClosedLoop.ai. She is a health actuary and population health executive whose specialty is combining analytics, health service innovations, and business models in ways that catalyze value-based healthcare.

Yaron Kinar, PhD is Chief Scientific Officer at Medial EarlySign, and he co-led the Geisinger/Medial EarlySign data science team in the CMS AI Challenge. He has 20 years of experience in AI/ML in health-related domains.

Aneesh Chopra, MPP will moderate the panel. He is President of CareJourney, an open data service that helps providers, payers and pharma market leaders make smarter decisions in the move to value. He served as the first U.S. Chief Technology Officer (2009-12) where he spearheaded efforts to make CMS data available for commercial use.

Opportunities and Challenges in Health and Clinical Informatics Careers and the Future of the Profession

Sponsored by the Continuing Professional Development Committee and Physicians in AMIA

Amy Y. Wang, MD, MBI1, Jodi Kodish-Wachs, MD2, Deepti Pandita, MD3, Thomas Agresta, MD, MBI4, Catherine H. Ivory, PhD, RN-BC, RNC-OB, NEA-BC5
1University of Alabama at Birmingham, Birmingham, AL; 2Vizient, Chicago, IL; 3Hennepin Healthcare, Minneapolis, MN; 4University of Connecticut, Farmington, CT; 5Vanderbilt University, Nashville, TN

Abstract

Health professionals who practice health informatics (HI) and clinical informatics (CI) are a core constituency in the AMIA community. This diverse group represents medicine, nursing, dentistry, pharmacy, public health, and other health disciplines. There are new developments, opportunities, and challenges as HI and CI evolves, including training, certification, continuing professional development, career paths and stages, and diversity, equity, and inclusion (DEI). In this interactive panel, HI and CI professionals representing diverse fields and stakeholder groups will discuss topics that are current and relevant to the HI and CI community. This panel is co-sponsored by the Continuing Professional Development Committee (CPD, formerly MOC Committee) and Physicians in AMIA (PINA, formerly CICOP) and supports AMIA’s strategic directive of promoting and building the field of informatics.

Learning Objectives

1. Discuss the current landscape and new developments in health and clinical informatics careers, including core content, competencies, training, certification, and continuing professional development (CPD).
2. Discuss current and future challenges and opportunities in health and clinical informatics careers and certification, including promoting diversity, equity, and inclusion (DEI).
3. Evaluate and plan various career paths and opportunities for learning, training, certification, and practice.

Introduction

Healthcare professionals in health informatics (HI) and clinical informatics (CI) apply informatics principles to improve health outcomes through the use of health information. While HI and CI may differ, there is significant overlap. CI refers to the field in which physicians become certified by a member board of the American Board of Medical Specialties (ABMS), while HI refers to the field in which health professionals become certified through AMIA’s Advanced Health Informatics Certification (AHIC). Excluding certification, for practical purposes, HI and CI are often grouped together and even used interchangeably. We advocate considering these fields together when possible, given the similarities and the benefits of a united community.

In response to the rapid growth of HI and CI and the need for specialists in the field, AMIA community has defined the CI specialty, core content, and training programs1-3. Initial efforts focused on board-certified physicians and have expanded to other eligible health professionals4-5. There has been ongoing research and discussion about the scope of practice, workforce, training programs, and board certification6-8. Given the wide scope of informatics practice in healthcare and diverse backgrounds of professionals entering the field, training and career paths ideally are individualized rather than uniform. Career paths may include varying combinations of leadership, administration, management, operations, quality improvement, teaching, research, software design, and information management within various settings (e.g., academic, community, industry, government).

Our aim is to present updates and opportunities and challenges in the HI and CI profession. Panelists represent diverse perspectives and will introduce topics and facilitate an interactive discussion. Topics and questions include:

1. **Impact of COVID-19.** (Deepti Pandit) How has COVID-19 and remote working impacted the field? How have training programs been affected? How did numbers and enrollment change? Did training become remote, and
what was the impact? Did trainees need to cross-cover other areas? Was education shortened with competing interests or expanded? How did certification numbers change? Were there unexpected effects?

2. **ABPM certification update.** (Thomas Agresta) What is the latest news from the ABPM, ABPath, and ACGME? How does one get certified? What changes have there been to eligibility for certification? Will the practice pathway be extended beyond 2023? What is longitudinal assessment, what do I need to know about it, and how do I get started? Will that change be permanent, meaning could there be no more high-stakes exams?

3. **Advanced Health Informatics Certification (AHIC) and Nursing Update.** (Catherine Ivory) What is AHIC? Who needs AHIC, and why? What does AHIC offer compared with CI certification? How and when can I qualify, apply, and prepare for the board exam? What certification do you recommend for nursing informatics?

4. **CI Training and certification.** (Deepti Pandita) Is board certification in CI necessary? Why and when? Physicians typically complete fellowships early in their careers, before entering practice. Will hiring organizations require board certification? If so, will aspiring mid-career health physicians be willing to leave established practices, start as fellows, and endure disruptions affecting the whole family, such as relocation and lost income? How can CI fellows continue practicing and maintaining their knowledge and skills in their primary specialties?

5. **Standard health and clinical informatics roles, qualifications, and job descriptions.** (Jodi Kodish-Wachs) Why are current job descriptions challenging? Why do roles not translate well to core competencies? HI and CI come from diverse backgrounds. For example, physicians differ in technical expertise, residency and fellowship completion, licensure, board certification, clinical experience, and current practice. How do these differences affect competencies, job descriptions, and roles? What are standard roles and competencies? How roles and competencies be more standard and defined to improve job searches based on keyword searches of roles, job descriptions, and qualifications? How can we crowdsource and share this effort?

6. **Diversity, equity, and inclusion (DEI).** (Deepti Pandita) Research has shown that more diverse groups improve creativity and problems solving. How can we promote DEI in HI and CI to encourage more women and underrepresented minorities to enter informatics and training programs and then thrive in HI and CI careers increase ethnic and gender representation and DEI to develop a cohesive yet diverse informatics workforce?

7. **Continuing professional development (CPD) and continuing certification (MOC).** (Amy Wang) What are the latest developments in CPD, including CE, CME, and MOC? How can I stay current in the profession? What happened to the multiple-choice questions for AMIA activities? Where can I get help with MOC? How do I complete MOC IV when I am not in a healthcare setting or have access to patient data, or I am self-employed?

**Intended Audience**

This panel is intended to include all healthcare professionals, trainees, educators, and mentors who are interested in learning about HI and CI changes, training, careers, and certification. This topic is timely given the role of HI and CI informatics in the COVID-19 pandemic as well as the many recent changes in certification requirements.

**Panelists**

**Amy Y. Wang, MD, MBI, FAAFP, FAMIA** (Organizer and Moderator) is Associate Professor of Medicine and Scientist in the Informatics Institute at UAB. She serves as Chair of the AMIA Continuing Professional Development (CPD) Committee and Member of the Women in AMIA Career Advancement Committee. A family physician, her expertise is in standards and interoperability, health terminology, electronic health records, and informatics education. She completed a medical degree at Northwestern University and a master’s degree in biomedical informatics at OHSU. Dr. Wang’s industry experience includes SNOMED CT development at the College of American Pathologists, EHR development at Greenway Medical, and terminology development at IMO. Most recently, she was Assistant Professor and Faculty Director of the Master of Health Informatics degree program at Northwestern University.

**Jodi Kodish-Wachs, MD, FAMIA** is a physician executive at Vizient and serves as Chair of Physicians in AMIA (PINA). She has eight years of clinical practice and nine years of experience at Cerner and Siemens, bridging people, clinical medicine, and information technology to optimize access to health information and tools, individualized health, and improved efficiency. She has practical expertise in ideation, strategy, prototyping, and validating start-up solutions, research, data analysis, health standards, AI, clinical modeling, knowledge management, population health, risk, outcomes measures and care processes. Dr. Kodish-Wachs graduated from Rutgers Robert Wood Johnson Medical School and trained in Physical Medicine and Rehabilitation at UAB.
Deepti Pandita, MD, FACP, FAMIA is Chief Health Information Officer, Director of the Clinical Informatics Fellowship, and Staff Physician at Hennepin Healthcare as well as Assistant Professor of Medicine at University of Minnesota Medical School. Her areas of expertise are care delivery, innovation, population health, data analytics and clinical informatics, and her passion is using technology to bridge health disparities, especially in Medicaid populations, to transform care and create healthy communities. Dr. Pandita completed her residency in internal medicine at University of North Dakota School of Medicine and Health Sciences. Prior to joining Hennepin, she served as physician EMR champion at Park Nicollet Health Services.

Thomas Agresta, MD, MBI is Professor and Director of Medical Informatics in the Department of Family Medicine at and Director of Clinical Informatics in the Center for Quantitative Medicine at University of Connecticut School of Medicine. He is Vice-Chair of the Clinical Informatics Sub-Board of ABPM. Dr. Agresta is a seasoned family physician, educator, administrator, researcher, and innovator who builds multidisciplinary teams to develop methods for creating, using, and evaluating technology in clinical and teaching settings. He completed a BS in biomedical engineering at Stevens Institute of Technology, medical degree at New Jersey Medical School and master’s degree in biomedical informatics at OHSU. He has held state-level leadership roles for health information exchange initiatives.

Catherine Ivory, PhD, RN-BC, RNC-OB, NEA-BC, FAAN is Senior Director of Nursing Research and Assistant Professor of Nursing at Vanderbilt University Medical Center and Vice-Chair of the AMIA Health Informatics Certification Commission (HICC), which oversees Advanced Health Informatics Certification (AHIC). Dr. Ivory earned her Master of Science in Nursing (MSN) from Georgia College & State University and a PhD in Nursing Science from Vanderbilt University. She practiced inpatient obstetric nursing and is a certified informatics nurse and a health services researcher especially interested in the use and re-use of data generated in nursing practice.

Participation Statement

I, Amy Y. Wang, confirm that all speakers have agreed to participate in this panel. Panelists are aware that no funds are available and that the CPD Committee and PINA are unable to reimburse registration or travel costs.

Panel: Demonstrations in Synthetic Data and the National COVID Cohort Collaborative (N3C)

Adam Wilcox PhD,a Randi Foraker PhD MA,b Jason A. Thomas BS,c
Jon D. Morrow MD MA MBA,d,e Noa Zamstein PhDf

aUniversity of Washington School of Medicine, Seattle, WA; bWashington University in St. Louis, School of Medicine, St. Louis, MO; cMDClone Ltd., Be’er Sheva, Israel; dNew York University School of Medicine, New York, NY

General Description

The COVID-19 pandemic has been significant in demonstrating the need for sharing data across institutions for broader analysis. As many organizations were facing different waves of the pandemic at different times in 2020, lessons learned from others experiences could be helpful in identifying indicators of pandemic trends, studying the effect of new therapeutics, and understanding variations due to population factors. Most sharing during the pandemic was via scientific hypotheses or demonstrations, or through public health reporting data. The National COVID Cohort Collaborative (N3C) gathered electronic health record data (EHR) from multiple academic medical centers across the country to allow deeper analysis of shared data. By centralizing the data for the cohort, studies could be performed with advanced analytics comparing multiple institutions and with analysts beyond existing institutional analytics groups. However, expanding access to data across multiple institutions requires new approaches to protecting patient privacy. Standard methods of data de-identification that involve date removal, shifting or obfuscation may not be useful when studying data for a pandemic, when predictions about patient severity may depend on different periods of the pandemic or when trying to use the data for overall incidence prediction. Creating synthetic data is seen as an approach that can both protect patient confidentiality and allow broader sharing of data for analysis and discovery. Because of this opportunity, it is important to demonstrate how synthetic data can be used effectively for analysis.

This panel includes a group of researchers who have studied the use of synthetic data for various real analyses related to the COVID-19 pandemic. Using a synthetic dataset derived from N3C data, they have performed studies of data characterization, epidemic measurement, prevalence prediction, and inpatient severity prediction, and compared the data to results drawn from the original dataset. Two of the individual studies have been submitted for publication. The panel provides a comprehensive review of how synthetic data can be used for analysis. While each of the studies could be considered separately, the combination of studies together creates an opportunity to clearly recognize the status of synthetic data validation, which can better advance the appropriate application of the technology in informatics broadly. Discussions with the audience will both provide clarity of the extent of the analysis and discussions of how synthetic data can best be used in our field going forward. This topic is timely due to the analysis of synthetic COVID data, with directly-relevant conclusions that can be applied to current COVID research. It is also important to discuss in our field as we pursue new models of EHR data sharing in disease areas beyond COVID, in ways that preserve patient privacy.

Panelists

Randi Foraker, PhD, MA, FAHA, FAMIA. Dr. Foraker is an epidemiologist and the Director of the Center for Population Health Informatics at the Institute for Informatics and a Professor of General Medical Sciences at Washington University School of Medicine in St. Louis. Dr. Foraker also serves as Director of the Public Health Data and Training Center for the Institute for Public Health. She specializes in the design of population-based studies and utilizing electronic health record (EHR) data for research. Her recent research has focused on the statistical validation of computationally-derived data comparing original data to synthetic data generated by MDCClone (Be’er Sheva, Israel). In her role on the National COVID Cohort Collaborative’s (N3C) synthetic data task team, she led the evaluation of three use cases comparing original to synthetic data, including (1) exploring the distributions of key features of the COVID-positive cohort; (2) training and testing predictive models for assessing the risk of admission among these patients; and (3) determining geospatial and temporal COVID-related measures and outcomes, and constructing their respective epidemic curves. She will be presenting the analyses exploring distributions of key features among the cohort and predictive models for assessing admission risk.

Jason A. Thomas, PhD Candidate. Mr. Thomas is a 4th year PhD candidate in the Department of Biomedical Informatics and Medical Education at the University of Washington with 10 years of experience in healthcare - both frontline healthcare delivery and analysis/modeling of the resulting data. He has expertise in analysis & data modeling of EHRs, clinical trials and longitudinal cohort data. His research interests are currently focused on data access and sharing, privacy preserving technologies, and data utility & quality. He is a member of the JAMIA editorial board and has had an active role in the N3C Synthetic Validation Task Team since June 2020. He will be discussing his analysis of synthetic geospatial and temporal epidemiologic data utility. Analyzing regular and synthetic data across the country in the N3C dataset, he demonstrated the capability of synthetic data for analyzing
temporal trends in prevalence, hospitalization and death. Analyses of geographic areas were done for individual zip codes; where zip codes represented regions with multiple patients, epidemic curves were similar with synthetic data and actual data. Differences were observed in zip codes with small numbers of cases, which is consistent with expectations due to data censoring to preserve patient privacy in the synthetic data derivation process.

Jon D. Morrow, M.D., M.A., M.B.A., F.A.C.O.G. Dr. Morrow is a medical informaticist and obstetrician-gynecologist who currently serves as the Senior Vice President and Physician Executive for MDClone, responsible for the company’s Medical Affairs activities in North America. As a representative of MDClone on the N3C Synthetic Clinical Data Validation Subgroup, he has been involved in the Subgroup’s efforts to demonstrate the utility of synthetic data for extracting new knowledge about COVID-19 from the vast N3C database. He is also a member of the AMIA Informatics Partnership Council. For this panel, Dr. Morrow will be discussing an analysis of synthetic data across multiple geographic regions used to predict epidemic curves for 90 days based on existing data. Epidemic curves, especially prevalence inflection points with the curves, were predicted successfully for 90 days beyond the data used. Critical to the analysis is the use of EHR data, especially emergency department visits for COVID patients, which is not available with standard public health reporting databases. He will be describing the importance of synthetic data for this analysis, since development of predictive models across geographic regions requires broader data sharing among institutions.

Noa Zamstein, PhD. Dr. Zamstein holds a PhD in computational chemistry and is currently the Senior Data Scientist at MDClone. She is engaged in many of the company’s scientific activities in Israel and North America, with special focus on MDClone’s synthetic solution and its implementation across various sites with the goal of liberating healthcare data. In the past year she has been extensively involved in the NIH-MDClone partnership, supporting various research projects conducted in response to the COVID pandemic. Dr. Zamstein will present the results of analyses characterizing hospitalized COVID patients, and using data available early in admission to predict hospital severity of disease.

Adam Wilcox, PhD, moderator. Dr. Wilcox is currently Chief Analytics Officer at UW Medicine and Professor of Biomedical Informatics and Medical Education at the University of Washington School of Medicine. His research in informatics has focused on applications of informatics principles to improve care, from developing decision support applications, to designing architectural strategies for health information exchange, to creating population health research databases to study issues of health disparities, to methods of improving the use of data and analytics in healthcare. Early in the COVID-19 pandemic, Dr. Wilcox advocated for improved approaches to data sharing to allow shared analytics of emerging datasets, as well as the development of shareable data. He has participated with the group in the analysis of synthetic data and represented the practical need for synthetic data in supporting practical discovery in the COVID pandemic. As moderator, he will focus the discussion of the findings to their broader, combined implications about the utility of synthetic data to support data sharing and broader analytics.

Discussion Questions

- What types of analyses can be done with synthetic data?
- Based on these studies, how do these types of analyses compare with those done with actual patient data?
- What types of analyses can be done with synthetic data but cannot be done with standard de-identified data?
- What are areas where synthetic data could be used to further analyses with healthcare data?
- What are barriers to data sharing that can be addressed by synthetic data? What barriers still remain?

All participants have agreed to participate on the panel at the AMIA 2021 Annual Meeting.
The Women in AMIA-led Podcast: 
Rebranding and Social Media Optimization to Focus on Diversity

Control and Prevention (CDC), Atlanta, GA, USA; 8Charles R. Drew University of  
Medicine and Science, Los Angeles, CA, USA

Abstract

Women and underrepresented minorities are entering biomedical informatics or achieving leadership roles at a lower rate than other groups. As part of the efforts to address this discrepancy, the Women in AMIA (WIA) Initiative developed the Women in AMIA Podcast in 2017 to showcase women at all stages of their informatics careers. The intent was to increase awareness of women’s contributions to informatics, counterbalance stereotypes, and build the pipeline to leadership. Although the podcast has some reach (an average of 220 downloads per podcast), the podcast leaders wanted to reach to a wider and more diverse audience. To this end, the podcast team partnered with WIA Leadership Program members to rebrand the podcast and launch on a broader scale. In this panel, we will report on the process and results of these efforts including 1) podcast rebranding, 2) social media approach to reach target audience, and 3) podcast and social media metrics of success.

Panel Description

Learning objectives
Understand techniques to: (1) increase podcast audience through branding methods. (2) reach women and underrepresented populations through social media dissemination. and (3) assess podcast impact using social media metrics.

Women and underrepresented minorities enter the clinical informatics pipeline at lower rates and have fewer roles in leadership

Clinical informatics fellowship applicants are majority male and do not include traditionally under-represented groups such as African Americans or those of Hispanic/Latin descent. Those that do enter the healthcare and clinical informatics space are frequently systemically undervalued (i.e., paid less than their counterparts). Women are increasing in numbers in the healthcare space in many domains (e.g., in 2019, 50.5% of medical students are women) but remain underrepresented in healthcare leadership roles, as they are estimated to make up 13% of CEOs and 30% of C-suite roles.

These conditions contribute to women and underrepresented minorities (especially those with intersectionality) not achieving their full potential in the workplace and possibly leaving the field. This can negatively impact business because it has been documented that companies in the top 25 percentile for management diversity were 15-35% more likely to achieve financial returns above their industry mean. Creating a diverse workforce will provide the knowledge and input to address industry pain points.

Podcasting as an educational tool
The digital medium of podcasts has exploded in popularity over the past 15 years. In 2019, at the time of the study, it was estimated that 70 million people had listened to a podcast in the previous month. Approximately 51% of podcast
listeners are male and 63% are white.7 Podcasts have expanded beyond the pop culture realm and into the educational domain.8 The market is expected to grow and expand in upcoming years.

The underrepresentation of women and minorities in clinical informatics is due to many factors, including implicit bias, which leads to stereotyping and results in fewer opportunities.9 Education and role modeling can counteract implicit bias.10 Podcasting can be an effective medium to educate the majority about the talent of underrepresented groups and subvert stereotypes. Podcasts can also foster a connection among underrepresented groups and increase awareness of those with similar or complementary goals.

The Podcast, hosted by Women in AMIA
The WIA Steering Committee started the WIA Podcast in 2017 with a plan to showcase talented women in informatics. As a part of the Pipeline Subcommittee within WIA, the podcast is a part of the larger goal of WIA to attract new women into the field, provide meaningful resources, and to retain women at various career stages. The podcast’s aim was to increase awareness, connect individuals with similar interests, disseminate practical information about how to achieve career success and manage work-life balance.11 The podcasts have featured over 15 women and men at different career stages in informatics and were downloaded close to 3,000 times (on average 220 downloads per podcast). In 2020, the podcast leadership wanted to include all underrepresented groups and broaden the reach of the podcasts and partnered with the WIA Leadership Program Seed Grant Awardees for this endeavor. This effort has included rebranding the podcast (title, logo, music, introduction) and increasing social media efforts. We will report on this process in more detail, including: 1) podcast rebranding, 2) social media approaches to reach women and underrepresented populations as well as increase listenership overall and 3) podcast and social media metrics of success.

Descriptions of Panelists and Presentations
All participants have agreed to take part on the panel.

Karmen S. Williams is an Adjunct Assistant Professor of the City University of New York. Her research focus is in public and population health informatics and increasing representation in STEM fields. She is the director of the podcast, an active member on the WIA Steering Committee, co-chair of the WIA Pipeline Subcommittee, and chair of the Dental Informatics Working Group. As the session moderator, she will provide a brief overview of the WIA led Podcast.

Tiffany Harman is a Nurse Informaticist and Business Development Manager at 3M Health Information Systems. Her focus is clinical terminologies and educating clients on the importance of using standardized data for interoperability and analytics. She was a participant in the WIA Leadership Program and recipient of their Seed Grant award. As a panelist, she will provide a history of the WIA Podcast and the WIA Leadership Program Seed Grant.

Mindy K. Ross is an Assistant Professor at the University of California, Los Angeles David Geffen School of Medicine, Department of Pediatrics. She is a pediatric pulmonologist and physician informaticist. Her research interest is focused on clinical decision support for more personalized asthma management through the patient portal and electronic health record. She was a participant in the WIA Leadership Program and recipient of their Seed Grant award. As a panelist, she will review the rebranding efforts of the podcast.

Maria Adela Grando is an Associate Professor of biomedical informatics at the Arizona State University and Adjunct Assistant Clinical Professor of Medicine at the Mayo Clinic. Her area of expertise in patient-centered technology. She was a participant in the WIA Leadership Program. She is a member of the WIA Podcast Team and a Podcast Host. As a panelist, she will present how to make effective podcasts, resources needed and how to reach your desired audience.

Zubin A. Khan is a Public Health Informatics Fellow at the Centers for Disease Control and Prevention (CDC) and assigned to field location at Utah Department of Health (UDOH). Some of his efforts are focused on the Data Modernization Initiative (DMI) along with Health Interoperability, Population Health and state/federal COVID response. He also serves as a chair-elect at student working group (SWG) at AMIA. As a panelist, he will review the social media marketing strategy and metrics.
Importance of the Panel
It is important to provide outreach to underrepresented women and minorities in clinical informatics to help combat systemic and implicit biases. We hope that disseminating a message of education and awareness will motivate women and underrepresented minorities to engage in leadership roles. By broadening the scope of the WIA-led podcast to include more groups, we aim to educate those in the majority and inspire those in underrepresented groups to choose this field and flourish in it. The WIA-led podcast is an educational resource that will provide the knowledge to influence healthcare leadership to rise into a new era. We hope to educate the audience about the rebranding process and discuss the role that social media plays in highlighting the informatics field. We hope to engage the audience in ideas to increase the reach of the podcast.

Discussion Questions to Enhance Audience Participation
1. Who benefits from the content of the WIA-led Podcast?
2. What could potentially enhance the reach of the WIA-led Podcast?
3. How can we incorporate the WIA-led Podcast in the classroom and broader education?
4. What discussion topics should be added to the WIA-led Podcast?

Opportunities to Advance Workflow Automation Using Health Information Technology

Teresa Zayas-Cabán, PhD¹, Grace Cordovano, PhD², J. Marc Overhage, MD, PhD³, Walter Suarez, MD⁴, Tracy Okubo⁵

¹National Library of Medicine, National Institutes of Health, Bethesda, MD; ²Enlightening Results, LLC, West Caldwell, NJ; ³Anthem, Inc, Indianapolis, IN; ⁴Kaiser Permanente, Washington, DC; ⁵Office of the National Coordinator for Health Information Technology, Washington, DC

Abstract

Inefficient health care workflows contribute to the variable quality and poor outcomes sometimes observed in U.S. health care. Increased adoption of health information technology (IT) systems provides opportunities to improve health care workflows through automation. Moreover, broader technology trends offer new possibilities to support more efficient and comprehensive workflows in care delivery. Other sectors making effective use of automation can provide key insights into how to automate health care processes effectively. Capitalizing on this opportunity, the Office of the National Coordinator for Health Information Technology (ONC) has explored opportunities to advance workflow automation in health care through the use of health IT. ONC has focused on the role of organizations, individual stakeholders, and technology to support system-wide transformation that increases efficiency, improves health outcomes, and delivers value. This panel will discuss workflow automation advancements and priorities and related actions needed to propel them further from multiple perspectives including industrial engineering, patients and caregivers, technology development, health care delivery, and health IT policy. Each panelist will summarize their perspective, allowing time for participant interaction. An essential objective of the panel is to discuss opportunities for the informatics community to advance workflow automation priorities and strategies.

Introduction

While the increased adoption and use of health information technology (IT) have created opportunities to more effectively leverage data and knowledge for care delivery, inefficient workflows in health care remain. With continued concerns about the cost, quality, and safety of health care and mounting provider burnout, there is an opportunity to use health IT to enable workflow automation to address these issues.¹ Automation is a means of assisting, augmenting, or replacing human operators with machines or computers to carry out functions that humans customarily perform.² Broader technology trends, such as the rise of the “internet of things” (IoT), advances in artificial intelligence and machine learning, and the evolution of workflow automation tools from assembly belt machinery to a combination of big data, advanced analytics, business intelligence capabilities, improved human-machine interfaces, and digital-to-physical transfer capabilities, have allowed other industries to reduce labor-intensive processes.³⁻⁴ Industries such as agriculture, food production and distribution, manufacturing, transportation, and hospitality have improved quality, productivity, efficiency, and operational safety through workflow automation in recent decades, fueled by modern computational science and democratized access to data.⁵⁻¹¹ Lessons learned from early adopters of automated workflows from these industries may be relevant to health care.

Automating Health Care Workflows through Health IT

The Office of the National Coordinator for Health Information Technology (ONC) has explored opportunities to accelerate workflow automation through the use of health IT.¹² ONC has identified six priorities to advance automation in health care: 1) mobilize nationwide scale automation in near-term “sprints” and long-term “marathons;” 2) enable de-novo discovery of redundant tasks; 3) ensure a ready clinician base for workflow automation; 4) allow all stakeholders to effectively and efficiently engage in health and health care tasks; 5) ensure automation improves patient and caregiver interaction within the health care system; and 6) leverage interoperable health data for automation. ONC has also identified strategies to advance these priorities through specific tactics aimed at educating and convening stakeholders, prioritizing and demonstrating the efficacy of prioritized workflows, and designing incentives and methods to scale successful workflow automation approaches. ONC’s effort has been informed through expert input, a literature review, and a multidisciplinary workshop, emphasizing understanding automation in other industries and identifying applicable lessons learned for health care.¹³ For example, the systems engineering field examines how micro-systems are embedded within macro-systems and operate with varying degrees of complexity.¹⁴
Human factors engineering studies the role of human decision making and action in workflows subject to variation and uncertainty.\textsuperscript{15}

The panel will present: 1) an overview of the factors that drove ONC’s interest in exploring workflow automation; 2) background on workflow automation in health care and other industries; and 3) the perspectives of experts from different fields; and 4) an overview of the identified priorities and actions. The panel members will seek participant feedback on strategies and discuss opportunities to support effective advancement of workflow automation.

**Panel Objectives and Presenters**

This panel aims to share opportunities to advance workflow automation through the use of health IT, and to invite participants to provide reactions and feedback. The panelists will represent a range of perspectives.

Ms. Tracy Okubo (moderator) is a Senior Program Analyst at ONC, where she managed ONC’s workflow automation initiative. She will present the drivers that influenced ONC’s efforts and the resulting priorities. She will also moderate the session.

Dr. Teresa Zayas (panelist) is the Assistant Director for Policy Development at the National Library of Medicine at the National Institutes of Health. While serving as the Chief Scientist at ONC through February 2021, her division led ONC’s scientific efforts including the workflow automation initiative. Through an industrial engineer's lens, she will present the lessons learned and opportunities from non-health care sectors that could be applied to advance health care workflow automation and implementation considerations.

Dr. Grace Cordovano (panelist) is a board-certified patient advocate and the founder of Enlightening Results, LLC. Through her work at Enlightening Results, as well as being the primary caregiver to two disabled adults and a patient herself, she will speak to patients’ and caregivers’ experiences navigating the health care system and opportunities for automation to simplify and improve their interacting with the health care system.

Dr. J. Marc Overhage (panelist) is the Chief Medical Informatics Officer at Anthem who recently led the Population Health Intelligence Strategy at Cerner and served as President and CEO of the Indiana Health Information Exchange. He will discuss how to approach population-level automation opportunities from a health information exchange and care delivery perspective. He will also contribute insights on designing a regulatory approach that advances innovation and observes multiple stakeholders' interests, including clinicians, patients, and payors.

Dr. Walter Suarez (panelist) is the Executive Director of Health IT Strategy and Policy at Kaiser Permanente. He will describe the experience of automating clinical and administrative workflows in an integrated delivery network and offer insights for automation innovation that apply to other delivery models. He will speak to the elements of public policy and market drivers to effectively advance workflow automation.

**Panel Discussion Questions**

The moderator will address the following types of questions to the panelists and encourage the audience to share their input and experience.

1. How can health care apply automation lessons learned from other industries? What factors make health care similar versus unique, and what are the implications for automation?

2. Considering the range of full to partial automation, and the multiple areas in health care where workflow automation can be applied (clinical, administrative, quality, safety), which workflows are suitable to full automation, and where should automation in health care consider retaining a human “in the loop”?

3. Workflow automation holds many promises to improve efficiency, lower costs, and increase safety. How might stakeholder goals, interests and priorities vary, including for patients and caregivers, and what are the implications for implementing the identified priorities?

4. What criteria should the health care sector apply in prioritizing health care workflows to automate?

5. What barriers exist to workflow automation, and how can the priorities address them?
Panel Learning Objectives

1. Participants will learn about opportunities to advance workflow automation.
2. Participants will understand examples of workflow automation in other industries and their potential application to health care.
3. Participants will learn the task and technology characteristics of workflows that make them well-suited for automation across industries.
4. Participants will learn approaches used to design, implement, and evaluate workflow automation.

Conclusion

With the increased availability and exchange of electronic health information through use of health IT, there are numerous opportunities to leverage health data to reduce redundant or inefficient processes via automation. However, additional solutions, resources, and governance may be needed to promote and foster use of health IT to advance automation. By sharing ONC’s efforts to understand opportunities to advance workflow automation, this panel aims to stimulate a rich discussion and gather participant feedback on pursuing impactful automation for multiple stakeholders.

Statement of Participation

Each of the panelists and the moderator have confirmed that they will participate if this submission is accepted, at the assigned timeslot during the Annual Symposium.

Advancing the Use of FHIR in Research: An Update on NIH’s Efforts

Teresa Zayas-Cabán, PhD1, Belinda Seto, PhD2, Paul Harris, PhD3, Allison Heath, PhD4, Viet Nguyen, MD5

1National Library of Medicine, National Institutes of Health, Bethesda, MD; 2Office of Data Science Strategy, National Institutes of Health, Bethesda, MD; 3Vanderbilt University, Nashville, TN; 4Children’s Hospital of Philadelphia, Philadelphia, PA; 5Stratametrics, Salt Lake City, UT

Abstract

On July 30, 2019, the National Institutes of Health (NIH) issued a notice “to encourage NIH researchers to explore the use of the Fast Healthcare Interoperability Resources® (FHIR®) standard to capture, integrate, and exchange clinical data for research purposes and to enhance capabilities to share research data.” Recently, the Office of Data Science Strategy, NIH, in collaboration with the National Library of Medicine, commissioned an assessment of the landscape of FHIR use in research. The summary findings suggest that FHIR is not yet broadly used for research purposes. There are several challenges from the institutional level to the individual level. Institutions’ decision to implement FHIR involves financial commitment not only to the technology but also to an ongoing need to train their staff. Few researchers currently know how to use FHIR or leverage it in their research studies. This panel will provide an update on NIH’s activities to advance the use of FHIR in research. Panelists will discuss the challenges and opportunities in using FHIR for research with attendees and solicit feedback on NIH’s work to date and input on strategies NIH can implement to better leverage FHIR in research.

Introduction

The increased adoption of health information technology (IT) has increased the availability of electronic health data for clinical care and research. Recent regulations require the use of the Health Level Seven International® (HL7®) Fast Healthcare Interoperability Resources® (FHIR®) standard to enable exchange of clinical and claim information. FHIR provides a standardized way of transmitting health data from one health information system to another through an application programming interface. Use of a standard such as FHIR could accelerate the use of clinical data for research. Additionally, FHIR provides a way to structure data generated from research in a manner that fosters interoperability and interchange of both research and clinical data.

These advancements have created new opportunities for biomedical researchers who may be able to leverage the FHIR standard to both use electronic health data in research as well as make data from a single research study useful for other research endeavors. Data standards are key to the interoperability and reusability of data, allowing data to be more easily analyzed, shared, and combined with other data. Use of data standards in research will help the National Institutes of Health (NIH) achieve its goals in data science and open science.

Advancing the Use of FHIR in Research

In 2019, NIH published a Guide Notice encouraging NIH-funded investigators to explore the use of FHIR to capture, integrate, and exchange clinical data for research purposes and to enhance capabilities to share research data. Subsequently, NIH awarded two related contracts designed to increase the availability of high-quality data using FHIR and published a request for information (RFI) regarding the application of FHIR to research data, including anticipated challenges and opportunities, current experiences, and needed tools. To address feedback received in response to the RFI, NIH is leading an assessment of the current landscape of adoption, implementation, and use of the FHIR standard for research. The landscape assessment includes a mix of targeted expert interviews, federal and stakeholder workshops, and a literature review.

The assessment has found that FHIR is not yet broadly used for research purposes and few researchers currently know how to use FHIR or leverage it in their research studies. The assessment has also uncovered challenges to, and opportunities for, leveraging FHIR in research. Identified challenges to using FHIR in research include: clinical and research needs, technical needs, and legal and regulatory barriers to data access. Some opportunities to leverage FHIR in research include: combining the use of FHIR and artificial intelligence to analyze diagnostic images, use of...
real-world data from electronic health record systems to recruit volunteers for clinical trials, and the ability to interoperate based on standards.

The panel will present an overview of NIH activities to advance FHIR in research to date as well as findings identified from the assessment. The panel members will seek feedback on identified challenges and opportunities and input into strategies NIH can employ to overcome these challenges to formulate its FHIR strategy.

Panel Objectives and Presenters

This panel aims to provide an update on NIH’s activities to advance the use of FHIR in research to date and to invite participants to provide reactions and feedback. The panelists will represent a range of perspectives.

Dr. Teresa Zayas Cabán (moderator and panelist) is the Assistant Director for Policy Development at the National Library of Medicine at the NIH. While on a previous detail at NIH, Dr. Zayas Cabán led the development of NIH’s strategy for the use of FHIR in research. Dr. Zayas Cabán will provide background on NIH’s activities to advance the use of FHIR and other standards in research. She will also moderate the session.

Dr. Belinda Seto (panelist) is the Deputy Director of the Office of Data Science Strategy at NIH, where she also co-leads the NIH FHIR Working Group. Dr. Seto will present on findings from the NIH landscape assessment.

Dr. Paul Harris (panelist) is professor of biomedical informatics and biomedical engineering with extensive experience working in the field of clinical and translational research informatics. He serves as director of the Vanderbilt University Medical Center Office of Research Informatics. Dr. Harris devised and created REDCap, a data collection platform that has seen widespread adoption by more than 4900 institutional partners and over 1.6 million end-users across 141 countries. Dr. Harris will describe methods developed at Vanderbilt and now deployed across the REDCap Consortium allowing research teams to set up automated FHIR-based data exchange between local EHR systems and REDCap. He will also describe current development work and use cases leveraging FHIR for other research-related scenarios, including survey metadata representation, documentation of research consents, and trial data exchange.

Dr. Allison Heath (panelist) is the Director of Data Technology and Innovation at the Center for Data Driven Discovery in Biomedicine at the Children’s Hospital of Philadelphia Research Institute. Dr. Heath has been working to solve big data challenges in the unique context of pediatric diseases and leads the development of the Kids First Data Resource Center. Dr. Heath will present on work she is leading to integrate FHIR into the Kids First Data Resource Center and efforts as part of the NIH Cloud-Based Platform Interoperability (NCPI) FHIR working group. These efforts support clinical and genetic data sharing to in order to accelerate discovery and improve clinical care.

Dr. Viet Nguyen (panelist) is Founder of Stratametrics, board member of HL7, and technical director of the HL7 Da Vinci Project. Dr. Nguyen will provide an understanding of the adoption of FHIR in data exchange between payers, providers and patients and how the adoption of FHIR establishes a foundation for the research community to leverage FHIR in clinical research.

Panel Discussion Questions

The moderator will address the following types of questions to the panelists and encourage the audience to share their input and experience.

1. What are some approaches we can use to overcome challenges to using FHIR in research?
2. What should NIH prioritize in establishing and advancing its FHIR strategy?
3. What are some key opportunities for researchers in using FHIR for their projects?
4. How can the FHIR specification be further developed to better support research needs?
Panel Learning Objectives

1. Participants will learn about NIH’s efforts to advance the use of FHIR in research.
2. Participants will learn about current limitations of the application of the FHIR specification in research.
3. Participants will learn about challenges and opportunities for using FHIR in research.

Conclusion

With the increased availability and exchange of electronic health information through use of health IT, there are numerous opportunities to leverage health data in research by using standards such as FHIR. By sharing NIH’s efforts to advance the use of FHIR in research and findings to date, this panel aims to stimulate a rich discussion and gather participant feedback that will inform the next steps in advancing NIH’s efforts.

Statement of Participation

Each of the panelists and the moderator have confirmed that they will participate at the assigned timeslot during the Annual Symposium if this submission is accepted.

Abstract
Uncovering and fixing errors in biomedical terminologies is essential so that they provide accurate knowledge to downstream applications that rely on them. Non-lattice-based methods have been applied to identify various kinds of inconsistencies in different biomedical terminologies. In previous work, we have introduced two inference-based approaches that were applied in an exhaustive manner to audit hierarchical relations in the Gene Ontology: (1) Lexical-based inference framework, and (2) Subsumption-based sub-term inference framework. However, it is unclear how effective these exhaustive approaches perform compared with their corresponding non-lattice-based approaches. Therefore, in this paper, we implement the non-lattice versions of these two exhaustive approaches, and perform a comprehensive comparison between non-lattice-based and exhaustive approaches to audit the Gene Ontology. The domain expert evaluations performed for the two exhaustive approaches are leveraged to evaluate the non-lattice versions. The results indicate that the non-lattice versions have increased precision than their exhaustive counterparts even though they do not capture some of the potential inconsistencies that the exhaustive approaches identify.

1 Introduction
Biomedical terminologies like Gene Ontology, SNOMED CT and NCI thesaurus have received an increase use in terms of knowledge management; data integration, exchange and semantic interoperability; and decision support and reasoning in biomedicine\textsuperscript{1–4}. Biomedical terminologies are constantly curated to reflect the state-of-the-art knowledge of the particular domain that they represent. Though great care is taken to make sure the terminologies reflect the biomedical knowledge accurately, it is inevitable that errors will be introduced due to the manual effort involved in maintaining them combined with how complex terminologies have become over time. It can be laborious to manually audit a modern biomedical terminology due to their size and complexity and hence, automated approaches are preferred.

Non-lattice-based auditing methods have been effectively employed for quality assurance purposes on various biomedical terminologies\textsuperscript{5–11}. These methods focus on subgraph fragments in terminologies that are error prone. In contrast, exhaustive methods focus on the entire terminology without restricting to such subgraphs. Leveraging the lexical features of concepts in non-lattice-subgraphs, various inconsistencies have been uncovered. The advantage of non-lattice-based methods over most other terminology auditing methods is that they are capable of not only identifying errors, but also suggesting remediation measures. Therefore, they require much less manual review effort from domain experts. According to the results of non-lattice-based methods, it is unquestionable that they are effective in uncovering errors in biomedical terminologies. However, a comprehensive comparison of non-lattice-based methods against exhaustive methods has not yet been performed to prove their effectiveness in uncovering inconsistencies.

In previous work, we have developed two exhaustive approaches to audit the hierarchical is-a relations in Gene Ontology (GO): one is a lexical-based inference approach\textsuperscript{12,13}, and the other is a subsumption-based sub-term inference framework\textsuperscript{14}. In this paper, we implement these two approaches on non-lattice subgraphs to detect potential inconsistencies in GO. Leveraging the previous evaluations performed by domain experts, we perform a comparison of the effectiveness of the exhaustive version and non-lattice version for both approaches.

2 Background

2.1 Methods to audit biomedical terminologies

Many approaches have been proposed to audit biomedical terminologies\textsuperscript{15}. Abstraction networks which are summary graphs of terminologies have been extensively explored to perform quality assurance\textsuperscript{16–18}. Zhe et al. have worked on identifying trapezoid structures in the hierarchies of a pair of terminologies to identify missing concepts\textsuperscript{19}. Bodenreider has introduced a method to uncover missing \textit{is-a} relations through inference of logical definitions constructed using lexical features of concept names\textsuperscript{20}. Zheng et al. have introduced a transformation-based method that leverages Unified Medical Language System (UMLS) knowledge to identify missing hierarchical relations in terminologies in the UMLS\textsuperscript{21}. Peng et al. have proposed a new algorithm to predict new GO terms and connect them to existing GO\textsuperscript{22}. Mougin et al. have reasoned over relationships to identify redundant relations in GO and detected missing relations by using compositional structure of the concept names\textsuperscript{23}. Xing et al.’s work combined dynamic programming with topological sort to detect redundant relation in biomedical terminologies including GO\textsuperscript{24}. More recently, deep learning has been explored to audit biomedical terminologies. Zheng et al. have proposed a method that leverage deep learning to predict the concept names of new concepts that comply with the naming convention of the terminology\textsuperscript{25}. Liu et al. have introduced a deep learning approach that can predict the placement of a new concept in the hierarchy of SNOMED CT\textsuperscript{26}.

2.2 Non-lattice subgraphs

Being a lattice is considered a desirable property for a well-formed terminology\textsuperscript{5,27,28}. A terminology forms a lattice if any pair of concepts have a unique maximal shared descendant and a unique minimal shared ancestor. A pair of concepts is known as a non-lattice pair, if they have more than one maximal shared descendant or minimal shared ancestor. For example, in Figure 1, concepts $A$ and $B$ form a non-lattice pair since they share two maximal common ancestors $E$ and $F$.

The non-lattice pair $(A, B)$ defines a non-lattice subgraph as follows. First, the maximal common descendants ($mcd$) of the non-lattice pair is obtained. For the non-lattice pair $(A, B)$, the maximal common descendants $mcd(A, B) = \{E, F\}$. Then we reversely compute the minimal common ancestors ($mca$) of concepts $E$ and $F$. This yields us $mca(mcd(A, B)) = \{A, B, C\}$. Then all the concepts and relations between $mcd(A, B)$ and $mca(mcd(A, B))$ is aggregated to form the non-lattice subgraph. This yields a non-lattice subgraph with six concepts $\{A, B, C, D, E, F\}$.

![Figure 1: An example non-lattice subgraph.](image)

2.3 Non-lattice-based auditing methods

Previously, we have investigated a number of non-lattice-based methods to audit biomedical terminologies. Four lexical patterns in non-lattice subgraphs were investigated to uncover missing \textit{is-a} relations and missing concepts in SNOMED CT\textsuperscript{5}. The same approach was applied to NCI thesaurus introducing two more lexical patterns\textsuperscript{6}. We also introduced a method that leverages enriched lexical attributes of concepts in non-lattice subgraphs in SNOMED CT to uncover \textit{is-a} relation inconsistencies\textsuperscript{7}. We applied similar approaches on the NCI thesaurus while also investigating the inheritance of lexical attributes from all ancestors and leveraging role definitions of concepts.

Next we discuss the two exhaustive methods from previous work that we will compare later with their non-lattice-based counterparts.
2.4 Lexical-based inference framework

To audit *is-a* relations in GO, we introduced a lexical-based inference framework. In this approach, we represented the name of each concept using two models: set-of-words and sequence-of-words. For each model, we generated hierarchically-linked and -unlinked Partial Matching Concept-Pairs (PMCPs), \((A, B)\), such that both \(A\) and \(B\) have the same number of words, and contain at least one word in common and a fixed number of different words \((n = 1, 2, 3, 4, 5)\). The linked and unlinked concept-pairs further infer corresponding linked and unlinked term-pairs (ITPs) respectively. If the same ITP is inferred by a linked and unlinked PMCP, this is considered as an inconsistency. Applying this approach to the March 28, 2017 release of GO, a total of 5,359 potential inconsistencies were found by the set-of-words model and 4,959 were found by the sequence-of-words model. A random sample of 250 potential inconsistencies identified through this method was evaluated by domain experts to validate their correctness. The results showed that the set-of-words model achieved a precision of 53.78% while the sequence-of-words model achieved a precision of 57.55%.

2.5 Subsumption-based sub-term inference framework

In previous work, we developed a subsumption-based sub-term inference framework (SSIF) to audit GO. In SSIF, we represented each concept \(A\) with a sequence-based representation \(E(A) = [e_1, e_2, e_3, ..., e_n]\), where each element is either a word or a sub-concept. We leveraged part-of-speech tagging, sub-concept matching and antonym tagging to construct the sequence-based representation for each concept. Then, we introduced three conditional rules: Monotonicity, Intersection, and Sub-concept that utilized the sequence-based representation to uncover problematic *is-a* relations. Here, we briefly discuss the three rules.

Monotonicity rule suggests \(A\ is-a\ B\) if both \(A\) and \(B\) have the same number of elements in their sequence-based representations \(E(A)\) and \(E(B)\) respectively, their corresponding elements \(A_i\) and \(B_i\) are either equal or if they are sub-concepts (discussed below) \(A_i\ is-a\ B_i\), and \(E(A)\) does not contain an element which is an antonym of any element of \(E(B)\).

Intersection rule suggests a missing *is-a* relation between a concept \(A\) and an intersecting concept \(X\) as follows. Suppose that \(A\) has a pair of ancestors \(B\) and \(C\). The intersecting concept \(X\) of \(B\) and \(C\) is defined as another concept that contains the lexical properties of both \(B\) and \(C\) and is lexically the most general concept that is a descendant of both \(B\) and \(C\). Therefore, since \(A\) is also a descendant of both \(B\) and \(C\), this rule suggests that \(A\ is-a\ X\). Note that \(A\) should not have an element which is an antonym of an element of \(X\).

Sub-concept rule suggests a missing *is-a* relation among a concept and its sub-concept. We say that a concept \(B\) is a sub-concept of a concept \(A\) if \(B\) is a proper substring of \(A\). Suppose that if the sub-concept \(B\) is the last element of \(A\), all other elements of \(A\) are either sub-concepts or belong to parts-of-speech noun or adjective, and \(A\) does not have an element which is an antonym of any element of \(B\), then the Sub-concept rule suggests \(A\ is-a\ B\).

Applying SSIF to the October 3, 2018 release of GO, 819; 691; and 669 potential inconsistencies were uncovered for Monotonicity, Intersection, and Sub-concept rules respectively. Domain experts evaluated a random sample of 210 potential inconsistencies uncovered by SSIF and the results showed that SSIF achieved a precision of 60.61%, 60.49%, and 46.03% for Monotonicity, Intersection, and Sub-concept rules respectively.

3 Methods

We first extract all the non-lattice subgraphs from both the March 28, 2017 and October 3, 2018 releases of Gene Ontology (the same versions used in the exhaustive approaches) leveraging an efficient large-scale non-lattice detection algorithm. Then we develop the non-lattice version of the two approaches as follows.

3.1 Non-lattice lexical-based inference framework

For both set-of-words model and sequence-of-words model, the non-lattice version of the lexical-based inference framework is as follows. A pair of hierarchically-linked or -unlinked concepts \((A, B)\) form a non-lattice PMCP if both \(A\) and \(B\) have the same number of words, contain at least one word in common and a fixed number of different
words \( n = 1, 2, 3, 4, 5 \), and are in the same non-lattice subgraph. From a non-lattice PMCP, a non-lattice ITP is derived by removing the common words across the two PMCPs. We say that an inconsistency exists in a non-lattice subgraph if it contains a linked non-lattice PMCP and an unlinked non-lattice PMCP, which infers the same non-lattice ITP. Figure 2 shows an example non-lattice subgraph that exhibits this scenario. Note that the concepts of linked PMCP are in green and the concepts of the unlinked PMCP are in red. This can be obtained by both the set-of-words and sequence-of-words models.

3.2 Non-lattice subsumption-based sub-term framework

Exhaustive SSIF proposed three conditional rules: Monotonicity, Intersection, and Sub-concept to uncover potential is-a inconsistencies. Here, we define their non-lattice-based counterparts as follows.

**Non-lattice-based Monotonicity rule** suggests \( A \) is-a \( B \) if concept \( A \) and concept \( B \) satisfy the following conditions:

- they are in the same non-lattice subgraph;
- they have the same number of elements in their sequence-based representations \( E(A) \) and \( E(B) \) respectively;
- their corresponding elements \( A_i \) and \( B_i \) are either equal or if they are sub-concepts, both of them are in the above-mentioned non-lattice subgraph where \( A_i \) is-a \( B_i \); and
- \( E(A) \) does not contain an element which is an antonym of any element of \( E(B) \).

Figure 2: A missing is-a relation (dashed link in red) identified by the non-lattice lexical-based inference framework. Concept pair of linked PMCP is in green and concept pair of unlinked PMCP is in red. The suggestion here is that peptidyl-threonine trans-autophosphorylation is-a peptidyl-threonine autophosphorylation.

Figure 3: A missing is-a relation (dashed link in red) identified by the Monotonicity rule of the non-lattice SSIF. Concepts in green exists as sub-concepts of concepts in red. The suggestion here is positive regulation of secondary heart field cardioblast proliferation is-a positive regulation of cardioblast proliferation.
Figure 3 shows a non-lattice subgraph exhibiting Monotonicity rule. This example shows a suggested missing is-a relation between concepts $A = \text{positive regulation of secondary heart field cardioblast proliferation}$ and $B = \text{positive regulation of cardioblast proliferation}$. Note that with the sequence-based representation, concept $A$ here is represented as $E(A) = \{\text{positive, (regulation of secondary heart field cardioblast proliferation)}\}$, i.e., the first element is positive and the second element is regulation of secondary heart field cardioblast proliferation which is a sub-concept. Similarly, concept $B$ is represented as $E(A) = \{\text{positive, (regulation of cardioblast proliferation)}\}$. Since $A$ and $B$ are both in the same non-lattice subgraph, have two elements each, their first elements are equal and the second elements are sub-concepts having an is-a relation which also exists in the same non-lattice subgraph (denoted by green circles), we suggest a missing is-a relation among these two concepts (denoted by red dashed line).

Non-lattice-based Intersection rule suggests a missing is-a relation as follows. Suppose that $A$ has a pair of ancestors $B$ and $C$ whose intersecting concept is $X$. If all $A, B, C$, and $X$ are in the same non-lattice subgraph, this rule suggests a missing relation $A$ is-a $X$ if $A$ does not have an element that is an antonym of an element of $X$. Figure 4 shows a non-lattice subgraph exhibiting Intersection rule. For instance, concepts $B = \text{regulation of establishment of cell polarity}$ and $C = \text{regulation of establishment or maintenance of cell polarity regulating cell shape}$ (denoted by green circles) which are in the same non-lattice subgraph has an intersecting concept $X = \text{regulation of establishment of cell polarity regulating cell shape}$ which is also in the same non-lattice subgraph. Concept $A = \text{regulation of establishment of bipolar cell polarity regulating cell shape}$ which also exists in the same non-lattice subgraph is a descendant of both $B$ and $C$. Therefore, we suggest a missing is-a relation between the concepts $X$ and $A$ (denoted by the red dashed link).

Non-lattice-based Sub-concept rule suggests a missing is-a relation between a concept $A$ and its sub-concept $B$ if

- both of $A$ and $B$ are in the same non-lattice subgraph;
- the sub-concept $B$ is the last element of $A$, and all other elements of $A$ are either a sub-concept or noun or adjective; and
- $A$ does not have an element which is an antonym of any element of $B$.

For instance, Figure 5 contains a non-lattice subgraph exhibiting Sub-concept rule. Here, concept $A = \text{positive regulation of phenotypic switching by regulation of transcription from RNA polymerase II promoter}$ is represented by the sequence-based representation as $E(A) = \text{positive, (regulation of phenotypic switching by regulation of transcription from RNA polymerase II promoter)}$. i.e. the last element of $A$ is a subconcept $B = \text{regulation of phenotypic switching by regulation of transcription from RNA polymerase II promoter}$ which also exists in the same non-lattice subgraph. The remaining element positive is an adjective. Therefore, based on the non-lattice Sub-concept rule, we suggest there exists a missing is-a relation between $A$ and $B$ (denoted by the dashed red line).
3.3 Evaluating non-lattice-based methods

To evaluate the performance of the non-lattice versions of lexical-based inference framework and SSIF, we leverage the evaluations performed on their exhaustive counterparts. If a potential inconsistency identified through the non-lattice approach exists in the evaluation sample of the exhaustive approach, then, that particular sample is considered for evaluating the non-lattice approach. So, we simply take the intersection between the non-lattice results with the exhaustive evaluation set to identify the evaluation samples obtainable by the non-lattice approach. Then, based on the number of valid inconsistencies and false positives, we compute the precision.

4 Results

In this section, we compare the potential inconsistencies uncovered by the exhaustive and non-lattice versions of the lexical-based inference framework and SSIF.

Table 1 shows potential inconsistencies identified by exhaustive and non-lattice lexical-based inference frameworks. For example, the exhaustive approach has identified 5,359 potential inconsistencies with the set-of-words model while the non-lattice-based approach has identified 1,875 potential inconsistencies with the same model.

Table 1: A comparison of all potential inconsistencies uncovered by exhaustive and non-lattice lexical-based inference frameworks.

5 Discussion

In this paper, we implemented the non-lattice versions of our previous exhaustive lexical-based inference framework and subsumption-based sub-term inference framework for auditing *is-a* relations in GO, and performed a comparison between exhaustive and non-lattice-based approaches.

5.1 Performance comparison

From the performance comparison in Table 3 for the lexical-based inference approach, it can be seen that the non-lattice approach has outperformed the exhaustive approach considerably. The precision of the non-lattice-based approach is better by 5.19% for set-of-words model and 13.88% for the sequence-of-words model. However, the non-lattice-based approach only uncovers 35% and 34% of the potential inconsistencies that the set-of-words and sequence-of-words of the exhaustive approach identifies respectively. For instance, by both the set-of-words and sequence-of-words models, the exhaustive version identifies the missing *is-a* relation *diadenosine polyphosphate catabolic process* *is-a* *small molecule catabolic process* which the non-lattice-based approach does not.

From Table 4, it can be seen that the non-lattice-based approach exceeds the precisions by 0.93% for Monotonicity, 1.54% for Intersection and 16.47% for Sub-concept rules. However, it can also be seen that the non-lattice-based approach identifies 42%, 96%, and 11% of the potential inconsistencies that Monotonicity, Intersection, Sub-concept rules of the exhaustive approach finds respectively. For example, with the Sub-concept rule, the exhaustive version identifies the missing *is-a* relation *skeletal muscle cell differentiation* *is-a* *muscle cell differentiation* that the non-lattice version does not.

Therefore, from the results it is clear that the two non-lattice-based approaches perform better than their exhaustive counterparts in terms of precision. It seems that this performance increase also depends on the method itself since some methods (e.g. Sub-concept rule of SSIF) has gained more than the others.

It can be also seen that non-lattice-based approaches miss some of the potential inconsistencies that exhaustive approaches are able to uncover. We did not expect non-lattice subgraphs would capture all kinds of inconsistencies that exists in biomedical terminologies. However, we expected that the concentration of errors in non-lattice subgraphs would be higher than that in the general terminology and therefore, if the same method is applied exhaustively and inside non-lattice subgraphs, the non-lattice version would achieve a better precision.
It is easier to analyze a non-lattice subgraph than analyzing the entire terminology. If non-lattice subgraphs have a higher concentration of errors, such analysis may lead to the identification of new types of inconsistencies. Strategies to uncover and fix inconsistency types identified by analyzing non-lattice subgraphs may be applied exhaustively to identify more inconsistencies that non-lattice subgraphs itself do not capture. Therefore, non-lattice-based approaches may influence future exhaustive approaches in turn uncovering much more inconsistencies than NLS approaches alone can uncover.

5.2 Level differences of concepts and their superconcepts in the potential missing is-a identified

Since the non-lattice-based methods focus on substructures of a terminology and exhaustive methods works on the entire terminology, we also performed a level-based analysis of the potential missing is-a relations identified by exhaustive and non-lattice-based methods. For a descendant and an ancestor of a potential missing is-a relation, we first computed the level in the hierarchy for the descendant and the ancestor. The level of a particular concept is the number of concepts in the longest path from root to the particular concept. For a particular potential missing is-a relation, we subtract the level of the ancestor from the descendant to get the level difference.

Figure 6 shows a plot of the level differences and the number of is-a relations for the lexical-based inference approach. It can be seen that the lexical-based inference approach favors low level differences for both exhaustive and non-lattice-based methods. This means that the concepts in the potential missing is-a relations tend to be closer to each other in the hierarchy of the ontology. Other than the set-of-words model in the non-lattice-based approach, all other models have most number of potential missing is-a relations with a level difference of 0.

![Figure 6: Distribution of level differences of descendant and ancestor in potential inconsistencies uncovered through exhaustive and non-lattice version of lexical-based inference framework.](image)

Figure 7 displays the plot for level differences and the number of is-a relations for SSIF. It seems SSIF also tends to suggest hierarchically closer concepts as potentially missing is-a. Other than the Sub-concept rule in the exhaustive approach, all others have most number of potentially missing is-a with a level difference of 1.

5.3 Future work

In this work, we leveraged two previous exhaustive methods to compare non-lattice-based and exhaustive methods. We leveraged evaluations from the exhaustive methods to evaluate the non-lattice-based methods. Because of this, the
In this work, we also focused on one terminology: Gene Ontology. In the future we expect to see whether these results are terminology specific by performing a similar comparison on other major biomedical terminologies like SNOMED CT and NCI thesaurus.

6 Conclusion

In this paper, we performed a comparison of exhaustive methods vs non-lattice-based methods for auditing biomedical terminologies. We implemented non-lattice versions of two of our previous exhaustive works in auditing the Gene Ontology: (1) lexical-based inference framework and (2) subsumption-based sub-term inference framework. We leveraged the domain expert evaluations performed for the exhaustive methods to evaluate the non-lattice-based methods. The results indicate that non-lattice-based methods achieved better precisions than their exhaustive counterparts though, they do not capture some of the potential inconsistencies identified by exhaustive approaches.

Detecting Fine-Grained Emotions on Social Media during Major Disease Outbreaks: Health and Well-being before and during the COVID-19 Pandemic

Olanrewaju Tahir Aduragba, MSc1, Jialin Yu, MSc1, Alexandra I. Cristea, PhD1 and Lei Shi, PhD1

1Department of Computer Science, Durham University, Durham, United Kingdom

Abstract

The COVID-19 pandemic has affected the whole world in various ways. One type of impact is that communication, work, interaction, a great part of our lives has moved online on various platforms, with some of the most popular being the social media ones. Another, arguably less visible impact, is the emotional impact. Detecting and understanding emotions is important, to better discern the emotional health and well-being of the global population. Thus, in this work, we use a social media platform (Twitter) to analyse emotions in detail. Our contribution is twofold: (1) we propose EmoBERT, a new emotion-based variant of the BERT transformer model, able to learn emotion representations and outperform the state-of-the-art; (2) we provide a fine-grained analysis of the pandemic’s effect in a major location, London, comparing specific emotions (annoyed, anxious, empathetic, sad) before and during the epidemic.

Introduction

Disease outbreaks have remained a problem over many years. Most recently, with the Coronavirus disease (COVID-19) pandemic rapidly evolving, people across the globe have become extremely vulnerable. As of March 2021, over 100 million people from more than 200 countries have been infected1. To suppress the virus, governments worldwide have had to introduce restrictions to human movement and social gatherings. The widespread disruption to human lives has led to stress, economic hardships, and uncertainties about the future2. Therefore, it has stirred a diverse range of emotional responses, such as anxiety, sadness and anger3. In the absence of face-to-face undertakings and meetings, people have resorted to using social media to express how they feel. Social media sites (e.g., Twitter) are essential platforms, where users self-report their thoughts and feelings during public health emergencies4, allowing at the same time access to the public emotional health and well-being pulse. As a result, user-generated contents have become useful to monitor public perceptions and sentiments during past disease outbreaks, such as Ebola and Zika epidemics5,6, and the current COVID-19 pandemic7.

Detecting fine-grained human emotions from text is a challenging research area, due to limited manually annotated data. Therefore, emotional cues, such as emoticons and hashtags from texts, have been used for distant supervision, to serve as emotion labels, to build powerful deep learning models and predict fine-grained emotions accurately. For example, hashtags, such as #sad, #angry and #happy, were used to automatically annotate general Twitter data with fine-grained emotions and further used to train models, to learn useful text representations in an emotional context8.

Although pre-trained language models have been successful in a diverse range of natural language processing tasks9, they fail to consider knowledge that is important for tasks related to the determination of emotions, valence, or affective states from text10. For instance, previous studies11,12 have shown that learning sentiment-specific knowledge during pre-training could enhance the understanding of the sentiments in text, thereby improving sentiment analysis performance. However, there is limited research on the use of emotion-specific knowledge in fine-grained emotion detection. As sentiment analysis is related to emotion detection, we argue that integrating emotional knowledge into pre-trained models will result in better performance for fine-grained emotion detection. To this end, our research questions are:

**RQ1**: Can incorporating emotion information in learning models increase the performance of these models to understand the effects of major health events, such as pandemics?

**RQ2**: How can fine-grained emotion detection related to emotional health and well-being be performed based on social media utterances?
Thus, our work presented in this paper makes the following contributions:

1. We propose a novel deep transfer learning framework modelling entity-invariant emotional representations, and EmoBERT, the model we learnt under this framework. EmoBERT infuses emotion-specific knowledge into a pre-trained language model (BERT), thus being capable of learning useful emotional representations, unlike those obtained from traditional pre-trained language models. We experiment and compare against several state-of-the-art approaches, to illustrate the importance of integrating such knowledge in pre-trained language models for predicting fine-grained emotions (i.e. detecting a specific emotion, e.g. 'sad', rather than its presence).

2. We conduct, to the best of our knowledge, the first study on how the COVID-19 pandemic has affected public emotions on Twitter users in London, United Kingdom. We compare annoyed, anxious, empathetic and sad emotions expressed in tweets from March 2020 with the same period in 2019. We also separately perform an analysis of the hashtags mostly used in tweets expressing the selected emotions.

The remainder of the paper is organised as follows: the Related Work section gives an overview of related literature in emotion detection. The Model section details our proposed approach. The Results section reports experimental results and findings. The Conclusion section presents the conclusions and directions for future research.

Related Work

Emotion detection has been extensively studied in various settings, including online health-related forums and social media sites. In particular, analysis of emotions on social media sites has attracted significant research in the public health domain, to monitor public sentiments during disease outbreaks. However, emotion detection during public health emergencies is challenging, due to the lack of annotated data. Previous studies focused on using existing resources that were developed for general domains. Due to the nature of social media texts, such analyses could be biased towards domain-general contexts. To address the problem with limited availability of labelled data in emotion detection, some studies experimented with automatically annotating user-generated data with cues (e.g., emojis, emoticons, hashtags) specific to such corpora. However, there is limited research on the usage of emojis as emotion labels in the context of public health emergencies. Based on this, we have focused on analysing emojis in tweets - as we arguably assume that a tweet expresses an emotion if it contains an emoji.

Furthermore, existing research proved that pre-trained language models achieve state-of-the-art performances on natural language processing tasks, such as text classification, named entity recognition and question answering. Such models’ standard workflow involved initially pre-training on large amounts of unlabelled corpus data using a language model loss function, and the pre-trained model would then be fine-tuned on labelled data, to adapt to an (often different) downstream task. While being successful in the analysis of sentiments and emotions, they failed to consider task-specific objectives that may improve performance. A recent research enriched their model with sentiment information, by masking sentiment words and predicting the masked words and managed thus to capture rich sentiment knowledge. Another related work aimed to incorporate sentiment knowledge, by masking emoticons in a text and predicting if the masked token was an emoticon or not. However, most of these techniques focused mainly on identifying positive or negative sentiments. Our work uses similar concepts to infuse information about a range of emotions, but with the aim to benefit fine-grained emotion detection.

Model

In this section, we describe our fine-grained emotion detection in tweets model: EmoBERT. The success of deep neural networks (DNNs) has provided the ability to learn useful representations from large data (with or without annotation). DNNs have been widely used in natural language processing. The captured knowledge can be leveraged and used in downstream tasks. As a result, pre-trained language models, such as Bidirectional Transformers for Language Understanding (BERT), have been empirically successful across various tasks. BERT utilised Transformer networks and was trained on large amounts of unlabelled data from the Bookcorpus (containing 800 million words) and English Wikipedia (containing 2.5 billion words). Other variants of BERT, such as XLNet and RoBERTa,
have been proposed since the launch of BERT. We thus employ a BERT-based architecture, infused with emotional knowledge, for our task of fine-grained emotion detection (detecting a specific emotion e.g. sad or anxious) in tweets. We aim to instil in our model a strong inductive power and learn useful emotional knowledge. We exploit unlabelled tweets data related to our target domain to learn this knowledge. By adapting the model to the data closer to the distribution of our target data, our model will be capable of learning emotion-related bias. Our approach follows the standard BERT workflow, pre-training and fine-tuning. However, our fine-tuning step involves an intermediate step that helps incorporate emotional knowledge into our model (see Figure 1).

Pre-Training

Pre-trained language models have become popular in recent years, because they became capable of learning knowledge that is useful for transfer learning in natural language processing. One of the best known pre-trained language models, as aforementioned, is BERT. It was pre-trained using two language modelling objectives: (1) masked language modelling (MLM), where randomly masked tokens are predicted, and (2) next sentence prediction (NSP), predicting two input sentences that are next to each other. The pre-trained BERT could then be used to fine-tune on downstream tasks, such as text classification. Due to limited computational power, we employ BERT-base, a version of BERT which contains 12 transformer layers, to initialise EmoBERT. As noted, we expect the general knowledge captured from pre-training BERT to be useful for our fine-tuning step.

Emotion Knowledge Enhanced Fine-tuning

The first fine-tuning stage is the major novelty of our approach. Our goal in this intermediate fine-tuning step is to enhance our model with emotional knowledge for emotion detection. Formally, given our target domain $D_T$, our source domain $D_S$, and the tweet representations $X_S \in D_S$ belonging to the source domain, we aim to learn the target domain tweet representations $X_T$ via modelling their marginal probability distribution $P(X_T)$ over the target domain $D_T$ with explicit modelling of emotion knowledge. Note that both $X_S$ and $X_T$ consist of $N$ tweets and can be denoted in the general form as $X = \{x_1, x_2, \ldots, x_N\}$. At this stage, we fine-tune BERT, by using the mask language modelling objective to recover emotion information, while learning about the tweet representations $X_T$ and the distribution of our domain data $P(X_T)$. Our intermediate fine-tuning task is based on two concepts: (1) extraction of tweets with emotion emojis, and (2) emotion word masking.

Figure 1: EmoBERT Architecture
Extraction of Tweets with Emotion Emojis

As discussed, we assume that if a tweet contains an emotion emoji, then it carries some emotional information. Facial expression emojis allow Twitter users to express their feelings with non-verbal elements in a tweet\(^9\). Although emojis in texts may not always reflect the emotions experienced by users, recent works have shown that they can still be used to classify the emotional content of a text\(^30,34\) accurately. For example, sad emojis such as 😢 and 😞 show a strong correlation with sad emotions in tweets, whilst anger emojis such as 😡 and 😡 are strongly associated with anger emotions\(^31\). Our use of tweets with emotion emojis has two advantages. Firstly, Twitter is very noisy, and it contains many tweets that do not express any emotion. This way, we can eliminate spurious tweets and preserve only tweets with, arguably, emotional information. Secondly, as discussed above, we can take advantage of the emotional cues from the emojis present and use this information to enhance the detection of emotions from tweets in our model. We use emojis that belong to the “Smileys & Emotion” category based on the official Unicode emoji set\(^1\), that are part of the most commonly used emojis on Twitter\(^2\), to filter out our unlabelled tweets datasets. Thus, we implicitly induce emotion specific biases, by only training on tweets that contain at least one emoji from our emoji shortlist.

Emotion Word Masking

We use the same MLM objective function as in the BERT paper\(^9\) to fine-tune the pre-trained model extracted from the Huggingface library\(^32\). The MLM objective was to predict the original tokens, given the masked token. BERT’s standard masking strategy involved randomly sampling and selecting 15% of the input tokens and then replacing 80% of these sampled tokens with a special masked token [MASK]. Another 10% were replaced with a random token, while the remaining 10% of the sampled tokens were kept unchanged. In addition to the standard MLM for BERT, our approach uses emotion word masking (see Figure 2) for learning emotional knowledge in the text. This masking process is different from the standard MLM in BERT. Since the emotion words are likely to impact on the emotion expressed in a tweet, we use a higher masking probability (50%) for masking emotion words.

To determine emotion words, we employ the NRC Word-Emotion Association Lexicon (a.k.a. EmoLex)\(^33\). EmoLex consists of 14,182 crowdsourced English words associated with eight basic emotions: anger, anticipation, disgust, fear, joy, sadness, surprise and trust\(^34\). Whilst there are other lexical emotion resources, such as DepecheMood\(^35\), we chose EmoLex due to its large size and coverage of broad emotional dimensions\(^36\). Additionally, past works such as\(^37\) have used this lexicon as a prior association of emotions, to detect emotions in texts automatically. An initial examination of the lexicon shows that some lexicon words are associated with no emotion category mentioned above. We remove such words, since they were deemed not useful for our emotion-word masking and select only words associated with at least one emotion on our list. After the elimination process, we use a total of 4,463 words from the lexicon.

![Figure 2: Emotion word masking](https://emojitracker.com)

---

\(^1\)https://unicode.org/emoji/charts/full-emoji-list.html

\(^2\)as indicated in https://emojitracker.com
BERT used the WordPiece algorithm as its tokenisation algorithm, to deal with words that are out of its vocabulary, by splitting them into sub-word tokens present in its vocabulary. We expected that some emotional words would be out of BERT’s vocabulary. For example, the emotion word “somatic” could be split into “so” and “##matic” by this BERT tokeniser. In our model, we define the masked emotion word as the sub-word tokens that correspond to the original emotion word.

Since emotion words appear in emotional contexts, our model aims to capture implicit emotion knowledge representations and preserve information that could be useful in detecting the emotions expressed in a tweet. For the intermediate fine-tuning task, we use a collection of original (no retweets) English tweets collected in April, 2020, related to COVID-19, using keywords such as coronavirus, corona, covid, covid-19, coronaoutbreak, 2019nCoV, pandemic, epidemic, wuhanandlockdown and sars-cov-2. Consequently, we filter the training tweet datasets to contain at least one emoji from our emoji selection and remove all duplicate tweets. In total, our training dataset contains 1,540,983 tweets after the data filtering process. Furthermore, we pre-process all tweets, by replacing all Twitter usernames and URLs with the common tokens: <user> and <url>, respectively.

**Emotion Detection Fine-tuning**

In the final step, we fine-tune EmoBERT on our downstream task: fine-grained emotion detection. Outputs from the emotion knowledge-enhanced fine-tuned model are trained to classify the emotion of a tweet. Following the fine-tuning setting in the original BERT paper, we use the last state vector of the classification token [CLS] as input and feed it into a feed-forward neural network, to predict the respective emotion.

**Experiment**

We use a publicly available annotated dataset, SenWave, providing fine-grained emotion labels of tweets during the COVID-19 pandemic, to evaluate our model. This dataset consists of 10,000 English tweets, labelled with 10 categories: optimistic, thankful, empathetic, pessimistic, anxious, sad, annoyed, denial, official report and joking. We consider 3 emotions (annoyed (anger), anxious and sad), which are part of the fundamental emotions from Plutchik’s model, and an additional emotion (empathetic), which has been shown to be expressed in discussions about chronic illnesses in online health communities. We believe the chosen emotions are related to individuals’ mental well-being and can provide some insights into the public mood during the COVID-19 pandemic. Figure 3 shows the distribution of the chosen emotions from the annotated dataset.

Since a tweet can be annotated with more than one emotion, we create 4 binary classification tasks: annoyed/non-annoyed, anxious/non-anxious, empathetic/non-empathetic and sad/non-sad, to determine if an emotion is expressed in a tweet. To create the negative samples for an emotion category, we sample an equal amount from the other emotion categories. Following this, we shuffle the positive and negative samples and perform an 80/10/10 split, to create the training, validation, and test sets, respectively. Although the number of positive and negative samples is matched

---

1 instructions on accessing data can be found at https://github.com/gitdevqiang/SenWave
and balanced, they are not necessarily the same number of samples in the training, validation, and test splits, thereby representing a more natural distribution of labels. Furthermore, we repeat the negative sampling (with replacement) 10 times for each emotion category, to create 10 dataset samples per emotion category. This aims to reduce any sampling bias in selecting the negative samples. Finally, we have 10 data samples for each emotion with train, validation, and test sets. We train our models with all data samples and report the mean performance across the 10 data samples per emotion category. For all models, we train using binary cross-entropy, loss to align with the target class distribution. We use the Adam optimiser with a learning rate of 5e-5 and set the number of epochs to 4 and batch size to 16 for the final model based on prior empirical experiments.

We compare our model with two general pre-trained models: BERT\(^9\) and XLNet\(^27\). These models, which have achieved state-of-the-art performance on various natural processing tasks, serve as our baselines.

**Results**

Table 1 presents the results obtained using our model, EmoBERT, compared with generally pre-trained language models, i.e. BERT and XLNet. EmoBERT achieves higher performance across all the considered emotion categories. On average, EmoBERT outperforms other state-of-the-art approaches by at least 3% F1 score. This shows that incorporating emotion-specific knowledge in pre-trained language models is effective for detecting fine-grained emotions.

Table 1: Emotion detection results averaged across 10 dataset samples. The numbers are percentages. Best results are in **bold**. Precision - P, Recall - Re and F1 score - F1.

| Model | Annoyed | | | | | | Anxious | | | | | | Empathetic | | | | | | Sad | | | |
|-------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|
|       | Pr     | Re     | F1     | Pr     | Re     | F1     | Pr     | Re     | F1     | Pr     | Re     | F1     | Pr     | Re     | F1     | Pr     | Re     | F1     |
| BERT  | 0.78   | 0.80   | 0.78   | 0.68   | 0.73   | 0.69   | 0.83   | 0.74   | 0.77   | 0.71   | 0.77   | 0.73   |
| XLNet | 0.74   | **0.83** | 0.77   | 0.63   | **0.81** | 0.69   | 0.73   | 0.67   | 0.69   | 0.69   | 0.77   | 0.72   |
| EmoBERT | **0.81** | 0.82   | **0.81** | 0.72   | 0.73   | **0.72** | **0.84** | 0.79   | **0.81** | 0.71   | 0.84   | **0.76** |

**Significance Test**

To determine if our results are statistically significant, we perform a paired T-test to test the differences between the model results for all 10 runs per emotion category. The result confirms that the improved F1 score results from EmoBERT over BERT are statistically significant at \( p < 0.05 \) across all emotions, except for the anxious emotion.

**Tracking Emotional Toll of COVID-19 on Twitter**

To further illustrate the power of our model, we present a focused analysis of the impact of the COVID-19 pandemic on well-being and emotions in London, United Kingdom (UK), using EmoBERT. We study a collection of tweets geo-located in London in March 2020 and compare them to the same period in 2019. The tweets were collected using the new Twitter API for academic research that grants access to the full Twitter archive\(^4\). Initially, we collected all tweets geo-located in the UK and then extracted from that pool tweets that contained London in the full name of the place information\(^5\). Non-English tweets, replies, and re-tweets were not included in the collected tweets. Our resulting sample consists of 361,384 tweets for March 2020 and 352,678 tweets for March 2019. We have selected that period because the lockdown due to COVID-19 was announced by the UK government in March 2020.

We classify each tweet from the respective periods with one of the 4 emotions (annoyed, anxious, empathetic and sad). Since we evaluate our model on 10 different dataset samples, the 10 classifier models for each respective emotion are ensembled and the average of their probabilities is used to predict the final class labels. For all emotions, each tweet is classified as expressing that emotion or not (e.g., sad/non-sad). The emotion expressed in each tweet is measured by the probability of the positive class membership of that emotion. We define the probability of emotion \( p_d \) present in tweets on day \( d \) and use the logistic regression classifier as follows:

\[ p_d = \frac{1}{1 + e^{-\beta}} \]

\[ \beta = \sum_{i=1}^{n} w_i x_i \]

where \( x_i \) are the features of the tweet and \( w_i \) are the weights.

\(^4\)https://developer.twitter.com/en/solutions/academic-research/products-for-researchers

\[ p_d = \frac{1}{1 + e^{\exp(-x_d)}} \]  

(1)

where:

\[ x_d = \frac{1}{N_d} \sum_{t=1}^{N_d} \ln\left( \frac{p_{td}}{1 - p_{td}} \right) \]  

(2)

Where \( x_d \) denotes the proportion of emotion present in tweets on day \( d \), \( N_d \) is the number of tweets on day \( d \) and \( p_{td} \) represents the probability of emotion expressed in tweet \( t \) on day \( d \). We take the mean of the logit function in equation 2, because the means of skewed variables are not necessarily representative of those variables. Probabilities tend to exhibit such skewness, because they are bounded, so it is often cleaner to do algebraic manipulations on an unbounded scale, such as logit, then back-transform\(^4\).

Figure 4 shows the comparisons of the emotions for each respective year. Generally, the proportion of tweets expressing emotions in 2019 show a similar trend over time. There is no notable change in the emotions for that period. Similarly, the tweets expressing annoyed and sad emotions in 2020 are consistent during the period. Interestingly, the tweets expressing the anxious emotion rise sharply after the 5th of March (after the first COVID-19 related death was announced in London)** before levelling off and declining around the 20th of March 2020. The tweets expressing empathetic emotion rise slightly in the middle of the month and begin to decrease after about 10 days.

![Figure 4: The trend of emotions from the 1st March through 31st March for years 2019 and 2020](https://www.bbc.co.uk/news/uk-england-london-56271001)

Although the trend in tweets expressing annoyed and sad emotions over time is similar in 2019 and 2020, the level of emotions is slightly higher in 2020 than in 2019.

We measure the effect size using Cohen’s \( d \) to determine the difference between each respective year’s emotions\(^2\) and report \( p\)-value after Benjamini-Hochberg p-correction. On average, more tweets expressed annoyed (Cohens \( d = 0.21 \), \( p = 0.05 \)), anxious (\( d = 1.99 \), \( p < 0.05 \)), empathetic (\( d = 0.73 \), \( p < 0.05 \)) and sad (\( d = 0.5 \), \( p < 0.05 \)) emotions in

\( **\) https://www.bbc.co.uk/news/uk-england-london-56271001
2020, compared to 2019, suggesting that there is a difference in the expression of emotions in tweets as a result of the COVID-19 pandemic.

To understand more deeply the distribution of emotions in tweets related to the COVID-19 pandemic, we further extract, from the tweets geo-located in London, those containing the following keywords: coronavirus, corona, covid, covid-19, coronaoutbreak, 2019nCoV, pandemic, epidemic, wuhan and lockdown and analyse them in-depth. We build a matrix of the emotion distributions with the most frequent hashtags that appear in the filtered tweets. Hashtags are strong indicators used to provide context, emotions or topics related to a tweet. Figure 5 shows the heatmap of the distribution of emotions and the top 40 hashtags. The distribution of emotions is calculated as the number of instances in which the emotion is expressed in a tweet with the hashtag, divided by the total number of tweets containing that hashtag from the body of extracted tweets\(^2\). As can be seen in Figure 5, tweets expressing sad and anxious emotions are prevalent in the hashtags used in the COVID-19-related tweets. Hashtags in tweets expressing empathetic emotions are common in campaigns about staying safe and staying at home, while hashtags in tweets expressing annoyed emotions are more related to the crisis and chaos in the UK, as a result of the pandemic.

The majority of the hashtags used in tweets expressing the sad emotion are #isolation, #quarantine, #londonlockdown and #coronapocalypse. London is a travel hub and, understandably, the tweets are expressing sadness about travel restrictions, such as quarantine, isolation and lockdown in London. The tweets also express sadness about what some people have regarded as the 'end of the world' because of the pandemic. Amongst tweets with the #coronavirusoutbreak, #covid-19, #coronavirusupdates and #coronaoutbreak hashtags, the anxious emotion is preponderant. This suggests that a significant amount of tweets are expressing anxiety about the COVID-19 pandemic and particularly around the updates provided on the virus.

![Figure 5: Top 40 hashtags for COVID-19 related London tweets in March 2020](image)

The majority of tweets with hashtags such as #coronavirusuk, #covid-19uk and #coronacrisisuk express the annoyed emotion predominantly. Amongst these, hashtags related to the coronavirus crisis in the UK are most common. It can be seen that #staysafe, #staysafelives and #nhs hashtags, which are related to the UK government official campaign advising people to “stay home, save lives and protect the NHS (National Health Service)”, appear more frequently in tweets expressing the empathetic emotion.

**Conclusion**

In this paper, we propose a new method to analyse the emotional health and well-being of global as well as local populations (here, London), by using a new model called EmoBERT. This model adds emotion representation to the previously cutting-edge BERT model, outperforming the current state-of-the-art. Additionally, we have selected emotions related to health and health communities, to showcase a methodology for an in-depth comparison between social media emotions before and during the COVID-19 pandemic. We further showed how these selected emotions can be used to understand the individual topics that are likely to evoke them. We applied the latter locally, on a major location, London, as we expected it to be strongly affected - as confirmed by our analysis. Similarly, for further work, other specific areas can be analysed with the methodology we have defined. Limitations of our approach include analysing only one (freely available) social media platform (Twitter), which may only reflect the emotions of a specific section of the population. Such results could further be extrapolated with other social media sites e.g. Facebook or Weibo, as well as data from the World Health Organisaton (WHO) or local health authorities, for a higher accuracy.

Abstract

The informed consent process is a complicated procedure involving permissions as well a variety of entities and actions. In this paper, we discuss the use of Semantic Web Rule Language (SWRL) to further extend the Informed Consent Ontology (ICO) to allow for semantic machine-based reasoning to manage and generate important permission-based information that can later be viewed by stakeholders. We present four use cases of permissions from the All of Us informed consent document and translate these permissions into SWRL expressions to extend and operationalize ICO. Our efforts show how SWRL is able to infer some of the implicit information based on the defined rules, and demonstrate the utility of ICO through the use of SWRL extensions. Future work will include developing formal and generalized rules and expressing permissions from the entire document, as well as working towards integrating ICO into software systems to enhance the semantic representation of informed consent for biomedical research.

Introduction

Informed consent (IC) is a process intended to ensure that an individual (or their legally authorized representative), has sufficient information and understanding to voluntarily make a decision about participating in a research study. IC documents provide individuals with the information needed to make a decision about whether to volunteer for a research study and serve as a record of the decisions made during IC. In this way, IC documents serve as an important communication vehicle between the research team and potential study participants (or legally authorized representatives). IC documents provide information about actions the signer of the IC document prescribes as allowable, given the information within the IC document.

The specific research context we address are studies that aim to collect and share biospecimens, the data derived from analysis of those specimens, and other sources of data that can be associated with the study participant. Informed consent documents, when signed, establish and preserve important linkages among the persons signing the consent form, the research team, stewards and managers of specimen and data repositories, and other potential future users of specimens and/or data; the IC documents become a ‘source of truth’ regarding the allowability of potential actions by the research team and others.

There are several notable efforts that focus on open, computable representations of permissions expressed in IC consent documents. For example, the Community Based Collaborative Care Resource Work Group within Health Level Seven (HL7) is developing a consent resource specification \url{https://www.hl7.org/fhir/consent.html}. The resource targets four use cases: (1) privacy consent directive, (2) medical treatment consent directive, (3) research consent directive, and (4) advance care directives. Currently, the published version (v4.01) is limited to the privacy consent directive. Of particular relevance to our interest, developers of the FHIR resource define a consent directive as “the legal record of a patient's (e.g. a healthcare consumer) agreement with a party responsible for enforcing the patient's choices, which permits or denies identified actors or roles to perform actions affecting the patient within a given context for specific purposes and periods of time.” A consent form is defined as “Human readable consent content describing one or more actions impacting the grantor for which the grantee would be authorized or prohibited from performing. It includes the terms, rules, and conditions pertaining to the authorization or restrictions, such as effective time, applicability or scope, purposes of use, obligations and prohibitions to which the grantee must comply.” The FHIR consent resource does not yet address the challenge of expressing the multiple consent directives that may be present in a single IC document, nor the challenge of linking detailed information such as actors, actions, and...
conditions to one or more consent directives within the document. Our teams have reviewed thousands of research and clinical IC documents, using both manual and machine learning based approaches. Many if not most of the documents we reviewed include multiple permission-directives (i.e., consent directives), are often stated ambiguously, and contain relations to clauses throughout the document that are necessary to understand the permission itself. Since the FHIR specification is not fully developed, value sets that reflect the full spectrum of terminology needs related to research permissions are not yet identified.

Another example of efforts to support computable representations of permissions in IC documents is published by the Global Alliance for Genomics and Health (GA4GH). Included in their regulatory and ethics toolkit are suggested consent clauses for genomic research and for rare disease research, as well as machine readable consent guidance. The consent clauses are intended to be used as a resource for researchers as they draft IC documents, with language that is consistent with the GA4GH standards for essential consent elements. Currently, the consent clauses are available only as text-based sentences; there is no machine-processable format. The GA4GH machine readable consent guidance similarly provides another resource for researchers as they construct IC documents, however this resource provides a mapping from a set of sample consent clauses to terms that have been adopted by the Data Use Ontology (DUO). DUO is published within the OBO Foundry suite of ontologies, and based on the Basic Formal Ontology that is the upper level ontology on which all OBO Foundry ontologies are built [http://www.obofoundry.org/ontology/duo.html](http://www.obofoundry.org/ontology/duo.html). The intent of DUO is to standardize downstream data use concepts into a machine-readable format while tagging datasets with restrictions about their usage; DUO lacks detail about the IC process and documents.

While the HL7 and GA4GH efforts are intended to support consistent and comparable exchange of information about consent directives and potentially more detailed information about permitted actors, actions, and conditions, neither supports full semantic interoperability including IC processes and entities expressed in IC documents. A desirable feature of full semantic interoperability is that it allows for the use of semantic reasoners, based on predicate logic, to infer relationships between information; in this case, information about permissions derived from the informed consent documents.

In this study, we build on our previously developed Informed Consent Ontology (ICO) [https://github.com/ICO-ontology/ICO](https://github.com/ICO-ontology/ICO). Intended for use as a reference ontology, ICO represents processes and information entities pertaining to informed consent in biomedical investigations. ICO is based on the upper level Basic Formal Ontology (BFO), and adheres to the OBO Foundry framework for authoring and editing BFO-based ontologies; it is licensed under the [Creative Commons Attribution 4.0 International Public License](https://creativecommons.org/licenses/by/4.0). The August 2020 ICO release includes a full alignment with DUO and a new set of ‘information content entities’ that reflect categories of information needed to fully express information about permissions, i.e. permission-directives as well as relevant-to-permission information. The two classes of ‘directive information content entity’ and ‘designative information content entity’ are hierarchical, with subclasses of ‘permission directive’ and ‘permission condition directive’, and ‘designated actor’, ‘designated action’ and ‘designated object’. Each of the subclasses has a small number of additional hierarchically modeled classes. We define a ‘permission-directive’ as a directive information content entity that prescribes an allowable action, where that action is otherwise impermissible. Permission directives are usually expressed in IC documents as statement(s) that, upon signature of the consent form, authorizes actions by actors that would otherwise not be allowable. Phrases such as “I consent to”, or “I agree to” may be indications of permission-directives. More specific information about what action may occur, when it may occur, why it will occur, and any conditions under which it may occur is commonly found in other clauses, and often not co-located with the permission-directive.

**Semantic Web Rule Language.** Semantic Web Rules Language (SWRL) is a W3C semantic web language extension to implement predicate logic on variables. SWRL’s benefit in relation to ontologies is to enable expressive machine-based rule reasoning for instance-level data and add additional expressiveness on top of the Web Ontology Language (OWL). The composition of SWRL contains two conditional propositions - antecedent condition (AC) and consequent condition (CC). The AC is a conditional body proposition that describes the "if" aspect of a rule statement and the CC is the head proposition that describes the "then" condition. Basically, the completeness of a SWRL is contingent on whether the conditions described in the body (AC) and the head (CC) conditions are satisfied. The expression below shows an example of a simple SWRL statement.

```
Person(?a) ^ of_age (?a, ?age) ^ swrlb:greaterThan(?age,18) ^ residesInCountry(?a, United States) -> Adult(?a)
```
For the simplified example described, a rule statement for determining legal adulthood is complete if only if the entity (?a) is a person that has an age greater than or equal to the value of 18 and resides in the United States. Each component within the statement is an atom which is the core building block of the statement. These SWRL atoms describe the classes (Person), individuals (a, age), data values (18), and other built in utility arguments. For this paper we introduce the possibility of expressing the complexity and execution of permissions in IC documents using SWRL and the ICO.

Research Objective: In an effort to extend the ICO, we intend to use SWRL to enhance the expression and application of informed consent. The application of SWRL could further enhance the expressive power of ICO by mapping specific data entities in the informed consent process (actors, data, agreement, etc.) and operationalize it for the software system. We presume that ICO through the extension of SWRL can express and operationalize permissions embedded in informed consent documents. The outcome of this study would demonstrate the practicality of using SWRL to extend the operational use of ICO for software systems.

Methods

To determine if our approach could successfully represent contemporary permission constructs we examined a single IC document, the sample primary IC document from the NIH “All of Us” research program, dated June 20, 2018. The All of Us program seeks to recruit one million or more diverse participants to a large observational trial with the end goal of supporting a variety of use cases within precision medicine (https://allofus.nih.gov/). When signed, an “All of Us” IC document authorizes the collection, retrieval, sharing, and reuse of participant’s basic data, health data, physical measurements, biological specimens, fitness trackers and additional data from sources such as health registries, pharmacies, and claims data. Content from electronic health records can be used if the HIPAA authorization form is signed. We selected this IC document for this study because of the scope and familiarity of the “All of Us” study, and because in our earlier review of IC documents retrieved from ClinicalTrials.gov, the readability of the “All of Us” document was at an easy to read level, and thus did not present our study with ambiguous language. We did not include the separate HIPAA authorization form that is required if participants choose to allow access to their electronic health record data.

The All of Us IC document includes 270 sentences. Only one was a permission-directive, 130 (48%) were relevant-to-permission sentences, and 139 (52%) sentences categorized as “other,” i.e. important information but not relevant to the purpose of this study. A single permission-directive was identified: “I freely and willingly choose to take part in the All of Us Research Program.” Examples of permission-relevant sentences included the following:

- “These are results that could be used by a healthcare provider to take better care of you. For example, if any of your physical measurements are outside of what we would expect, we will tell you so you can follow-up with your healthcare provider.”
- “If I give a blood, urine, or saliva sample, it will be stored at the All of Us biobank. This includes my DNA.”
- “Information that researchers learn by studying my samples will be stored in the All of Us databases.”
- "Researchers will do studies using the All of Us databases and biobank. Their research may be on nearly any topic."

With each permission there are one or more consent directives that link the designated instance data for designated actors, designated actions, designated purposes, and designated objects. Essentially a data instance of a consent directive would link to instance data, and related entities from the consent document. As we will show later, through semantic rules, additional links based on the few links described will be inferred to show implications of agreeing to the consent. Definition 1 of our model elucidates the notion that IC documents may contain various permissions and that each permission has a consent directive entity. Definition 2 further elaborates on our model with designated entities of actors, action, purpose, and object.

Definition 1. For any informed consent form icf there exist a set of permissions P belonging to an informed consent form icf. Also, there exists one consent directive cd for every permission P.

\[
\{P_1, P_2, P_3, \ldots, P_n\} \in icf
\]

\[
cd_n \in P_n \text{ where } n > 0
\]

Definition 2. We define designated entities DE as a set of designated action da, designated actor dr, designated purpose dp, and designated object do, that has a relation ret about with a consent directive cd that describe A.

\[
DE = \{da, dr, dp, do\}
\]

\[
ret_{about}(cd_n, DE_m) = A; \text{ where } n > 0 \text{ and } m > 0
\]
Each permission describes probable designated actors that include the subject (the person signing the consent form – the designated permitting actor), the institutions and organization that may be involved – e.g., National Institute of Health, some research organization, All of Us initiative, and the research team members including the principal investigator (the designated permitted actors). Additionally, designated object for each of the models are described if the permission refers to subject’s data – e.g., general health information, personal health information, or some biospecimen. The models also include the designated purpose and designated action that expresses motivation (research, therapy, etc.) and the general action on the designated object for which permission is being given (disclosure of data, data collection, etc.).

The permission includes planned processes that are described in the informed consent ontology where the designated entities link either explicitly or implicitly (through machine inference). For the former and depending on the expression, there is a defined implication that consenting is act of authorizing some type of permission to another actor. For the implicit links to the planned process, there are allusions to future processes if the subject consents – e.g., granting permission to the researchers to use the shared data, agreeing to inform the patient of change of care, storing the subject’s data, etc. These implicit inferences, since the entities are modeled as instance data, will be derived from Semantic Web Rule Languages (SWRL) to be discussed in the next section. Definition 3 explains that for a permission, there are predicates (defined as A) that are members of a permission of an informed consent. These predicates make references to planned process(es), which can be inferred.

**Definition 3.** Every permission P of an informed consent form entails a subset A that produces an allusion → to some planned process pp. Essentially, any derivative of A is an allusion → to some planned process pp.

\[
P \ni \{\{A_1, A_2, \ldots, A_n \rightarrow pp\}\}
\]

where \(A \iff rel^{about}(cd, \{da_m, dr_m, dp_m, do_m\}), m > 0\)

\(\vdash rel^{about}(cd, \{da_m, dr_m, dp_m, do_m\}) \rightarrow pp\)

With our general defined model of abstracting permissions from informed consent documents, we developed SWRL expressions that can be reasoned on the available entity data extracted from the permissions to infer entities that may be implied when agreeing to participate in a study. We chose the aforementioned four permissions from All of US document to test our approach.

**Results**

For each of the aforementioned examples (Use cases 1 through 4), we produced individual SWRL expressions to generate implied agreement for procedures based on entity data derived from the informed consent document. We populated the ICO ontology with instance level data associated with probable entities in Protégé 5.5. We executed the SWRL rules and reviewed the generated inferences to assess execution of the rule in an iterative process to refinement. We utilized the built-in Hermit reasoner of Protégé which supports the generation of inferred axioms from SWRL.

**Use Case 1.** This use case involves understanding the process of participating in the informed consent process for collection of participant’s health data (designated process of collection and designated health information) for research (designated biomedical research purpose). The underlying assumption that once the subject agrees to this permission (consent directive) there is presumed permission (legally effective consenting) and that the researchers have informed the participant of the study process (explaining to participant candidate in informed consent process) and met the baseline requirements for informing, which are inferred and reasoned through the ontology. Following the participant (designated permitting actor) providing consent, the research actors become designated permitted actors by inference. Figure 1 models Use Case 1 permission, and Code Listing 1 shows the SWRL expression to execute our use case.
Please check the box below if you agree to take part: I have read this consent form (or someone read it to me). I understand the information in this form. All of my questions have been answered. I freely and willingly choose to take part in the All of Us Research Program.

**Figure 1.** Use Case 1’s instance-level ontological model

Listing 1. Use Case 1’s SWRL expression.

The SWRL code from Listing 1 successfully executed the embedded rules (See Figure 2). From the figure, it shows:

1. The participant (designated permitting actor), through inference and formally agreeing to the permission, participating in (participates in) the legally effective consenting (legalconsent).
2. The research team consisting of the primary investigator (“pi”) and the team (“team”) are inferred as designated permitted actors as a result of the subject executing consent to the permission. In addition there’s an expectation of participation in (participates in) explaining details of the study as expressed in the informed consent form (see 4).
3. participates in is an object property of ICO that has an inversed version, has participant. As a result, the ontology reasoned has participant for the subject that consented to the permission (“I”) with the legally effective consenting (a planned process) as the domain.
4. Similar to 3, the planned process of explaining to potential participant through study informing process inferred has participant for the research team and the PI (“pi”). There was also a set of planned processes relating to explaining the study information in the informed consent form that was reasoned. Through implication, these covered the informed consent requirements when discussing the study.
Use case 2. The second use case outlines the permitting actor’s agreement (after consent) that, if participant data were to have indications that were abnormal, then the researchers’ responsibility is to inform the participant about results in order that he/she may seek a health care provider; the expectation is that participant will follow through. This use case model infers (participates in) that the consenting permitting actor, is likely to seek standard medical treatment and infers that the researchers, both the primary investigator and the team will carry out (participates in) the informing process (act of informing). Similar to first case, the researchers, upon the subject’s agreement, will be designated permitted actors. Figure 2 visualizes this use case model’s execution of the permission’s agreement by the subject and Listing 2 shows the corresponding SWRL code.

Results that might change your medical care. These are results that could be used by a healthcare provider to take better care of you. For example, if any of your physical measurements are outside of what we would expect, we will tell you so you can follow-up with your healthcare provider. You will have to pay for the cost of follow-up care with your own healthcare provider.

Figure 3. Use Case 2’s instance-level ontological model.

Listing 2. Use Case 2’s SWRL Expression.

From the execution of the SWRL coding, the following figure (Figure 4) shows the various inferences:

1. The designated permitting actor (the subject who agreed to the permission) is inferred to comply in participating in (participates in) following up with medical care if the subject’s data is abnormal.
2. The investigation team of the primary investigator (“pi”) and cohort (“team”) is inferred in participating in informing (“toinform”). This also includes assigning them as designated permitted actor(s).
3. The SWRL execution also includes inferring the inverse of participates in (has participant) for the designated permitted actors and designated permitting actor.

Use Case 3. The third use case describes a model where upon the subject’s execution of agreement, it permits the execution of authorizing (act of authorizing) the sharing of his/her biospecimen data (act of data sharing) and the storage of subject’s biospecimen data (act of storing a specimen) by the inferred designated permitted actors of the primary investigator and his/her team. The data to be stored is restricted (via restricted to) just to the urine, blood, and saliva. This use case’s SWRL code is described in Listing 3.

Listing 3. Use Case 3’s SWRL expression

The results of SWRL expression from Listing 3 are presented in the figure below (Figure 6). As a result of the research subject executing consent here are the inferred expectations:
1. The research subject who consented to sharing data participates in act of data sharing (“tosharedata”).
2. The subject authorization is restricted to storing and sharing of his data – “tostoredata” and “tosharedata”.
3. Research team members involved are inferred to be designated permitted actor(s) and are inferred with the expectation to store the subject’s data with participates in.

4. From the participates in inverse feature, the ontology infers participant for act of data sharing (for the subject “I”)...

5. …and for act of storing a specimen (for the “pi” and “team” — researchers). Additionally, the storage of data is restricted to just the participant’s saliva, blood, and urine with an inference of is restricted to.

Figure 6. Series of screenshot showing inferences generated through SWRL for Use Case 3.

Use case 4. The model for this use case expresses conditions that indicate restrictions based on the data available from the participant (urine, blood, saliva of type designated biospecimen) and their use will be for any research topic in the future (designated process of unspecified use and designated research purpose). Structurally, the abstraction for this model shares some similarity with Use Case 3. If the research participant consents, then the permitting actor authorizes (act of authorizing) the use of the data by the researchers (inferred as designated permitted actors) is restricted to (by inference) the subject’s urine, blood, and saliva. The code listing (Code Listing 4) shares some similarity with the previous that was executed.

Figure 7. Use Case 4’s instance level ontological model.
Listing 4. Use Case 4’s SWRL expression

The following figure (Figure 8) shows the successful execution of the use case’s model from Listing 4. In the figure we show:

1. The act of authorizing by the subject is restricted to the act of using study participant data.
2. Similar to the other example use cases, the research team is inferred to be designated permitted actor(s) and they will participate in using the data (act of data using study participant data).
3. Like Use Case 3, the act of using study participant data is restricted to subject’s blood, urine, and saliva, and through the inverse of participates in, expresses the inference that this act involves the research team of the primary investigator (“pi”) and his/her research team (“team”)

Figure 8. Series of screenshots showing inferences generated through SWRL for Use Case 4.

Discussion

In this project, we demonstrate the utilization of the Semantic Web Rule Language (SWRL), an extension of OWL, to provide inferencing of entity instance data from informed consent documents. The use of SWRL could effectively enhance the application of ICO to manage complex and essential IC data that must be linked for understanding permissions. Moreover, this work could be potentially integrated into software systems. In this way, we address the gap in establishing traceability from details included in the consent form to repositories and other systems.

Figure 9. Software system for managing and querying informed consent showing the integration.

While much of what we presented was implemented through the Protégé environment, with the SWRLAPI combined with the ICO model, one can potentially create custom software integration to be incorporated into software systems, as shown in Figure 9. The study participant, through an interface, confirms his/her agreement to participate in a study by signing an IC document. The data from the IC document, along with the contextual and meta-data information that are not explicitly stated, are transferred from the software interface to the system. The system software converts these data to instance data. This instance data is added and labeled to ICO, and with the assistance of SWRL extensions, reasoning is performed on the data. The consent data (including the reasoned consent data) can later be queried by clinicians.

From our four use cases we demonstrated the utility of our proposed method. Each use case demonstrated not only translating the permission to a computable format using ontology language (OWL and SWRL), but they also demonstrated predictability inferencing, using ontology-based reasoning to generate links to entities that may not be explicitly evoked in the consent form (e.g., identifying designated actors).

Several limitations are noted. The rules and the ontological translations are only examples, and used to show proof of concept; they are not comprehensive or complete since we limited our sample to one IC document with one permission-directive. In addition, we have only used the “is about” relation; our goal here was to identify information content that could be tagged and serve as a foundation for use in computable semantics such as inferencing operations.
There were a handful of concepts that could not be precisely expressed, due to a lack of coverage of minor entities. Some of this apparent lack of coverage in ICO may result from the need to import content from other BFO-based ontologies in the OBO Foundry. These cases need to be enumerated and then used to either identify gaps in ICO itself, or negotiate inclusion in other ontologies in the OBO Foundry. ICO provides a general model of informed consent and does not include in its scope the modeling of regulatory concepts; there is a need to support the creation of SWRL rules to help extend legal, regulatory, and policy expressions. One probable future goal is to automate the translation of SWRL rules from informed consent documents. However, a more achievable and transparent method would be a visual authoring tool to create the SWRL expressions that align with the permissions in the informed consent document. We are encouraged from our experience in authoring the expressions based on the ontology and the SWRL rules, that this could be generalized for most of the informed consent documents as there are consistent semantic structures involved in accurately expressing permissions. Our group is pursuing the creation and validation of such models. Finally, the focus of the work we presented is permissions embedded in the informed consent document. Our observation in the use cases are of similar and repeated abstractions, and contexts that were on the document or meta-level but not explicitly stated on the permission level. Part of our future direction is to approach the ontological expression on a "document level" that would collapse or merge the abstraction to avoid repetition and redundancy.

Conclusion

Through the use of semantic web rule language (SWRL) that enables machine-level reasoning on the instance-level data of ICO, we were able to demonstrate our proof of concept method to link and generate information from entities derived from four permissions in the All of Us informed consent document. Our efforts allowed us to extend the application use of ICO to be potentially integrated with software systems to manage complex authorization information that can later be supported by queries. Our future direction is to work towards formalizing a set of generalized rule extensions for ICO to accurately express document-level permission entities from informed consent.

Children’s Designs for the Future of Telehealth

Erin Beneteau, MS¹, Ann Paradiso², Wanda Pratt, PhD¹
¹University of Washington, Seattle, WA; ²Microsoft Research, Redmond, WA

Abstract

Telehealth has increased dramatically with COVID-19. However, current telehealth systems are designed for able-bodied adults, rather than for pediatric populations or for people with disabilities. Using a design scenario of a child with a communication disability who needs to access telehealth services, we explore children’s ideas of the future of telehealth technology. We analyzed designs generated by six children and found three provocative overarching design themes. The designs highlight how improving accessibility, accommodating communication preferences, and incorporating home based sensor technologies have the potential to improve telehealth for both pediatric patients and their physicians. We discuss how these themes can be incorporated into practical telehealth designs to serve a variety of patient populations—including adults, children, and people with disabilities.

Introduction

The design of telehealth technologies for the pediatric population is currently an under-explored area, as is the design of telehealth systems for children with disabilities. Children’s ideas for technology design can provide unique insights, particularly when designing technologies geared towards children as primary users. Concepts such as inclusive design have also shown how designing for disabled users can benefit people with a range of abilities. Our study explores how telehealth can better serve the pediatric population including, but not limited to, pediatric patients with disabilities. This paper describes how designs created by children, using the design prompt of a disabled pediatric patient, can inform the development of future telehealth technologies.

Telehealth and telemedicine incorporate a wide variety of platforms and services spanning synchronous, online video visits to asynchronous electronic health records (EHR). The majority of telehealth systems assume that users are able-bodied adults. However, designing health technologies for the able-bodied alone can perpetuate healthcare inequities. Moreover, with the increased use of telehealth as a result of the COVID-19 pandemic, we question how telehealth systems geared towards adult users can be designed to better support children’s engagement with their primary healthcare provider. In a recent opinion piece in the Journal of the American Medical Association, pediatricians called for the medical community to seize this defining moment in history and to reconsider how telehealth can best serve the pediatric population. Drawing on user-centered design principles, we chose to ask the potential users themselves, children, for their ideas of the future of telehealth.

We conducted one-on-one, online co-design sessions with six children between the ages of 9 and 13. Our findings revealed three provocative design themes: (1) drones, robots and sensors to the rescue: expanding the scope of telehealth, (2) health data is controlled by the family: sharing with clinicians is optional, (3) beyond talking heads: supporting diverse communication needs. In this paper, we explore what these design themes entail and how they can be practically applied to existing and near-future telehealth technologies. We also discuss how building on these themes can benefit a wide range of telehealth users.

Related Work

A historic review of the literature shows that the role of children in medical communication interactions has been underexplored, with the medical research community frequently undervaluing the contributions children can make to their medical care. Thankfully, this historic perspective in pediatric medical research has begun to change, particularly in the field of medical informatics. The perspectives of children and adolescents on their healthcare communication, information sharing and decision making has been recently explored through qualitative interviews, participatory design, and user studies.

Garth et al. explicitly investigated the perceptions of healthcare communication and partnership of pediatricians, parents, and children with motor, mobility and communication disabilities. The authors found that pediatricians and parents viewed children as important contributors to the healthcare partnership. Pediatricians made explicit efforts to engage with pediatric patients to encourage the child’s participation, including talking about topics of interest to the child and being at the same eye level as the child. While this study is specific to in-person healthcare
visits rather than telehealth, the concepts of including the pediatric patient as a partner in healthcare and ensuring that communication is tailored to the child’s level, are important themes that can be applied to pediatric telehealth.

Co-design with children for technology and disability

Participatory design and co-design methods are commonly used in the Human Computer Interaction (HCI) and Computer Supported Cooperative Work (CSCW) research communities to generate insights on people’s needs and ideas to support those needs. These methods are particularly useful when designing technologies that may be used by children. Druin states that “the better we can understand children as people and users of new technologies, the better we can serve their needs”.

A frequent approach to co-design with children is to begin with a story which establishes the design problem. Light, et al. created a story in which they described a child who was unable to use their voice to communicate and who required some form of augmentative and alternative communication (AAC) technology. Light’s team recruited six children to generate designs of AAC systems. The children created designs which were not constrained to communication alone, instead they incorporated multiple functionalities. The design features generated by the children included functionality that is now pervasive in mainstream smartphone technologies such as the ability to play music, access email, play games, integrate popular themes, and have text to speech output. At the time of the study, these features were not ubiquitous as an all-in-one technology. Light et al.’s work demonstrates how presenting children with a design problem scoped to meet the needs of a child with a disability can lead to design concepts which can ultimately be used by a wide range of users.

To engage children who have chronic health conditions or complex disabilities, researchers need to consider the stress and burdens the co-design procedure may place on participants, particularly when participants are minors. In their design of a support system for children with cancer, Ruland et al. chose to recruit healthy children for early stage co-design sessions, involving children with cancer at later stages of the design and development process. Similarly, Light et al.’s team did not include children with disabilities in their early-stage exploratory design work but focused the design prompt on technology for a child with communication disabilities.

Building on the co-design methods used in prior work, we chose to explore the area of pediatric telehealth using a scenario of a child who is not able to use their voice to communicate, and instead uses an AAC device. By choosing this scenario, we investigate telehealth design “from the margins” instead of designing for the “typical” able-bodied, adult. In our study, we learn how designing for this specific scenario leads to provocative, creative designs that have the potential to be practical and useful to a variety of telehealth users.

Methods

Our study design is inspired by Light et al.’s work and based on concepts by Druin, in which child co-design participants are considered experts in their knowledge domain and treated as equals to adults in the design process. Due to COVID-19, we conducted our co-design sessions over video conferencing in one-on-one sessions with six children. Our co-design protocol was carefully crafted to consider the ethical implications of working with children. Our study was reviewed and approved by the sponsoring organization’s institutional review board.

Participants

We used purposeful sampling of existing networks to identify children who could engage in a video conference session for approximately one hour in length. Due to the inherent abilities required when conducting co-design sessions over video conferencing, we did not recruit any children with disabilities for this initial, exploratory study. Parents were emailed both a consent and an assent form. Parents were instructed to review the assent form with their child. Signed consent forms were obtained from the parents of all participant children prior to scheduling the co-design sessions.

We contacted 10 families and had six children volunteer to participate within the study’s timeframe. To maintain diversity in our participant sample, we only included one child participant per family. To protect participants’ identities, we provide generalized demographic information. Participants ranged from age 9 to age 13. Three participants identified as male, two as female, and one preferred not to specify. Three participants identified as white, two identified as white and Asian, one identified as Asian. Participants had family members working in a variety of settings including healthcare, education, transportation, and technology industries.
Procedure

To support children as experts and equal design partners, parents were asked to not participate or be present during the co-design process. The sessions began with the researcher reviewing the assent form with the child, highlighting the purpose of the research and that the child could stop at any time. All six children verbally stated that they wanted to participate. The researcher began by sharing a story of a child named Pat, who was unable to communicate with their voice and used a computer to speak. Pat became sick but could not go to the doctor’s office and the doctor could not go to Pat’s home. Participants were asked to finish the story by describing how Pat was able to get help from the doctor without seeing the doctor in-person.

Both the researcher and the child participant had paper and writing materials available to them in their separate locations and they each independently spent between 5 and 10 minutes of quiet time to sketch and draw their initial ideas of how the story would finish. In this way, the study was designed so that both the child and researcher were considered as equals, engaging in the same tasks. After the quiet time, the researcher asked the child if they wanted to share their story ending first or if they wanted the researcher to share their story first. The majority of children wanted to share their story ending first. If asked by the participant, the researcher shared their own story ending, which was intentionally created to model a design that seemed far-fetched—such as the doctor having an extendable stethoscope.

After the initial story endings were shared, the researcher prompted children for further ideas and additional sketches. Prompts included statements such as “let’s get really out-there and think of some sci-fi options,” “how would the doctor know what Pat’s health was like?” and “what if Pat isn’t able to walk or use their hands? What would we create then?” At times, the researcher would expand on the child’s ideas and ask the child if they liked the expanded idea or would like it to be different. In this way, the co-design sessions became a cooperative exercise between researcher and participant, discussing ideas and building on them, with the researcher always following the child’s lead.

Analysis

Co-design sessions were recorded for review and analysis. During the co-design sessions, the researcher took notes in real-time and wrote memos, synthesizing the co-design sessions. The first author reviewed recordings and photographs of the designs, using an inductive approach to compare, contrast, code and categorize design elements. All authors reviewed images of designs placed in the initial categories and discussed the design concepts, ultimately refining the categories into three broad themes.

Summary of Designs and Thematic Design Elements

Participants generated multiple designs during each co-design session. Initially, participants generated ideas using existing technologies, such as using video conferencing, text messaging, or emailing. Our analysis focuses on designs that children generated after prompts to expand on existing technologies, such as thinking of “sci-fi” options, ideas that “didn’t need to be real,” or additional design constraints such as “what if Pat can’t use their hands to type?” Based on our analysis, we found three conceptual design themes which we describe in detail, below.

Theme One: Drones, robots and sensors to the rescue: Expanding the scope of telehealth

In this theme, participants designed ways for the physician, patient and/or patient’s parent(s) to collect health data that is normally obtained during an office visit. Solutions focused on: (1) transporting and using medical equipment and sensor technologies, (2) providing a better view of the patient than traditional video conferencing solutions, and (3) using health sensor data.

Transporting and using medical equipment and sensor technologies

Our participants created a variety of solutions for collecting health data in the home environment including various forms of “sending” standard office visit medical equipment to the patient’s home. Participants who created solutions where equipment is sent to the home emphasized the need for it to be easily cleaned and used by the child and/or their parent(s). For example, one participant designed a drone (Figure 1) that could have sanitized equipment placed inside it (such as a thermometer, oxygen measure, blood pressure monitor, etc.). The participant explained that the doctor’s office would pack the equipment within the body of the drone and the drone would fly to the patient’s home. As part of the equipment package, disinfectant wipes were included, particularly for items that would be returned to the doctor’s office. The drone would be clearly marked with red crosses to indicate it was a medical drone. The drone would also have a speaker through which the doctor could announce the drone’s arrival. The drone also was equipped with a camera, so that the doctor could pilot the drone around the patient to obtain a 360° view of the patient during the exam as a solution to overcoming one of the limitations of video calling.
Providing a better view of the patient than traditional video conferencing solutions

Children addressed the issue of the doctor needing a comprehensive view of the patient in a variety of ways. In addition to the idea of the drone with the camera, another participant addressed the challenge of the doctor being able to examine the patient remotely by designing a device which the patient could use to create a video of themselves (Figure 2). In this participant’s scenario, the patient is able to use the handheld device to take photos and video of their injury and could toggle into an “x-ray mode” so that the doctor could get the best images possible of the patient’s injuries. In addition, the patient is able to narrate the video and photos they take using their augmentative communication device. In both the instance of the drone camera and the photo/video recording device, we see that a portable, movable camera is at the crux of the design solution for providing the doctor with a more comprehensive “view” of the patient.

As an alternative to “real” images of the patient, one participant created an interactive three-dimensional, rotatable drawing of a body (Figure 3). This tool would allow either the child or doctor to visually highlight areas of the body that they were discussing, overcoming the current “view” limitations of telehealth video conferencing systems.

Another participant expanded the concept of home-health visits to include virtual reality and robotics (Figure 4)*. The participant created two options in which an in-person visit could be conducted in the patient’s home, without the doctor being physically present. In the first option, the physician controls a robot using virtual reality, so the physician has an “in-person” view of the patient. In the second option, the robot itself would be able to perform basic medical exams and basic diagnoses (such as temperature and blood pressure). The participant noted that in both designs, safety and accuracy were primary concerns and that the robot’s actions should be checked by humans if there are any

---

* This participant declined to share their hand-drawn sketches created during the co-design session and preferred to share digital concept sketches of their designs. Figures 4 & 10 are screenshots of their digital concept sketches.
concerns, including the use of a triage system for “option 2” in which the human doctor reviews the robot doctor’s diagnosis and exam procedures. The home visit robot would provide additional safety protections both for the patient and for the doctor during a pandemic. Both robot options designed by the participant are similar in concept to an existing prototype robot designed for basic inpatient services. However, unlike the prototype, the participant’s designs are geared towards telehealth medical care which can be conducted in the patient’s home.

Using health sensor data

During the co-design sessions, participants were prompted with variations of the question: “how would the doctor get the same kind of health information that they normally get during an office visit, such as temperature?” In response, our participants included traditional “office visit” equipment such as thermometers and stethoscopes in their designs in addition to creating apps or other technologies which could measure basic health data through attachments to a smartphone or tablet (Figure 5). One participant created a special sensor that could be placed on the chest of the patient to measure a variety of biosensor data all at once, which could be easily taken off once the health data was collected (Figure 6). Another participant explicitly combined the concepts of a “thought reader” with sensor technologies to create an all-in-one communication and medical exam wearable device (Figure 7). Initially, this participant designed an apron with embedded sensors which could easily be taken on and off. They continued to iterate on the idea of a wearable which resulted in a jacket with embedded sensors to measure respiration, temperature, blood pressure, and other health data. Addressing our design scenario of a child who uses technology to communicate, the jacket includes a hood, which can read the child’s thoughts and transmit those thoughts through a wire to the doctor’s computer. The hood can be easily put on and taken off by the child, so that they have control of when they communicate with the doctor. This design, like so many others from our participants, incorporates user-controlled privacy options through the inherent design of the technology, in addition to combining health sensing data.

Theme Two: Health data is controlled by the family: Sharing with clinicians is optional

As we see with the health sensor designs, participants’ designs implicitly had privacy controls with the ability for the sensors to be easily removed by the user (or the user’s parent). While some participants explained that the child’s parent(s) would use the equipment, other participants indicated that the child might be able to use some of the equipment independently. Ultimately, the designs were flexible enough that the choice of who would use the equipment was left to the family.

Participants discussed different needs for information sharing based on the child’s particular health situation, the child’s abilities, and the child’s health history. A strong, recurring theme between multiple participants’ designs is that the user (child and/or parent) has control of any health data sharing with the physician. Multiple designs across different telehealth platforms feature a “send” button, in which the patient and/or their parent(s) choose to intentionally share health data with the physician (Figures 8-10). One participant developed the concept further to include options for personal health tracking which can be visualized and saved for the patient’s own reference and personal health records (Figure 10). Another participant explained that they included a “send” button in their design (Figure 8) because the child’s parents will know if the child’s temperature is “normal” for their child or not, since some people can have a slightly higher or lower temperature as their “normal” temperature.
Analysis of the participants’ designs reveal an inherent distrust of technology automatically making the judgement on whether to share personal health data with the physician. We see an explicit and intentional design that makes the patient and/or their parent(s) the owners of their data, in control over how they share that data. We also see that designs are created so that the patient and/or their parent(s) are able to obtain the health information data that they want to capture for themselves as a primary feature of the technology. The design assumption is clear: it’s important to capture health data and once the data is captured and reviewed by the child and/or their parent(s), the family members will then decide if it needs to be shared with their medical provider.

**Theme Three:** Beyond talking heads: Supporting diverse communication needs

Our design scenario of a child who cannot use their voice and uses a computer to speak inherently lent itself to design solutions which accommodated many methods of communication. Participants generated design ideas with a focus on direct communication between the pediatric patient and their doctor, in ways that would be easiest for the child to interact. Participants noted that it might take extra time for the child in the scenario to communicate, and as a result, designs incorporate elements that enable faster, easier synchronous communication and asynchronous communication.

One participant modified the design of current video conferencing systems to feature the text-based chat function as the primary visual interface of the telehealth system (Figure 11). The chat shows both the patient’s text as well as the physician’s text in the main window of the screen, similar to many text messaging interfaces. This participant also incorporated a variety of features to enable increased speed and effectiveness of text-based communication through design elements such as: highlighting of important text, word/phrase prediction, speech to text/text to speech, and the use of emojis. The option for sharing video is also available in this design but must be intentionally turned on as a menu item by the patient, instead of being the default focus of the telehealth interaction.

In contrast to existing telehealth systems, our co-design participants focused on telehealth communication methods that would be best utilized by the pediatric patient. One participant explained that they use YouTube for gathering most of their information instead of Google searches, and that they follow different YouTube channels on topics they’re interested in and that they learn of new events and developments by subscribing to those channels. Building on the concept of YouTube, this participant designed a private, asynchronous video chat that the pediatric patient could have with their doctor (Figure 12). The doctor would create short videos to interact with the patient, for example, asking the patient to follow through with a treatment regime or instructions for an upcoming examination. The child would be able to respond to the physician through text-based comments and chats in response to the video. The participant emphasized multiple times that it was extremely important that the videos from the physician concluded with something funny, so that the pediatric patient would watch the full video all the way to the end. We can think of this solution as a pediatric version of a patient portal, in which the pediatric patient is able to asynchronously interact with their care team in a way that is understandable, familiar, and useful to the patient themselves.
Our co-design participants put their design emphasis on ensuring that the pediatric patient’s information needs were met during the telehealth visit. One participant placed additional emphasis on ensuring that the telehealth system was accessible to the patient, no matter what their abilities were (Figure 13). This participant designed an app which provided multiple forms of feedback to the participant, including haptics, graphics, color-coding, audio and text-based information. The participant described that the app had to be accessible, and that some people who are color-blind would not be able to rely on color coding feedback, and that people with hearing loss would not be able to hear auditory feedback. In addition, this participant discussed the emotional and cognitive load that receiving medical information can have on a patient and discussed that the app would provide synthesized information to the patient—such as “good” instead of providing the raw data itself (such as a temperature or blood pressure numeric reading). The participant explained that sometimes patients are told a number by the medical professional, but that neither the child nor the parent(s) might understand what that number means, which can cause anxiety. To decrease patient anxiety and to increase clarity of information, it was important for the app to let the patient know if the sensor reading was something that they should be concerned about or not.

Another participant designed a system to address the problem of the patient being unable to communicate with their voice by designing a “brain reader,” in which the patient is able to communicate with their doctor by wearing a solar-powered hat which can read and speak their thoughts (Figure 14). This participant’s brain reader design and the hood thought reader design discussed earlier (Figure 4) emulate brain-computer interface (BCI) technologies, which are being developed to help people who are “locked in” and are unable to speak with their voice or use their hands to access mainstream technologies. Unlike most current BCI technologies, the brain reader hat design allows the child user to communicate either through voice output or through images. Here again, we see our participants generate creative design solutions which have the potential to be used by both adults and children.

Discussion

We framed our study to address the needs of a pediatric patient with a communication disability. Yet, many of the design solutions our participants created incorporate features that will, in fact, be useful to a broad population—including both pediatrics and adults, as well as both able-bodied and disabled individuals. In our discussion, we focus on some of the key lessons learned from our participants’ designs and how they can be practically incorporated into existing and near-future telehealth systems.
Telehealth technology should be negotiated at the family level, not dictated by design

Our participants naturally designed technologies in which the user is at the center of the design. The use of the technologies and the information shared are controlled by the user. In the case of a pediatric patient, the user could be defined as the child themself and/or their parents. Regardless of whether the child or their parent are the primary user, all designs were oriented towards being child-friendly, mirroring the experience of in-person pediatrician visits. It is important to note that our participants did not impose their views on who should ultimately have control of the technology, the child or parent(s), but left their designs flexible so that the choice could be made at the family level. We recognize that research has investigated how and when adolescents should have access to their health data and that opinions and policies on the topic vary. In the case of telehealth technology design, our participants assumed that the choice of access would be up to the families themselves, and not dictated by the technology designers. We encourage telehealth designers to adopt a similar design philosophy, in which the pediatric telehealth system can be utilized by both adults and children. We suggest that using this design approach will be useful not only to families, but also to caregivers of adults, and to individual adult patients.

Telehealth technologies should provide a holistic view of the patient’s current health (using sensor and visual input)

Our participants’ telehealth designs focus on the importance of obtaining the necessary information a physician would need in order to provide medical care to the patient. Participants created a variety of systems to capture medical data typically taken during an office visit, incorporating familiar tools such as thermometers. In some cases, such as with the drone design and the virtual reality robot, the physician was able to see and communicate with patients in real-time and could help assist in capturing the medical data needed. Surprisingly, none of our participants incorporated existing wearables and sensors, such as an AppleWatch or Fitbit, into their designs. However, the app designed by one participant and the removable sensor designed by another participant essentially function in a similar way to existing wearables, with the difference being that the participants’ solutions are designed specifically for the purposes of capturing data for telehealth visits. We recognize the use of mainstream wearables to gather medical data is an emerging area of exploration. Some healthcare providers have used home-based devices, such as blood-pressure cuffs and Fitbit data, during COVID-19 in an attempt to provide more holistic care through telehealth. Our findings for the future of telehealth suggest that healthcare providers can assist patients in the correct usage of a variety of sensor technologies as tools to supplement telehealth visits. Our participant’s YouTube design example is one way in which educational materials regarding the use of home-based medical devices could be shared in a pediatric-friendly way. We encourage telehealth designers to consider how they might incorporate educational information into the proper use of home-based devices and wearables so that the data collected could be useful for telehealth visits. The educational information would also need to include explicit instructions on how users choose to share their home health data with medical staff. As our participants’ designs indicate, the choice of sharing health information collected at home should ultimately be up to the family.

In addition to health data, another common design theme is the ability for the physician to view more than just the face of the patient during the telehealth visit. Our participants’ designs included views of the patient that are directed by the patient (e.g. the handheld video device with x-ray mode) and video solutions directed by the physician (e.g. the drone and robot). Based on these early conceptual designs, we suggest that telehealth systems be designed with the option for both patient-controlled and physician-controlled views. The interactive 3D body design, for example, could easily incorporate both physician and patient controlled views. Once again, we can imagine scenarios in which having a comprehensive view of the patient would be useful beyond the scenario described in our design prompt. We anticipate that adults, children, able-bodied and disabled populations would utilize one or more of these tools during a telehealth visit with their doctor.

Telehealth technologies should be accessible using multiple communication methods

Our participants’ designs show how telehealth systems can incorporate multiple modalities of communication. Children do not communicate in the same way as adults and we do not think that telehealth systems should be designed with only one communication approach available. Garth et al.’s research showed that pediatricians deliberately communicate at the child’s level to foster the pediatrician-patient relationship during in-person office visits. Telehealth systems should afford for the same types of communication adaptations. Telehealth systems should capitalize on communication methods children prefer, such as using asynchronous videos with commenting for sharing information. We encourage designers to embrace a multi-modality communication approach into telehealth technologies. Designing for one communication method alone is not enough. Current video conferencing
platforms can be modified to more explicitly include multiple communication modalities, such as improving
chat/text-based communication by making this option more visually accessible, and by incorporating phrase and
word prediction and incorporating emojis. Emojis could be particularly useful in patient-provider communication to
add more descriptive information into how the patient is feeling, which can benefit children, adults, people who are
literate and people who have limited literacy. Emojis could also be used to supplement traditional pain scale
questions as part of the telehealth exam.

Our design scenario of a pediatric patient with a disability prompted our participants to creatively think about other
accessibility features that could be incorporated into telehealth design. Using multiple modalities such as color
coding, text, visuals, haptics, and auditory feedback within the telehealth system can benefit many different potential
users in a variety of situations.

**Limitations and Future Work**

Our study is an exploratory study and more work needs to be done before any of our findings can be put into practice.
We have a small participant size, which is appropriate for this type of early-stage study, but a larger participant size
would be needed for future stages of research, such as prototype design evaluations. We also recognize that while our
scenario featured a child with disabilities, we did not include any design participants with disabilities. We believe that
future work in this area, especially early-stage prototype designs, should include participants with disabilities.

**Conclusion**

We conducted co-design sessions with six children on the topic of telehealth. Using a design scenario of a child with
communication disabilities, we explored how telehealth technologies could be improved. We found that children’s
ideas for telehealth systems were both provocative and practical. Our participants considered the perspectives of the
entire family’s use of telehealth in their designs, creating designs which could be used by both adults and children.
Moreover, our participants created designs which emphasized privacy measures controlled by the family as part of
the health data sharing process. Our participants were empathetic towards Pat, the character in our design scenario,
and as a result they designed solutions which could accommodate different communication and physical abilities.

Our study is an exploratory study of the potential of telehealth in the near-future. We believe that telehealth systems
that do not embrace concepts such as user-driven personal health data will ultimately be left-behind as the use of
telehealth grows. Fiks et al. argued that COVID-19 has created an opportunity for defining the future of pediatric
telehealth⁵. Our six co-design participants have provided inspiration for what the future of telehealth could be: user-
driven, flexible, and accessible technologies.

**Acknowledgements**

We sincerely thank our co-design participants and their families.

A Framework for Inferring Epidemiological Model Parameters using Bayesian Nonparametrics

Oliver E. Bent, PhD, Charles Wachira, BSc, Sekou L. Remy, PhD, William Ogallo, PhD, RPh, Aisha Walcott-Bryant, PhD
IBM Research Africa, Nairobi, Kenya

Abstract

The use of epidemiological models for decision-making has been prominent during the COVID-19 pandemic. Our work presents the application of nonparametric Bayesian techniques for inferring epidemiological model parameters based on available data sets published during the pandemic, towards enabling predictions under uncertainty during emerging pandemics. We present a methodology and framework that allows epidemiological model drivers to be integrated as input into the model calibration process. We demonstrate our methodology using the stringency index and mobility data for COVID-19 on an SEIRD compartmental model for selected US states. Our results directly compare the use of Bayesian nonparametrics for model predictions based on best parameter estimates with results of inference of parameter values across the US states. The proposed methodology provides a framework for What-If analysis and sequential decision-making methods for disease intervention planning and is demonstrated for COVID-19, while also applicable to other infectious disease models.

Introduction

The COVID-19 pandemic is one of the most important public health concerns of the twenty-first century. Globally, more than 118 million COVID-19 cases and 2.6 million COVID-19-related deaths had been reported by March 2021. The United States, with more than 29 million COVID-19 cases and 540 thousand deaths over the same period, disproportionately bears most of the COVID-19 burden. A key characteristic of COVID-19 is that multiple timely interventions along with behavioral compliance to the interventions by populations are critical to contain the spread of the disease. However, although the intervention options and behavioral aspects may be limited, tackling the COVID-19 pandemic has, in part, been hindered by the insufficient understanding of data and models that can adequately inform the decision-making process of stakeholders.

Overall, non-pharmaceutical interventions (NPIs) such as quarantine, mask-wearing, and school closures have played a critical role in substantially slowing the spread of COVID-19 across different populations and geolocations\(^\text{1}\). To this end, research efforts have been directed towards curating NPI datasets from publicly available data sources\(^\text{2,3}\), tracking government responses by scoring the stringency of imposed NPIs\(^\text{4}\), and developing a plethora of models for forecasting COVID-19 outcomes to support policymaking\(^\text{5-8}\). At the same time, researchers are actively investigating the dependence of COVID-19 on human behavior. For example, studies have investigated human mobility as a measure of the stringency of travel restrictions during COVID-19\(^\text{9}\) and as a predictor of the spread of COVID-19\(^\text{10}\). Unfortunately, however, little is known about the interactions between imposed NPIs, human behavior, and COVID-19 outcomes especially to improve the calibration and learning of model parameters in compartmental models.

The overarching goal of this study is to introduce a framework and method for inferring epidemiological model parameters by integrating non-traditional epidemiological model drivers and surrogates as inputs during the model calibration process. Specifically, we demonstrate how the stringency of NPIs and human mobility data can be used to train a Gaussian process regressor, and subsequently infer values of parameters like the transmission rate in an SEIRD (susceptible, exposed, infectious, recovered, dead) compartment model using example states in the United States. A key contribution of this work is the ability to conduct What-If and scenario analyses that decision-makers can use to estimate the transmission rates given based on NPI stringency and human mobility.

Related Work

Besides compartmental models such as the SEIRD, a wide range of modeling efforts has been directed towards understanding and controlling COVID-19. For example, pharmaceutical intervention discovery has employed crowdsourcing in pandemics, with the use of Machine learning and computational tools to rapidly triage compounds and design...
synthetic routes, reducing the time it takes to find treatments with the most promise\textsuperscript{11,12}. Machine learning-based models, trained on specific biomolecules, have also offered inexpensive and rapid implementation methods for the discovery of effective viral therapies\textsuperscript{13} along with direct applications to the design of clinical trials and experiments through the use of causal inference and Reinforcement learning methods\textsuperscript{14}. Recently, researchers have also developed Non-Pharmaceutical Intervention repositories which have been extended through automated extraction of global NPI details from Wikipedia articles using NLP\textsuperscript{2} which run in parallel to intensive manual data collection projects\textsuperscript{4}.

Early in the pandemic, Google and Apple released human mobility data sets that capture mobility patterns for specific types of locations or activities. Google’s COVID-19 Community Mobility reports\textsuperscript{15} contain data that represents the percentage difference in mobility from a "pre-pandemic" baseline for six types of locations: retail and recreation, supermarket and pharmacy, parks, public transport, workplaces, and residential. Apple\textsuperscript{16} offers mobility data based on the number of requests for directions for three types of modes of transport: driving, walking, and public transport. Such data are critical for the pandemic and serve as a proxy measure in understanding the public behavior in response to the pandemic and adherence to NPIs imposed by governments. Several researchers have leveraged mobility data and other environmental data to support modeling efforts and infer public behavior throughout the pandemic. For example, in Nouvellet et al.\textsuperscript{17}, the relationship between mobility and COVID-19 transmission is explored, specifically the reproduction number using EpiEstem\textsuperscript{18}, for 52 countries at different phases of lockdown. In another study by Oliveira et al.\textsuperscript{19}, the authors explore the relationship between mobility and lockdown phases at different points during the pandemic, and describe disparities in this relationship across South American countries. Mobility data has also been used to explore its relationship to COVID-19 outcomes at a county-level or set of counties in Arizona by Wang et al.\textsuperscript{20}. Work by Kuo et al.\textsuperscript{21}, combines mobility data with demographic and environmental data into a hybrid ML model to predict incidence at different response phases (e.g., lockdowns) during the pandemic. While these methods incorporate mobility data into understanding the pandemic across various geographies, they do not provide an inference framework that includes the stringency of NPIs and mobility to infer parameters for compartmental models, and further are not directly used in What-If analysis and intervention planning.

Long-short term memory (LSTM) networks are increasingly popular as a deep learning alternative to traditional epidemiological modeling. LSTMs are a type of recurrent neural networks that can learn long-term temporal dependencies\textsuperscript{22}. They are particularly popular because of their ability to address the limitations of traditional time series forecasting techniques such as the need for restrictive assumptions of linearity in data, resulting in more accurate models. These techniques have been used by researchers for modeling COVID-19 time series data. For example, Chimmula and Zhang\textsuperscript{23} use LSTMs to forecast future COVID-19 cases and possible stopping time in Canada, and the rest of the world. Similar approaches have also been applied by other researchers\textsuperscript{24–28}. Kirbas et al.\textsuperscript{7} and Devaraj et al.\textsuperscript{29} found LSTMs to be more accurate than techniques such as Auto-Regressive Integrated Moving Average (ARIMA) and Nonlinear Autoregression Neural Network (NARNN) in predicting COVID-19 cases. Among different variants of LSTM models for COVID-19 forecasting, researchers report better accuracy for bidirectional-LSTM models\textsuperscript{8,30,31}. Researchers have also combined LSTMs with other techniques\textsuperscript{32}. It is worth noting, however, that most of the techniques discussed above are typically black-box models that are often not readily interpretable or grounded in epidemiological processes.

Epidemiological Model Structures

The major forms of mathematical models for epidemiological systems may be classified into three groups:

- **Black-box** models are entirely data-driven models and their structure is not guided by any underlying physical mechanism. Such model types are common in machine learning and statistics. In either case, the model parameters are learned from observation.

- **White-box** models are considered to be mechanistic and attempt to describe the underlying physical mechanisms. As an example of white-box models, agent-based models are constructed based on interactions between multiple agents of the epidemiological system and aim to create a closer resemblance to real-world dynamics.

- **Grey-box** models consist of mixtures of phenomenological (black-box) and mechanistic (white-box) models.
For our work, we will consider all models as black-boxes, epidemiological models therefore acting as a set of exposed parameters, which allows us to switch seamlessly between the use of different model types and between diseases. This ground-up approach of extensibility and scale is perhaps rooted in the premise that much of machine learning considers models as black-boxes across application domains. In the case of epidemiology, challenges in reproducibility, and lack of sharing or a set of standard benchmarks, limit the amount of work that effectively compares the results of different modeling approaches. Consequently, instead of focusing on the analysis of epidemiological model structures, we look at mappings between inputs and outputs from various models for forecasts or predictions under uncertainty, ultimately to be exploited for the task of decision making.

While the internal mechanisms of the model used remain as black-boxes, different approaches return deterministic or stochastic results. This is of note with regards to how uncertainty may be handled from the model. A deterministic epidemiological model principally takes the compartmental form of Kermack and McKendrick. Such models are deterministic in the sense that, once we know the population numbers of each compartment (initial conditions) and the rate constants between the compartments, the system is fully determined and has a single outcome or prediction, while for any real-world scenario, reducing the problem in such a way is unlikely to be realistic, or have strong predictive performance. We may inject some randomness into deterministic models through quantifying uncertainty in the model parameters or initial conditions. Deterministic compartmental models tend to be suited for large well-mixed populations, with relatively small numbers of recovered individuals. Typically a deterministic approach may be evaluated much faster, as differential equations have efficient solvers with a single outcome being computed. Stochastic simulations may need many more computational cycles to model the atomic transitions of a stochastic agent-based model in comparison.

Taking a common footing for both modeling approaches through uncertainty quantification can lead us to the following classifications. Uncertainty in predictions arising from the uncertainty in the model parameters is called epistemic uncertainty. This could lead to a distribution of outputs from a deterministic model if parameter distributions were defined on the model parameters, or based on a stochastic model’s own description of epistemic uncertainty. This kind of uncertainty may be better quantified with more data or observations. Consequently, epistemic uncertainty should be higher in regions of little or no training data and lower in regions of more training data. Uncertainty arising from the inherent noise (or imprecision) in the disease dynamics is an example of aleatoric uncertainty. It cannot be reduced if we get more observations; in principle, we have to accept that the future is uncertain.

**Gaussian Process Regression**

The Gaussian Process (GP) is a well-known statistical learning model, used extensively for probabilistic non-linear regression. The task of regression aligns with parametric, phenomenological, or black-box epidemiological model design for prediction, specifically how predictions as forecasts of future epidemiological state may be learned. Although Gaussian process regression (GPR) is not a standard modeling approach in epidemiology, there are examples of its use in geospatial modeling. We focus on motivating its use in a pipeline for temporal decision-making using epidemiological transmission models. GPR targets a functional approximation for an underlying stochastic process, a natural fit for capturing uncertainty from epidemiological model training examples.

The outputs used from epidemiological simulations are considered as stochastic, either through mechanisms of stochasticity within the model or based on stochastic distributions of model input parameters, samples of which generate a stochastic output. Firstly a general overview of GPR is necessary before generating the appropriate mapping for the learning of model parameters for prediction tasks.

A GP is fully specified by its mean function \( m(x) \) and covariance function \( k(x, x') \). This is a natural generalization of the Gaussian distribution, whose mean and covariance are a vector and matrix, respectively. The GP entertains a probability distribution over some (real) underlying stochastic process \( f(x) \). Defining:

\[
    m(x) = \mathbb{E}[f(x)]
\]

\[
    k(x, x') = \mathbb{E}[(f(x) - m(x))(f(x') - m(x'))]
\]
K runs. The covariance pairings of these random variables represent the value of the stochastic process \( f \) at a location \( x \in X \). The location variable in our application is over epidemiological model parameters. While considered a Bayesian nonparametric learning technique, GPR does involve the specification of a limited set of parameters, almost entirely contained with the covariance kernel function. Judicious choices of kernel function and parameter values need to be made for the successful application of GPR.

**Inference of Predictions based on Changing Epidemiological Model Parameters**

The specification of the covariance function implies a distribution over functions. To see this, we can draw samples from the distribution of functions evaluated at any number of points; in detail, we choose a number of input points denoted \( X_* \).

\[
f_* \sim \mathcal{N}(0, K(X_*, X_*)^{-1})
\]

In which \( X_* \) is a vector of our test inputs (or locations) of the regression, \( f_* \). Therefore, without observations or training inputs, this fully specifies our Gaussian process prior.

We consider an underlying stochastic or noisy epidemiological function \( y = f(x) + \epsilon \), \( \epsilon \) being additive independently identically distributed (i.i.d) Gaussian noise with variance \( \sigma^2 \), Here we’ve assumed that the underlying stochastic process is unbiased and \( m(x) = 0 \). Without other reasonable prior knowledge e.g. periodicity this is a reasonable assumption, along with our beliefs of the underlying process that we have specified through the GP covariance function. Our stochastic epidemiological function \( y \) is therefore distributed such that:

\[
y \sim \mathcal{N}(0, K(X, X) + \sigma^2 I)
\]

This now allows us to specify the joint distribution of the observed training values \( X \) and the function values at the test locations \( f_* \) under the GP prior.

\[
\begin{bmatrix} y \\ f_* \end{bmatrix} \sim \mathcal{N} \left( 0, \begin{bmatrix} K(X, X) + \sigma^2 I & K(X, X_* ) \\ K(X_*, X) & K(X_*, X_*) \end{bmatrix} \right)
\]

(3)

If there are \( n \) training points and \( n_* \) test points then \( K(X, X_*) \) denotes the matrix of the covariance function evaluations at all pairs of training and test points and \( X \) the vector of our training inputs or results from epidemiological runs. The covariance pairings of \( K(X, X), K(X_*, X) \) and \( K(X_*, X) \) follow respectively from test points \( (X_*) \) and training points \( (X) \).

Through constructing the conditional distribution based on the assumption of Gaussian prior observations this gives us the following:

\[
f_* | X, y, X_* \sim \mathcal{GP}(m(x_*), k(x_*, x'_*))
\]

In the case of a zero mean function prior this reduces the prediction functions to:

\[
m(x_*) = K(X_*, X)[K(X, X) + \sigma^2 I]^{-1}y
\]

(4)

\[
k(x_*, x'_*) = K(X_*, X_*) - K(X_*, X)[K(X, X) + \sigma^2 I]^{-1}K(X, X_*)
\]

(5)

The above results have direct solutions conditioned on our GP hyper-parameters \( l, \sigma^2 \) and \( \sigma^2 \), which we shall term \( \theta_{GP} \). While judicious approximations can be made for these values, we rely on an optimization scheme to fit them based on observation across tasks. This may be done through maximization of the log marginal likelihood:

\[
\log p(y | X, \theta_{GP}) = -\frac{1}{2} y^T (K(X, X) + \sigma^2 I)^{-1} y - \frac{1}{2} \log |K(X, X) + \sigma^2 I| - \frac{n}{2} \log(2\pi)
\]

(6)
Performing Maximum Likelihood Estimation (MLE) based on maximization through gradient-based optimization, recovers an empirical Bayes estimate to $\theta_{GP}$. While full Bayesian inference may be performed to generate the posterior parameter distribution, the computations are analytically intractable, approximate methods are therefore deployed, as exemplified by Markov Chain Monte Carlo (MCMC) algorithms for sampling the GP prior.

**Learning Model Parameters from Observation**

A calibrated model implies that the model parameters ($\theta_m$) have been selected, either as single values or distributions. This calibration may have been performed by the model developer for the specific disease and location, for which the model has been specified. The process of calibration takes the designed model structure and exposes meaningful parameters ($\theta_m$) to tuning such that a model achieves higher predictive performance. A model developer may have designed a model with physical parameters in mind and reference the literature for these parameter values, and simply look for the model structure to represent observations. Alternatively, a grid-search of parameter values may be performed, which exhaustively evaluates model runs and fixed interval perturbations of the parameter values, specifying a hyper-dimensional grid in the number of parameters. The vertex associated with the parameter set that provides a best-fit (or minimum loss) then being chosen. In this work, we advocate for an algorithmic approach to achieve best-fit, which may both improve the efficiency of our search for a parameter set, under computational constraints, while also providing additional information with regards to parameter sensitivity and allows us to incorporate additional information around parameter distributions.

We assume a predefined model structure with exposed model parameters ($\theta_m$), and consider the mechanisms of the model as hidden under the black-box abstraction. Simply being given access to a disease model structure almost always requires tuning or calibration of that model to generate meaningful predictions. Therefore, we develop mechanisms that can efficiently achieve this, enabling large-scale use and comparison of epidemiological model predictions.

The size of the parameter set being calibrated for a mechanistic epidemiological model is often in the order of $10^3$. When performing calibrations for models of the same disease and same location, a mapping of any common parameter sets and to get similar model performance is noted to be a complex task. In addition to this task, we consider the task of separately calibrating single models for a new geography. To perform such calibrations, reference observational data such as cases, deaths, and vector numbers are required. We may then interrogate further the impact of parameter values with regards to this observational data and model outputs.

**Bayesian optimization**

Bayesian optimization is a principal global optimization method driven by the exploration-exploitation paradigm and used in black-box optimization of computationally expensive functions. Priors on our parameters may build in human expert knowledge from epidemiologists; and an acquisition function which guides the exploration process, reducing unnecessary evaluations of expensive objective functions while maximizing information. Importantly, Bayesian optimization leverages approximations in the form of a surrogate model or response surface to remove the computational expense of direct evaluations of the objective function. This surrogate model is almost always a Bayesian nonparametric model, the Gaussian Process. While other surrogate modeling methods exist for sequential model-based optimization, we have developed a consistent set of approaches based on the GP posterior and will not divert, though methods such as Parzen Estimator approaches exist. As epidemiological models tend not to be written with closed-form solutions, we are led to approaches that treat the environment against which a candidate solution is being evaluated as a ‘black-box’. Specifically we seek to approximate an optimal solution given that the:

- Objective function ($f(x)$) is unknown, non-linear, non-convex, non-derivative and stochastic.
- Candidate solutions ($x$) are a high dimensional vector from the set of possible actions. ($A \subset \mathbb{R}^d$), typically with $d \leq 20$.
- Evaluation of $f(x)$ is computationally very expensive.
Therefore by framing the process of exploring model parameter solutions $x$ as an optimization problem:

$$\max_{x \in A \subset \mathbb{R}^d} f(x)$$

(7)

For the purposes of calibration, these candidate solutions $x$ exist across dimensions $d$ (often a rectangular hyperspace with uniform ranges $x \in \mathbb{R}^d : a_i \leq x_i \leq b_i$), which are evaluated towards the maximization of some objective function $f(x)$. The objective function returns a scalar reward that quantifies the performance of the solution.

In outline, we use Bayesian optimization as a sequential optimization schedule that combines our GP surrogate model with the acquisition function which is detailed in the following section.

**Algorithm 1:** Bayesian optimization Steps

```
for $t = 1, 2, ..., n$ do
    select new $x_{t+1}$ under acquisition function $\alpha$;
    $x_{t+1} = \arg\max_{x \in A} \alpha(x; D_t)$;
    run model simulation to provide $y_{t+1}$;
    new observation $D_{t+1} = \{D_t, (x_{t+1}, y_{t+1})\}$;
    Update GP Posterior: mean and covariance
end
```

In Algorithm 1 we have introduced the notion of an acquisition function ($\alpha$), this may have several functional forms. Popular acquisition functions are UCB, EI and Thompson Sampling - they may be grouped in the optimistic, improvement-based and information-based search methods respectively

**Loss Function**

A loss function ($L$) maps our parameter estimates to a scalar value ($L : \mathbb{R}^d \rightarrow \mathbb{R}$) from function outputs against which Bayesian optimization may be performed. In this framing of a loss function for calibration, the optimization minimizes the loss. The search for a minimum Normalized Root Mean Square Error (NRMSE) is equivalent to the maximum likelihood estimate, a point estimate of calibration parameters.

$$L = NRMSE = \sqrt{\frac{1}{n} \sum_{t=1}^{n} (y_t - \hat{y}_t)^2}$$

(8)

Such a loss function is standard with epidemiological model calibration and is not an innovation but included for completeness as to which we demonstrate results of a Bayesian optimization process.

**Results using a SEIRD Compartmental Epidemiological Model**

We used stringency index and mobility data to generate an input time series data set for all the states of the United States of America. The stringency index quantifies the strictness of government-imposed NPIs in a location while the mobility data captures the daily changes in movement compared to pre-pandemic baselines. For each state, the study period ranged from the day it reported its first case to August 3, 2020, to capture the first wave of the epidemic. We used an SEIRD model and learned parameter values for the defined periods. These parameters included: death rate $\delta$, recovery rate $\gamma$, and the transmission rate $\beta$. The parameters were learned by applying Bayesian Optimization to fitting the model to the recorded confirmed cases and deaths. We also used six values of $\beta$, i.e. five changes in the transmission rate during the calibration duration. We ran 20 calibration events for all the states and used the Mean Absolute Percentage Error (MAPE) of 4 weeks prediction of confirmed cases and deaths to identify 47 states where the MAPE was below 4. We trained a GP to estimating the impact of stringency and mobility on $\beta$.

Figure 1 shows the predicted and observed confirmed cases, as well as the learned $\beta$ and $R_0$ values for the selected states of Florida, Georgia, and New York. The projected values generated from the calibrated parameters closely follow

222
the observed data. There are some similarities and differences to note between these states. Each state is observed to have a high (>1) transmission rate at the beginning of the pandemic that starts to reduce later in the pandemic. New York was able to get $\beta$ down to very manageable levels in May, but like Florida and Georgia, by the end of July, values were increasing once more. After their first reported cases, Georgia and Florida followed similar trends, both approaching 100k cases in July, even though the trajectories for $\beta$ follow different paths. It is clear that the dynamics of the pandemic in each of the states have followed distinct courses, and both the governance and the practices of the population are certain to have played critical roles. This is why we selected the stringency and mobility values as features in our inference method, as they serve as a proxy to how governments and the population have responded.

**Learning Parameter Distributions from Data**

In Figure 2 we present the one- and two-dimensional functions learned from the data for the State of New York. Figures 2a and 2b present the mean and covariance for the GP trained to estimate the relationship between $\beta$ and stringency and mobility respectively. Of note in Figure 2a is that in New York, stringency values have a narrow range between 0.5 to 0.8, implying that the state remained fairly strict throughout the study period. As would be expected, there seems to be a negative correlation between the stringency and the predicted $\beta$ values. Figure 2b suggests that there is minimal correlation between observed mobility and predicted $\beta$ values. This implies that if there is a relationship between the two, that relationship is either complex or confounded by other factors that warrant further investigation. These include the timing of the enforcement of stringency measures that affect mobility, the context of which the measures were implemented, the measures that were already implemented, and the number of cases that were prevailing. All of these influence the assessment of the impact on transmission rate, making causal inferences difficult to extrapolate.

Figure 2c presents the mean of the surface learned from mapping both of these values to $\beta$. As with the other two subfigures, there is a strong signal indicating a relationship between these values, and the interaction between stringency and observed mobility with $\beta$. The mean value of $\beta$ represented in the pixel value in the range $[0, 1]$. 

**Figure 1:** Calibrated SEIRD model output of the total confirmed cases as well as the learned $\beta$ and $R_0 = \frac{\beta}{\gamma}$ values.

**Figure 2:** Plots of the mean and covariance (including the parameter samples) learned from GP regression for the State of New York. Figure 2a illustrates the relationship between stringency values and calibrated transmission rates ($\beta$). Figure 2b illustrates relationship between observed mobility and $\beta$. Figure 2c illustrates the relationship between both stringency and observed mobility with $\beta$. The mean value of $\beta$ represented in the pixel value in the range $[0, 1]$. 

and mobility is also at play. In each of these cases, one might consider these figures as a prescriptive yet noisy way to infer the impact of changes to the way that governments or populations respond to the pandemic and the ability of the disease to propagate through the state. If the learned signal is truly representative, it provides a means to perform What-If scenario evaluations, permitting decisions to be made based on the expected impact on transmission. Specifically, the regressed GP can be used to define the values of input parameters (in this case $\beta$, but one can readily see that others could have been learned as well). Here $\beta$ would be a distribution defined by the selected stringency and/or observed mobility.

Even though different states have different approaches to managing the pandemic, we can estimate the impacts of their strategies. Aggregating the samples from multiple states provides one mechanism to increase the range of predictions and to incorporate additional information for regions of the surface which are captured in any given states. This aggregation might increase the uncertainty in the projected impact in some regions, which is important as it represents a diversity of outcomes that are possible depending on the state, the pandemic context, and how their population might respond to interventions. To aggregate, we train the GP with samples from 47 states which have Mean Absolute Percentage Error (MAPE) of less than 4 on 20 independent calibrations events of the SEIRD model. Using the resulting GP, predictions for the values of $\beta$ were generated and used as input for the compartmental model.

Performing Model Predictions with Learned Parameter Distributions

The learned parameter distribution was used in the SEIRD model to predict confirmed cases for the states of Florida, Georgia, and New York. As shown in Figure 3, a four-week prediction from August 3, 2020 is plotted for SEIRD-model, where the last model calibrated beta value is held constant for the prediction period; and for GP-regression, where $\beta$ values are learned from the GP. The observed confirmed cases are also illustrated. The GP-regression plot despite over-predicting compared to SEIRD-model plot, carries information about how strict the interventions are and how people are moving as a factor of the transmission parameter, which is key in intervention planning.

Predictions were performed for one, two, three, and four weeks from the last calibration date. For each prediction, the MAPE was computed on the predicted confirmed cases and deaths. Table 1 shows the MAPE for the 3 states and each of the experiments.

Table 1: Mean Absolute Percentage Error (MAPE) measuring the accuracy of SEIRD model ($\beta$ values learned directly from calibration) and GP-regression ($\beta$ values influenced by stringency and observed mobility) in forecasting COVID-19 cases within 4 time periods, and across 3 states

Conclusions

In this work, we have presented an application of Bayesian nonparametrics in the form of the GP to provide a surrogate model in calibrating epidemiological model parameters via Bayesian optimization. Further, we presented a process to tie parameter calibration to relevant model drivers, Stringency and Mobility, thereby capturing changes in the model parameters. These changes may themselves be inferred through a GP regression against relevant available data. Our results demonstrate that inferred model parameter values of transmission rate ($\beta$) for US states approach the predictive performance of the best-fit $\beta$ parameter values for each state. Finally, the steps presented in this work are provided as open-source tools for the reader to interact with and extend the presented Bayesian nonparametric approaches to their own model structures and input datasets. Future work can focus on hyperlocal modeling of extended pandemic periods with different epidemic waves across multiple geographical locations.

Abstract

The increased prevalence of voice search presents opportunities to address consumer challenges accessing online health information. However, it is essential to understand how users’ perceptions of voice affect their search processes for health information, concerns, and different scenarios for using voice for health information tasks. We conducted semi-structured interviews with 16 younger (18-25) and older (60-64) adult participants to understand and compare their perceptions of using voice and text-based search for non-health-related and health-related tasks. While most participants preferred traditional text search, younger adults were not inclined to use voice search for health information due to concerns about privacy, credibility, and perceived efficiency in filtering results. Older adults found voice search potentially beneficial for reducing manual query generation burdens; however, some were unsure of how to use the technology effectively. We provide a set of considerations to address concerns about voice search for health information tasks in the future.

Introduction

While consumer-facing voice technologies (e.g., browser-based voice search, mobile assistants) have been around for some time, advancement in speech recognition and natural language understanding have led to a growth in the use of these technologies in everyday life. Some online voice-search technologies such as Google Voice and Microsoft Cortana allow users to navigate visual user interfaces by performing traditional keyword searches using their voice. Others such as Apple Siri and Amazon Alexa act as assistants to find information on behalf of the user. Each approach has pros and cons, but for each approach voice is perceived as a more natural and convenient way of interacting with information and for completing search tasks.

The availability of voice technologies and their perceived efficiency has also led to an increased interest in using these technologies to support health information tasks. Several researchers have investigated the potential usefulness of voice to help different users obtain information and resources regarding their health. Yet, early findings are mixed as some users see potential while others feel that using voice for health tasks poses safety concerns. Despite concerns, research in this area is growing leading to a need for closer examination and additional empirical evidence of users’ experiences with voice for health search tasks to identify ideal use cases and ways forward.

In this paper, we build on prior work to examine older and younger adults’ perceptions of voice search for consumer health information tasks. We purposefully recruited to compare older and younger adult experiences due to potentially different generational and technology experiences. We conducted semi-structured interviews with 16 participants (6 younger adults and 10 older adults) that searched for online health information using text-based input and voice. For the purposes of this study, we did not limit voice search to a particular type of device (e.g., online voice search vs. voice assistant) because we wanted to understand a wide range of experiences with the two different online voice search methods. We found that both older and younger adults utilized the Internet as a supplement to doctor’s advice and explore alternative treatments. Both appreciated the convenience of being able to search for health information online and felt that it provided them an opportunity to become a more informed patient. However, both groups experienced challenges with searching for information online particularly with gauging the credibility of the information and health literacy. When it came to voice however, younger adult participants were more critical, sharing that they believed that using voice did not provide the depth of insight needed to be able to compare information when searching for health topics. In comparison, older adults were more receptive and hopeful about using voice for health, suggesting that if some open issues could be fixed, they felt it would be more convenient than traditional text-based keyword search. We discuss our findings in relation to prior work and make suggestions for improving older and younger adults’ experiences with voice search for health in the future.
Related Work

The Internet has become a key resource for finding and accessing information and helping patients become more engaged in their care. However, for some tasks such as for health information search, finding and navigating information can be challenging. Over the years, there have been many efforts to improve users’ interactions with online health information through computational means, many of which have focused on older adults. For example, some researchers have explored guided search to assist older adults with navigating health information online. Other interventions have focused on improving older adult’s online health literacy. However, in recent years, there has also been widespread interest in examining how voice technologies can support health and wellness.

A review of the use of conversational agents in healthcare reveals that voice technologies and other conversational user interfaces are increasingly being explored to support healthcare tasks ranging from mental health to chronic disease management. With the increase in voice-based technologies available to consumers, interest in exploring technologies such as voice assistants for both clinical and home healthcare delivery is also growing. Studies have explored using emerging voice-technologies to support independence and wellness in the home of older adults. Several researchers have also explored voice technologies to support aging in place while others have examined the potential of voice technologies for navigating and providing access to different types of health information. For example, recently researchers have explored the use of voice assistant technologies for supporting healthcare delivery tasks during the pandemic noting the benefits and barriers of existing voice assistant devices.

For older adults and other users, voice-based technologies are often perceived as more efficient and are thought to provide advantages for supporting access to information among older adults and people with disabilities. Because of these perceived advantages, voice technologies have gained renewed attention in recent years to examine uses for informational tasks such as health search. For example, O’Brien and colleagues examined reviews of popular commercial voice assistant technologies to understand how older adults are using devices, and beyond typical uses such as entertainment and smart home control, they also found that older adults were using voice assistants for memory aids, companionship, and emergency communication. Nullam and colleagues found that low-income older adults perceived voice assistants as a potentially efficient way to improve their access to health information and resources at home but like others, had concerns about the privacy and security of health information shared with the device. On the other hand, early research suggests that using certain voice-based technologies might leave users susceptible to other risks. Bickmore and colleagues for example, found that while most commercially available voice assistant devices can make the search for health information more efficient, they also place users at risk for unsafe behaviors, particularly if the user acts on the advice without proper knowledge of how to use the information returned. However, despite concerns, some suggest that with improvement voice and other conversational technologies could transform how older adults engage with health information and resources. But, there is still limited understanding of the usefulness of voice search for health. In this paper, we examine younger and older adults’ experiences searching for health information online to compare their experiences and perceptions of using voice search for consumer health information tasks.

Method

We conducted semi-structured interviews with 10 older adults and 6 younger adults to understand their experiences using traditional, keyboard and emerging, voice search technologies for health-related and non-health-related tasks. In this section we discuss our purposeful recruitment method and our data collection and analysis procedures.

Participants

Participants’ ages ranged between 18 to 64. Because one goal of our study was to compare experiences, we purposefully recruited participants in the age range of 18-35 (younger adults) and above the age of 60 (older adults). Our reasoning for selecting these groups was to understand if differences in responses might occur based on generational experiences with technology. Older adult participants were recruited from a local senior center, while younger adult participants were recruited from the local community. Prior to their selection, potential participants were informed of the main inclusion criteria: experience using traditional, text-based keyboard or voice search and experience searching for health information online. Interviews were conducted either in person or remotely at a time of convenience for both participants and researchers. Interviews took place before the COVID-19 pandemic. Of the sixteen participants, nine of the older adult participants were female and one was male. Half had a college degree, either an associate’s or bachelor’s degree, two participants had a high school degree, one had vocational training, and the remaining two participants had college credit but no degree. Three older adult participants had physical impairments and two had visual impairments; however, these impairments did not prevent them from searching online.
using typed search and voice search. Of the ten older adult participants, seven used computers, four used mobile devices, and one used a tablet. For younger adults, six used a computer and four used mobile devices. Of the six younger participants, four were female and two were male. Half of the younger adult participants had bachelor’s degrees, two had a high school diploma, and one graduated with an associate degree. No younger adult participants reported a disability or impairment.

Figure 1. Participants preferred online search methods and experiences with voice search tools.

Older adults and younger adults preferred text-based keyword search for finding information online, however many older adults preferred to use different methods for different situations (See Figure 1). Younger adult participants used Google voice search or Siri while older adults used a wide spectrum of voice search tools including Google voice search, Microsoft Cortana, Amazon Alexa, and Siri. Google voice search was the most used voice search tool among both groups (See Figure 1).

Data Collection

Before commencing interviews, we obtained approval from the Institutional Review Board at Indiana University. During interviews, after informing participants about the study and their rights, we asked participants to complete a background questionnaire to collect demographic data and information about their current technology use for searching information online. We then engaged participants in semi-structured interviews. In interviews, we asked participants to reflect on their experiences by sharing particular instances where they searched for health and non-health related information using each approach. For each scenario they shared, we asked them to reflect on the benefits and challenges of the approach and what they might do differently, if the content (health vs. non-health related) or approach (voice vs. traditional) were changed. To fully understand the common deterrents and benefits of each approach (i.e., voice or text-based search) we asked participants to share their general Internet search practices and preferred approach (voice or traditional search), reason and processes for searching for health and wellness information, experiences with voice-based search, and experiences using voice search for health and wellness. To conclude the interview, we focused discussions on the effectiveness and relevance of information provided by their preferred search approach, the benefits and challenges of their preferred approach, and suggestions for future improvements. All interviews were recorded and then transcribed. Participants were asked for consent prior to the recording of the interview. Participants were provided with a $20 grocery gift card for their time.
Data Analysis

We used thematic analysis\(^{41,42}\) to identify emerging themes from the data. Our analysis process entailed two researchers independently noting common codes based on an initial review of each of the transcripts. Following the initial independent coding, the two researchers met to discuss and consolidate codes which led to an initial set of codes that were used in a second round of analysis to code data. Example codes included themes such as search preferences, device reasoning, challenges, and reasons for online health search. In addition to thematic codes, we also grouped the responses of older and younger participants to examine similarities and differences in their responses and approaches. The final stage of analysis included several meetings where the two researchers met to consolidate similar codes under high-level themes which correspond to the subcategories listed in the findings section.

Findings

We discuss and compare younger and older adults’ experiences with using voice and traditional, text-based search for health and non-health related tasks.

Experiences with voice and traditional, text-based search for everyday search tasks

While the focus of our interview was to investigate online health search within a broad spectrum, we also sought to compare participants’ experiences with the efficiency of voice search versus text-based search for different tasks. Both younger and older adult participants shared different experiences. During interviews, we asked participants about their preferences when searching online, not limited to health information tasks. Less than half of the older adult participants (N = 4) reported feeling comfortable using voice search and preferred it in comparison to traditional, text-based search. The other half of older adult participants were not opposed to voice search but preferred traditional search because they were more familiar with searching for information that way. Three of the older adult participants in this group mentioned they would be willing to use voice search more often if they had better instructions on how to use it. Some older adult participants therefore were hesitant to use voice technologies due to what they perceived as a barrier of entry, and they were not inclined to search online for instructions for a product they used infrequently.

All younger adult participants (N = 6) preferred traditional text search, with only two mentioning consistent use of voice search. Younger participants’ inclination towards traditional search was due to their belief that traditional text search was more efficient and accurate. In comparison to voice search, younger adult participants felt that when using traditional text search, there was less of a chance of their query being incorrectly interpreted. Participants also liked being able to manually type in their queries; any mistakes they made could be quickly fixed opposed to the potential additional steps to fix issues related to speech recognition errors. Participant 12, stated, “I think usually people want information as quickly as possible so if they have to do it manually by typing it out, they’ll do that. I don’t see the huge need for voice-based search engines unless someone has a disability, that’s where I think they’re necessary”. Security and reliability were also raised as concerns about using voice search. Participant 9 mentioned, “Because it [voice search] doesn’t feel totally reliable for me these days. I’m pretty sure that it’ll change in 15, 20 years when they develop and improve the technology, but I don’t like the way it works right now”. This participant’s criticism with voice search related to the prior concerns about being able to control the search process, participants felt that voice search provided less control for generating queries but also manipulating queries to customize the search. Participants felt that currently the lengths they needed to go through to correct a query mistake ended up outweighing the benefits of a hands-free experience. For those younger adults that used voice search frequently, the reason for use was convenience, specifically when multitasking. Thus, these participants reflected on using voice search in moments such as taking transportation or conducting housework, where they felt the availability of voice search outweighed the occasionally jumbled or misunderstood queries. Therefore, the benefits and participants preferences for traditional search compared to voice search were related to the usability issues they encountered when carrying out search tasks using voice such as issues with speech recognition, use of small screens, and lessened ability to compare results.

Reason for searching health information online

Online health search for most participants, both young and old, provided what participants believed was a good amount and variety of information to support their health decisions compared to other information sources (e.g., books, magazines, etc.). Participants also believed the variety of online materials represented far more people and situations compared to other information sources which they felt was important. Both older and younger adults had similar sentiments about using the Internet to support their information needs regarding their health. Both parties, older and younger, agreed that they would not solely trust the Internet for pertinent health information. However, there were also differences.
All (N = 10) older adult participants mentioned using online health search often. For example, all the older adults interviewed have access to a patient health record or portal that they frequently used to obtain health information provided to them by their medical professional. Participants shared that initially they had to adjust to checking these applications to make updates to their information or view changes in their own health record such as a change in medication or posting of test results. As this became a part of their daily routine, they shared that they would use the Internet to supplement their understanding of a diagnosis of illnesses or new medication. Participant 1 described, “It’s been a little over a year. But I was diagnosed with pulmonary fibrosis. So, you know, the doctor gave me information and stuff. But I was able to get information [online] to know where I am at, you know, giving me more in-depth information that I could read at my leisure. So, I like that all that information is handy [online], and you can find support groups and all that type of stuff, too”. Older adults appreciated the ability to seek out information beyond the scope of a clinical setting and felt that searching online was far simpler than what they perceived as waiting on a delayed response from doctors. However, as Participant 1 discussed, older adult participants often shared that they consulted the Internet as a secondary source of information compared to younger adult participants. Older adults shared that they were more often searching the Internet for information about chronic or acute diseases, or medication, thus they were more inclined to seek help from a medical professional to verify the information they found.

Younger adults felt that online health search provided a simpler way to find information and keep it in one place. Young adult participants’ discussions of online health search pertained to finding information for themselves when they were ill or providing information to others who have asked them for suggestions. Some younger participants also suggested that being able to search for information online could help mitigate feelings of stigma when attempting to find information on a topic they felt might be difficult to talk about with others. Participant 8 explained, “I think [about online health search for] something like a mental health issue, like anxiety it’s just something that’s kind of a stigma that’s hard to talk about … I think online is somewhere that you can look up this information without feeling stigmatized and without feeling shame.” Younger participants also brought up concerns about the expense related to seeking information in clinical settings. If it was not a “grave” emergency some younger participants felt it was more economical to search for something for free using a search engine. Participant 12 stated, “But sometimes you just don’t want to go out your way to talk to somebody else or sometimes it might be private and just a really simple question and you don’t want to have to go to the doctor about it […] Plus I mean Googling something, that’s free. To go into the doctor is a little expensive.” Finally, younger adults also felt searching online allowed more opportunities to find instances of what they might be going through. Participant 11 shared, “I feel searching online is better because the person I might talk to may not have complete knowledge of medicine and may not have faced the sickness I am going through right now. There might be other users who have gone through my state, and who might actually have those similar symptoms where they can confirm they had a particular disease. In that way, I can confirm that I might have a sickness or disease. It might be more confirming than getting information from one person”. Participants shared that they sometimes found solidarity with others in similar circumstances and at times it brought them comfort in addition to the ideas of different solutions that might address the health problems they are facing.

Overall, health search was categorized as advantageous only to the extent that it was taken simply as supplemental advice, and with awareness that the information could be false. Participants were comfortable searching for health information online if it was not “extremely” serious. Therefore, participants expressed that finding credible sources online that could be backed by a healthcare professional was a key part of their home health management strategies.

Challenges Searching for Health Information Online

The previous section highlighted a common theme among all participants regardless of age concerning credibility when searching health information online. In this section, we provide additional insight on the challenges participants encountered searching for health information online. All participants discussed that they were keenly aware that not all information online represented fact and they took this into consideration when filtering through online websites. Participants were also aware that information found about symptoms could not be confirmed without a formal diagnosis from a medical professional. Participant 8 echoed this sentiment, stating, “But the problem is that you don’t know if it’s accurate. For example, I can look up symptoms, but I don’t know if it’s really the same as my health issue. So, it’s really vague. I would say that you don’t know which source is trustworthy compared to other information so maybe you can know for sure if it’s accurate”. Most participants felt that filtering information for credibility was challenging due to different users’ capacity to find and process information relevant to their situation. However, older adults mentioned this concern more often. Four older adult participants acknowledged that they found it difficult to discern whether information found in an online health search was relevant or pertained to their situation. Several older adults provided as an example their experience of looking online to search for a symptom they were having only to realize after talking with a medical professional that they were led to diseases that were far worse than what they were
facing. Therefore, while the amount of information on the Internet was sometimes useful, the abundance of information on the Internet also could be problematic.

Establishing credibility when looking for online health information was varied among all participants, with some explaining a more elaborate plan for determining relevance compared to others. Younger adult Participant 11 explained how he filtered through a certain number of queries as follows, “If I have three symptoms which are related to a disease, ... I type those three symptoms and I get multiple results. I verify with each website, at least four to five websites so they will be mentioning other symptoms that could associate with that disease... So that is how I process the information from the results that I get and also maybe two or three websites that say the same thing, I will go with that result as well.” One older adult participant, Participant 6, shared that this type of filtering information can be frustrating, “It’s just general, you know, it’s just like if I would put in rashes or something, so many things would come up and I don’t want to search through this long list of things looking for that particular type of rash or whatever it is.” Older adult participants overall however were lenient to taking more structured approaches to improve the query by selecting more concise word choices or including additional words even though they acknowledged it was not always clear that it might lead to better information. For example, participant 2 an older adult participant stated, “and you kind of have to fly by the seat of the pants because you can’t tell what’s perfectly real and what’s not on the Internet. But if you get 2 or 3 different opinions or answers and theirs similar, I think you can take that as its real. I don’t trust everything on there that I read like some people do.” Like P11 and P2, other participants expressed that they often compared information on different websites to gauge credibility and were more likely to gain confidence with data if it was repeated on different websites. In addition to repetitiveness, participants also found assurances in information and assistance from health professionals.

Participants also mentioned they sometimes did not understand the information discussed in online articles due to jargon which made searching for health information online difficult. Participants mentioned issues with health literacy and terminology as one of the main reasons they were often inclined to talk to a health professional for information rather than searching online. Participants also mentioned challenges due to the overwhelming amount of online content. Participant 7 explained, “That’s a hard part. Like I said, you know you put in one subject in the computer, and it pulls up 50 things for you to look at, you know? That could be very confusing.” To accommodate challenges some participants attempted to develop strategies to narrow down the amount of information and reduce the time it takes for them to parse through. Some younger adult participants shared strategies of how they would skim through different websites rather than read them completely, because they knew not all information pertained to them. These participants felt that getting the gist of information was more important than complete details. For example, one younger participant shared, “If I go onto a website and there’s just a lot of information like an overwhelming amount, usually I’ll skim and try to I guess highlight what I’m interested in. That’s usually what I’ll do for most websites because I don’t want to read every single paragraph knowing that it doesn’t relate to what I want to know about.” Participants suggested that sometimes skimming through websites provided enough information to satisfy their reason for search. However, the amount of information returned, and the time needed to parse through it was still discussed as a source of contempt among many of the participants.

Perceptions of Using Voice for Health-Related Search

Participants varied slightly when asked their comfort level when using voice search for online health. Each group addressed specific concerns that were related to their specific perceptions of using voice technologies for health search. The dominant theme that emerged among older adult participants was that they appreciated having a wide set of health information available online regardless of the search tool. However, they felt that voice search could make it easier to access information, improve accessibility and reduce the challenges associated with generating and typing queries. Participant 6, an older adult, described the efficiency of voice-technologies as a benefit, “Just convenience is the main thing. Um, not that it takes a long time to type it in, but you have to worry about hitting the wrong buttons and all that. So, it’s so much easier just to say, ‘Hey, Google’.” Another older adult participant also reiterated the convenience of not making mistakes while typing, sharing that they felt using voice created less confusion and more of the work was being placed on devices opposed to the user. Four of the ten older adult participants had never used voice search at all for online health search but mentioned that they were not opposed to it. Participant 2 stated, “I wouldn’t be opposed to it ... I don’t have it on my phone. I suppose if I had a phone that would access it [voice search] I would be more inclined to do it”. The other three participants provided similar reasoning stating that they simply did not understand how to use voice search; however, if they were guided, they would be more likely to use it for online health search.

Younger adult participants were more critical of using voice search for online health than the older adult participants. Only two of the seven participants had used voice search in the past for online health and both participants discussed
that the negatives outweigh any benefits. Participant 12 described, “It wasn’t bad, but the experience could’ve been a lot more beneficial to me. It gave me websites that were related to what I was trying to search but they weren’t that detailed or in depth as I wanted them to be.” Being able to access sufficient information was a concern many participants had with voice search even when not conducting online health information. Participants also shared that they felt that the number of responses returned by voice search queries particularly on mobile and standalone devices are fewer, so users are not able to listen and compare multiple sources of information. Unlike older adult participants, all younger adult participants preferred to search for online health information through traditional search methods to gather a wide variety of information and to be able to manually compare results. Younger participants, unlike older adults also felt it more efficient to type and customize queries manually rather than relying on speech recognition. In addition to criticisms about voice supporting effective online health search, participants were additionally concerned about privacy and mentioned that they would be hesitant to ask about certain health topics in public and they might not be for non-health related topics. One participant therefore mentioned that they would limit online health search to situations where they were alone out of fear of revealing personal information.

Discussion

Our findings suggest that older and younger adults have different perceptions of the usefulness of voice search for consumer health information tasks. Most younger adult participants preferred traditional text search for non-health related and health related search tasks citing that voice search can make search in general more complicated and time consuming. Older adults on the other hand saw potential in the use of voice search for improving the efficiency of the search process by reducing challenges they faced with query generation and typing. Therefore, voice search for online health remains a point of contention for both older and younger adult groups. In the following suggestion we discuss potential ways forward for better utilizing voice search to support online health information search processes.

Improving Voice Interactions for Health Search

Our findings align with prior work that has explored the benefits and barriers of voice search more broadly. Prior work notes that older adults often prefer voice for its efficiency\(^1,4\) and there have been concerns about the practicality of voice search for health-related tasks\(^1\). Our findings imply that despite the growing interest and availability of consumer-facing voice technologies, open challenges exist in using these systems for health-related search tasks. From a younger adult perspective, the potential conveniences provided by voice search were counteracted by the limited set of results often returned. While voice search options are available on web browsers and return comparable results similar to traditional, text-based search, participants often equated voice search with something to be used on the go. Thus, most often participants’ discussions of online voice search were concentrated on mobile or standalone devices which have distinctive design principles that may not be ideal for some health search tasks. Thus, improving voice search for health and more generally may require a closer examination of existing conversational design principles used to guide voice assistant interactions and how these interactions can be reimagined for supporting voice health search. For example, younger adults felt that limited results returned from voice queries did not suit their needs of being able to filter through options. To accommodate a broader range of results, voice search could implement similar abilities to traditional search such as providing a broader range of options but personalize and rank the results based on prior knowledge of the user or using an approach that reveals different options based on predetermined categories. The conversational design could also be altered to provide follow-up dialog to alleviate the potential usability issues that arise when presenting long lists of options on smartphone or voice-only interfaces. Providing interactions that allow users to compare results could move forward voice search for health.

In parallel, older adults raised concerns about not knowing how to use voice search. Older adult participants’ main deterrent to voice health search was a lack of knowledge on how to use technology. Supporting discoverability or a user’s ability to successfully uncover and explore the capabilities of voice-based systems is an open challenge particularly in voice-only systems\(^37,43\). To advance voice search for health, use cases should consider options for guiding users through the voice search process. Some participants mentioned that in-person instruction might be the most suitable method for learning as opposed to the typical online and offline user guides. Guides such as these have been found problematic among older adults for promoting transparency in the past\(^16\). Thus, moving forward, it would be useful to further explore both technical and non-technical solutions to increasing older adults’ agency in voice search for health.

Addressing Trust and Safety Concerns

Trust and safety concerns mentioned by participants when using voice for health were linked to the lack of credible information available in search results and lack of knowledge of where health-related search queries were being sent.
Apart from voice health search, participants raised gauging credibility of online information for health purposes as difficult. Although participants shared different filtering methods, it was not clear whether different methods garner more verifiable information. The ability of users to identify credible information online in health-related searches is a known issue and we know that the ability to gauge credibility can be impacted by demographics and information source\(^{39,40}\). Participants’ criticisms regarding credibility implied that voice technologies provided less transparency and therefore made it more difficult to make decisions which they felt was key to facilitating online health information search.

Gauging credibility of websites prior to displaying results and then providing users with access to that information within the search result list may partially address this issue. For example, systems could rank results based on a credibility score. For voice only systems, the device could capitalize on existing approaches that announce where the information came from (e.g., “according to WebMD diabetes is …”) to provide users with data to help them decide if they want to use the information or not. However, it might be helpful to also provide information to help people gauge credible sources. For example, include information about the website itself to help users decide if they want to take information from that website (e.g., “WebMD is a credible consumer source of information based on …”). Therefore, providing some indication of the credibility of the information might help users better trust voice-based search and gauge potential risks.

**Limitations**

While we collected data until we began to see recurring themes in our data (i.e., reached saturation), our study may be limited by our participant demographics. Our participants younger and older were primarily female and most had some sort of college experience. While younger and older adults had different technology experiences, most did use technology. While some participants were familiar with voice search and had used it in the past, there were several participants that shared that they no longer used voice search or limited their use. Also, most participants that used voice for search used voice assistants which are designed to provide different types of search interactions compared to text-based search in a web browser. Therefore, our findings might be limited due to context and the specific demographic of participants. As our study is qualitative with a smaller number of participants, we do not aim for generalizability. We expect that our findings will transfer to similar groups and contexts\(^{41,42}\) however additional studies may be needed to determine relevance to other populations of users.

**Conclusions**

Our study compared experiences with text-based and voice search among older and younger adults for health and non-health related tasks. We found some differences in older and younger adults’ perceptions of the usefulness of voice for conducting health search tasks. Our findings suggest that the potential to use voice for health information search tasks still requires several improvements. A combination of increasing transparency of search results when interacting with voice-based technologies and improving voice search recognition and filtering will be essential to increase acceptance and use. Continued studies examining participant concerns, especially studying individual use, is one of our next steps to better understand the usefulness and feasibility of voice for supporting health information tasks. In addition, we will further divulge the necessary requirements for improving conversational design to accomplish transparent and efficient voice-based health search.

**Acknowledgements**

We would like to thank our participants who shared their experiences with us. We would also like to thank the Indiana University EMPOWER program for providing funds to support this research. We would also like to thank the Indiana LSAMP program (IN LSAMP) for supporting several of the undergraduate research scholars involved in this research.

Controversial Trials First:
Identifying Disagreement Between Clinical Guidelines and New Evidence

Florian Borchert, MSc, Laura Meister, Thomas Langer, Dipl. Social Scientist, Markus Follmann, MD, MPH, MSc, Bert Arnrich, PhD, Matthieu-P. Schapranow, PhD

Abstract
Clinical guidelines integrate latest evidence to support clinical decision-making. As new research findings are published at an increasing rate, it would be helpful to detect when such results disagree with current guideline recommendations. In this work, we describe a software system for the automatic identification of disagreement between clinical guidelines and published research. A critical feature of the system is the extraction and cross-lingual normalization of information through natural language processing. The initial version focuses on the detection of cancer treatments in clinical trial reports that are not addressed in oncology guidelines. We evaluate the relevance of trials retrieved by our system retrospectively by comparison with historic guideline updates and also prospectively through manual evaluation by guideline experts. The system improves precision over state-of-the-art literature research strategies while maintaining near-total recall. Detailed error analysis highlights challenges for fine-grained clinical information extraction, in particular when extracting population definitions for tumor-agnostic therapies.

Introduction
With the amount of published medical evidence steadily growing, it becomes increasingly challenging for practitioners to keep up with the latest developments in their field. Clinical practice guidelines (CPGs) are designed to summarize the currently available evidence regarding specific clinical questions and provide recommendations based on well-defined and methodologically sound criteria. Despite advances in the development of living guidelines, even the most recent CPGs are ultimately static documents in a constantly evolving landscape of new evidence in the form of primary research articles, e.g., reports of randomized controlled trials (RCTs), or even unpublished results.

Finding and ranking relevant medical evidence is a well-investigated information retrieval problem. Medical literature search engines allow users to apply fine-grained search filters, based on string patterns as well as manually or automatically derived metadata, such as Medical Subject Headings (MeSH). In addition, a ranking of most relevant articles given a user query is desirable, which can be based on additional intrinsic properties of the document. In the case of a clinical trial report, this could be the study design or sample size.

While a growing amount of hand-curated and automatically derived semantic information is available for medical information retrieval, current software systems do not take into account the relationship of new evidence to the currently established CPGs, in particular as their applicability depends on the location of the user. Prospectively, new evidence may disagree with the statements in these CPGs, e.g., when an RCT presents new results that are not (yet) accounted for.

In the remainder of this work, we will refer to such evidence as controversial, which shall broadly incorporate any kind of disagreement with current CPGs. This information is relevant to a variety of audiences, for instance:

- Maintainers of CPGs, who wish to identify update signals with the potential to necessitate a CPG update
- Readers of CPGs, who need to verify whether a CPG still reflects the latest evidence
- Specialists interested in new treatments beyond CPG recommendations, e.g., for specific subgroups of patients, as it is common in precision medicine

In this work, we propose an automatic approach to identify such controversial evidence. The system is based on metadata automatically derived via natural language processing (NLP) from scientific articles and CPGs from clinical guideline repositories.
Figure 1: Overview of our approach to detect RCTs with drug interventions not covered by CPGs. Here, we consider the German CPGs in oncology in GGPONC. CPGs and RCTs from Trialstreamer are matched based on the CPG topic and the extracted population concepts of the RCT. The set of intervention concepts is compared to the drugs / chemicals mentioned in GGPONC to flag RCTs with interventions currently unmentioned in the CPG as controversial. Term expansion is performed using MeSH and SNOMED CT to account for synonymy and hyponymy.

Due to the country-specific nature of CPGs, they are typically published in their respective national language. Therefore, the underlying NLP problems are inherently multilingual. We address this issue by automatically mapping the extracted information to the Unified Medical Language System (UMLS), thereby establishing a novel link between primary and synthesized evidence across languages.

Different types of disagreement can be defined over such information using transparent rules, which enables users to reason about the validity of the identified disagreement. We demonstrate the feasibility of the proposed approach by implementing and evaluating the detection of a highly relevant form of disagreement: RCTs mentioning drug interventions not included in current CPGs, as outlined in Figure 1. To this end, we leverage two recently published resources, the Trialstreamer database of RCTs and the German Guideline Program in Oncology NLP Corpus (GGPONC).

A prototype of the system is publicly available: https://we.analyzegenomes.com/nge.

The remainder of this work is structured as follows: in the following section, we set our approach in the context of related work, followed by a description of the used datasets and components of our system. We proceed by presenting the output of the system for specific clinical indications and the evaluation in an information retrieval setting. Results are interpreted and limitations discussed thereafter, followed by a conclusion and outlook.

Related Work

Information retrieval of the medical research literature has been studied extensively in the last decades. A multitude of approaches have been proposed to filter and rank by relevancy collections of RCT reports and other medical publications.

PubMed is probably the most widely used medical search engine and allows fine-grained filtering based on text matches, MeSH terms and other metadata. Recently, PubMed has introduced a new Best Match sorting option, taking into account different metrics and user queries. The Trip database allows more advanced search options based on the Population-Intervention-Control-Outcome (PICO) framework and a ranking of articles by relevancy, such as latest and greatest. There is a wide selection of systems that enrich PubMed with additional semantic information and employ them for document retrieval, for instance using automatically extracted biomolecular entities and relations.
In practice, literature search strategies for initial CPG creation and updates are based on elaborate Boolean search queries in different literature databases, carefully hand-tailored for the specific clinical questions covered by the CPGs[1]. These queries can be continuously applied to identify update signals, i.e., research results that would necessitate an immediate update or amendment to a CPG[1]. Reviewing of the results and subsequent data extraction is done manually.

RobotReviewer is a system that automatically extracts structured information from RCT reports and predicts the risk of bias (RoB) of an RCT according to the Cochrane RoB tool[15]. Recently, Marshall et al. (2020) released Trialstreamer, combining the predictions of RobotReviewer and other components leveraging machine learning (ML) into a living database of RCTs along with their extracted metadata[6]. Based on this metadata, the Trialstreamer website allows to filter RCTs by their PICO elements and prioritize large and high-quality RCTs.

To the best of our knowledge, there is currently no system that combines information from published research results and CPGs to expose additional relevancy criteria for information retrieval.

Datasets

**Trialstreamer** is a publicly available, regularly updated database of RCTs derived from automatically screened PubMed articles and the WHO International Clinical Trials Registry Platform[9]. For this work, we focus on PubMed articles, which are included in Trialstreamer according to an automatic classification of articles that describe RCTs in humans. From the corresponding abstracts, structured metadata is extracted using different ML- and rule-based NLP methods.

For our system, we use the extracted sample size, PICO spans and PICO concepts. For the evaluation, we combine the base version of Trialstreamer and all PubMed updates up to December 28th, 2020, resulting in a dataset of around 699k RCTs. In the live version of the system, updates to Trialstreamer are automatically integrated on a weekly basis.

**GGPONC** is a metadata-enhanced text corpus based on German CPGs in oncology, currently consisting of 25 CPGs with around 1.3M tokens and more than 4k recommendations covering a diverse set of indications[7]. It is currently one of the largest publicly available text corpora of CPGs in general and of German medical text in particular. GGPONC has been automatically annotated with entity classes from different UMLS semantic types, for instance, Disorders, Procedures, Chemicals & Drugs, and Anatomy from the German subset of the UMLS. Gold-standard annotations from human experts are available for around half of the corpus.

In addition, GGPONC provides a variety of metadata for individual recommendations, e.g., timestamps, which allow us to simulate past guideline versions by excluding elements introduced after a certain point in time. GGPONC is freely available upon request[†]. New CPG versions are automatically integrated into the system upon release.

**Named Entity Recognition and Normalization**

To find drug mentions in GGPONC, we use the same dictionary-based JCoRe (i.e., UIMA-based) pipeline as in Borchert et al. (2020)[14]. In contrast to our earlier work, we configured the pipeline with a larger dictionary of substances derived from the UMLS (version 2020AB) using the JuFIT tool (v1.1)[17]. The goal of using a larger dictionary is to improve recall (sensitivity), at the expected cost of precision. Therefore, we consider all preferred English terms of the UMLS semantic type Chemicals & Drugs in addition to the German terms, yielding a dictionary of around 1.26M entries compared to only 34.550 from the German UMLS subset. With this extended dictionary, recall for the recognition of Chemicals & Drugs measured on the human-annotated subset of GGPONC increases from 0.600 to 0.788, whereas precision decreases from 0.917 to 0.520. Due to the nature of this dictionary-based approach, all extracted entities are already linked to UMLS CUIs (concept unique identifiers).

The Trialstreamer database already contains automatically derived metadata relating to PICO elements. Entities within PICO spans are linked to UMLS CUIs using a re-implementation of Metamap Lite[18]. Recall for PICO concept extraction under relaxed comparison reported by Marshall et al. (2020) is relatively high (0.85 for intervention and 0.78 for population), while precision is rather low (0.57 for intervention and 0.30 for population)[5].

Identifying Controversial RCTs in Trialstreamer

The current version of our system enables the detection of controversial RCTs in Trialstreamer by linking the extracted PICO concepts to CPGs from GGPONC as outlined in Figure 1. In the following, we describe the rule-based algorithm that detects RCTs concerning drugs unmentioned in current CPGs. Other types of rules can be implemented similarly.

For all RCTs in Trialstreamer, we identify those with intervention CUIs contained in the large UMLS-based dictionary of drugs and chemicals described earlier and retain only such trials where at least one intervention is a drug or chemical, as opposed to other kinds of treatments. For each guideline topic, e.g., lung cancer, we perform a term expansion step to identify synonyms and hyponyms, such as pulmonary neoplasm, lung adenocarcinomas, or bronchogenic carcinoma, which we refer to as topic concepts. This expansion was performed based on the MeSH and SNOMED CT terminologies using PyMedTermino and the entity linking module from scispaCy.

To obtain all potentially relevant RCTs for an existing CPG topic, we filter Trialstreamer by the automatically extracted population CUIs that overlap with the set of topic concepts. For each of these topic-related RCTs, we determine whether at least one of the intervention CUIs is not contained in the complete set of drug CUIs extracted from the corresponding CPG at a particular time point. Such RCTs are flagged as controversial. Term expansion is also performed on the level of interventions, to account for mentions of drug classes, i.e., an RCT mentioning a more general term (e.g., protein kinase inhibitor) should not be considered controversial if a narrower term (e.g., afatinib) is already included in the CPG. This step also accounts for synonymy due to the use of experimental, non-proprietary, and trade names of drugs.

This simple rule over the extracted metadata is completely transparent to the user. Moreover, it is easily extensible and adaptable to different requirements, e.g., when a different trade-off of precision and recall is desired, and can be easily implemented within medical search engines. We provide a prototypical user interface, displayed in Figure 2, that allows users to browse RCTs per CPG topic and to display only controversial results, in addition to filtering based on the publication year, sample size, and free-text matches. It should be noted that even simply filtering by sample size is not available in typical literature search engines and only enabled by the NLP-derived information in Trialstreamer.
Figure 3: Development of the number of RCTs for the top 15 drug names not mentioned in the previous CPG for two topics and update intervals. We show the initial number of RCTs in the year of the previous CPG update as well as the cumulated number of RCTs until the current update. Drugs marked as incl. have eventually been included in this last update, whereas drugs marked as not incl. are (still) not mentioned in the current CPG version.

Evaluation

Retrospective Scenario Using the temporal metadata in GGPONC, we simulate CPG versions at a past point in time by manually identifying and removing all drug mentions from the CPGs that were first included after that point in time. Two CPGs and simulated versions are investigated: a 2010 version of the lung cancer (LC) CPG, which has received an update in 2018, as well as a 2017 version of the renal cell carcinoma (RCC) CPG, updated in 2020. For these two topics, we process all RCTs from Trialstreamer and flag them as controversial if at least one of their interventions is a drug not yet included in the historic CPG.

In Figure 3, we show the drugs with highest numbers RCTs identified in this way. At the points in time the CPGs were issued, there are only very few interventions mentioned in RCTs that are going to be included in future CPG updates — the respective CPG can be considered up-to-date. In the following time preceding the next update, evidence relating to the most commonly mentioned drugs has accumulated. However, for both CPGs, there is a noticeable tail of drugs investigated in clinical trials that do not end up in the respective CPG.

Retrospective Evaluation of Retrieval Performance In the considered scenario, where our goal is to find interventions not currently part of CPGs but with the potential to become CPG-relevant in the future, a typical requirement is near-perfect recall, generally at the cost of precision. Using the controversial flag as an additional filtering criterion for retrieving RCTs from PubMed, we evaluate retrieval performance in terms of (1) precision with respect to retrieved documents actually describing an RCT with a newly CPG-relevant drug, as well as (2) recall with respect to the proportion of retrieved drugs from the set newly CPG-relevant drugs. The results are given in Table 1. Note that retrospective assessment of recall in terms of documents is actually not possible based on our data, since a particular CPG update cannot be reliably attributed to a single RCT. This would require manual reconstruction of the literature screening process, which might be partially based on existing systematic reviews not included in Trialstreamer.
Table 1: Retrospective evaluation of retrieval performance under different filters evaluated against past CPG updates. The baseline strategies are filters by Year (Y), by drug interventions only (I\textsubscript{Drug}), by matching the study population to any sub type of Cancer (P\textsubscript{Cancer}), or to the respective CPG topic (P\textsubscript{Topic}). We compare these to advanced filters based on the sample size of n from Trialstreamer, and the controversial tag from our method (Controv.). We identify all RCTs in Trialstreamer matched by these criteria over the period between two consecutive updates and report precision (Pr.) in terms of documents and recall (Rec.) in terms of retrieved drugs newly mentioned in the current CPG version. Very high precision can be obtained by our method based on the controversial tag, in particular in combination with a filter based on the sample size (n > 100), while maintaining the same recall as the most specific baseline strategy.

Prospective Evaluation In a real-world deployment, we want our system to detect controversial trials based on the current CPG versions, in contrast to historic versions used in the retrospective evaluation. Therefore, to evaluate the system prospectively, we consider the current versions of the German CPGs on Ovarian Cancer (OC) and Malignant Melanoma (MM), both with a last update in the early 2020, and identify controversial trials with respect to these topics in 2020. As the interventions relevant for the next CPG version are still unknown in the scenario, the output of the system was manually evaluated by guideline experts from the German Cancer Society.

The manual evaluation results are shown in Table 2. 41 RCTs are found by our system for Ovarian Cancer and 21 for Malignant Melanoma in, resulting in a total of 62 articles from 2020 used in this evaluation. 23 of these have been categorized to have direct potential to be relevant for future CPG versions, corresponding to a precision of .355, when applying the same standard as in the retrospective evaluation. When we also consider early-stage RCTs as relevant and also ones reporting negative results, precision increases to .645. In effect, only 35.5% of results are actually clearly irrelevant, because of errors in downstream components of the system. This number is very low compared to usual Boolean searches in PubMed. We will analyze the different error conditions in the next section.
### Table 2: Prospective evaluation for the system configurations based on the current German CPGs on Ovarian Cancer and Malignant Melanoma, both from early 2020. For all identified interventions, we report the expert decision regarding the potential relevance for a future CPG update. We also denote if an RCT does not meet the criteria for CPG inclusion due to an early phase or negative results. If there is more than one publication per intervention, this number is denoted in brackets. Actual false positives are designated in the last column, with the error type distinguished by origin between ontology incompleteness (O) and errors in Trialstreamer: RCT document classification errors (TS-D), intervention extraction errors (TS-I), and population extraction errors (TS-P).

**Notes:**
- †Description of the trial design only.
- *Relevant for the population, but not the underlying clinical questions used during CPG development.
- **No or unclear relevance in the EU / Germany.

#### Error Analysis

**Phase I/II Trials, Negative Results, and Study Withdrawal**  Phase I or phase II trials, e.g., for TRC105 in RCC or cabazitaxel in OC, are not immediately relevant for CPG inclusion. Negative results in such phase I or II trials or study withdrawal occur frequently. These types of results have to be considered as false positives with respect to the goal of identifying CPG update signals, and are counted as such in the retrospective evaluation. However, they can be of great interest to other users of the system. Being able to distinguish the particular type and design of an RCT automatically would be a useful feature in a future version of the system, but would require a more elaborate semantic understanding of study contents through NLP. Negative results for drugs included in current CPGs would constitute a different type of disagreement that we would like to be able to detect.

**Misalignment of Topics and Populations**  When the scope of a CPG is not fully defined by the population alone, some results might be relevant for the topic but not (yet) covered as a clinical question in the CPG. For instance, supportive therapy with royal jelly or the use of local anesthetics might be relevant for the considered population, but covered in a separate CPG on such cross-cutting concerns. Addressing this problem comprehensively would require a complete formal specification of the clinical questions underlying each CPG.
**False Negatives** For this type of error, drugs would be relevant, e.g., for future CPG versions, but we retrieve no RCTs mentioning them (lower recall). In the retrospective evaluation, recall is < 1 only for LC after applying a population filter, because the drug dabrafenib, newly mentioned in the 2018 guideline, was missed. Dabrafenib could not be found in Trialstreamer after filtering by population, as all RCTs on the drug mention more general population terms, such as solid tumors, which is not captured by our term expansion strategy.

**False Positives** For this type of error, RCTs are retrieved that mention drug names which are not included in the future CPG version (lower precision). Sources of false positives, by example of the drugs depicted in Figure 3 and Table 2 are:

- Ontology incompleteness (O): if no mapping of a concept exists in the UMLS for the language of the CPG (here German), it would not be extracted from the current CPG and therefore not be considered as already mentioned. Incomplete terminologies in the UMLS can also be a source of false negatives, e.g., when novel drugs have not yet been curated. Such a false negative, however, did at least not occur in the retrospective evaluation.
- Document classification errors (TS-D): errors introduced due to a misclassification of a publication as an RCT. In one case, a narrative review on denosumab has been misclassified as an RCT.
- Intervention extraction errors (TS-I): for example, rapamycin is extracted as an intervention in Trialstreamer and normalized to sirolimus, although it only occurs as part of a larger entity mammalian Target of rapamycin. Given the high reported accuracy of Trialstreamer with respect to the extraction of interventions, this error type is only encountered occasionally. This class of errors includes incorrect abbreviation expansion, as in the case of DCA, which was considered as a chemical but supposed to mean decision curve analysis in the RCT.
- Population extraction errors (TS-P): in some cases, the study population has been extracted incorrectly in Trialstreamer. These problems can be rather obvious, e.g., for an RCT with breast cancer patients performed at the Center for Familial Breast and Ovarian Cancer. Other instances are more subtle, e.g., when the population malignant melanoma is assigned to an RCT with choroidal melanoma patients in Trialstreamer.

**Discussion**

**Limitations** Our detailed error analysis highlights limitations of the system as currently implemented. The initial population matching strategy is currently unable to account for drugs like dabrafenib, whose target population is based on molecular characteristics rather than specific tumor entities, i.e., tumor-agnostic therapies.

In general, the performance of our system strongly relies on various downstream components, in particular the ML-based components used to populate Trialstreamer as well as the dictionary-based information extraction from German CPGs. Reliance on currency and completeness of the UMLS is problematic in particular for new concepts and low-resource language communities. While the NER step could be solved using an ML-based approach, matching of entities across languages without access to a multilingual ontology will be challenging. It further needs to be investigated if truly controversial treatments will be detected by current NER solutions, as they might not be adequately represented in terminologies or training data.

An assessment of recall and an error analysis of false negatives in the prospective setting is still missing, as it would require a screening of all articles to account for false negatives in the classification of RCTs by Trialstreamer as well as incompleteness of the UMLS with respect to novel drugs. In a future evaluation, we will apply the system in parallel to an ongoing major update of the German LC CPG, including a full literature screening for relevant RCTs.

The current binary scheme, which flags each RCT as either controversial or not, could be enhanced by softer relevancy criteria. These should account for the inherently probabilistic outputs of downstream NLP components and incorporate relationships to multiple, potentially disagreeing CPGs. Using such criteria would enable the implementation of a true ranking of results and the use of ranking-based evaluation criteria, such as P@K or AUC.

**Other Types of Evidence** While RCTs are the gold standard in evidence-based medicine, they are by far not the only source of medical evidence. For many uses cases, interventions investigated in ongoing RCTs or with unreported results (publication bias) will be relevant and therefore clinical trial registers, such as ClinicalTrials.gov should be
considered. This information will be easier to incorporate in the system, as data in these registers is usually available at least in a semi-structured format, and already included in Trialstreamer. Other types of published research, such as case reports, are not included in Trialstreamer and will require custom NLP solutions for information extraction and normalization.

In addition, results which were not published in medical journals and other types of so-called grey literature can be of interest to some users. Incorporating these sources of evidence is likely to yield much more controversial information compared to published RCTs. However, these sources will contain a substantial proportion of completely irrelevant information. They are also expected to be more challenging to process via NLP due to large linguistic heterogeneity.

**Other Controversial Results** There are many types of controversial evidence not yet covered by our methodology. A different type of intervention would be addressed by the UMLS semantic type Procedures, e.g., for radiation therapy or other nonpharmaceutical interventions. Here, we expect cross-lingual matching to be more challenging compared to drug names, which are mostly single-token proper nouns.

Other types of disagreement could occur on the level of outcomes, where new results regarding efficacy and safety of a CPG-recommended drug can influence decision-making. Extraction quality with respect to outcomes is lowest for all PICO elements extracted in Trialstreamer, so a detailed investigation and improved NLP solutions are necessary.

**Conclusion and Future Work**

In this work, we presented a system that allows to detect controversial trials, i.e., ones that disagree with current clinical practice guidelines. The system relies on the NLP-based extraction of metadata from RCTs and CPGs and simple rules to identify disagreement based on this data. While the evaluation results are encouraging in an information retrieval setting, there is ample opportunity for improvement.

With more and more drugs targeting specific genetic alterations, this information should be incorporated into the population matching strategy, in particular for other types of users, e.g., participants of molecular tumor boards. Information extraction of molecular entities has been studied extensively by the BioNLP community, albeit rarely in the domain of RCTs. Such an extension would make the system also useful for curators of clinical evidence in precision oncology knowledge bases.

To enable the implementation of rules for other types of disagreements, future work will focus on the inclusion of information regarding outcomes within the PICO framework as well as different published and non-published types of evidence. To further improve system performance in the investigated multi-lingual setting, we will need to improve clinical NLP methods for languages other than English, which are still restricted by the shortage of publicly available research dataset and, in comparison to the English language community, a lack of modern ML-based information extraction solutions.

A prototype of our system is online available for evaluation at [https://we.analyzegenomes.com/ng](https://we.analyzegenomes.com/ng). We will continuously improve the prototype to allow users to find other types of disagreement, incorporate different kinds of evidence and extend the scope to other CPGs from other medical fields and countries.

Abstract

Unhealthy alcohol use represents a major economic burden and cause of morbidity and mortality in the United States. Implementation of interventions for unhealthy alcohol use depends on the availability and accuracy of screening tools. Our group previously applied methods in natural language processing and machine learning to build a classifier for unhealthy alcohol use. In this study, we sought to evaluate and address bias through the use-case of our classifier. We demonstrated the presence of biased unhealthy alcohol use risk underestimation among Hispanic compared to Non-Hispanic White inpatients, 18- to 44-year-old compared to 45 years and older medical/surgical inpatients, and Non-Hispanic Black compared to Non-Hispanic White medical/surgical inpatients. We further showed that intercept, slope, and concurrent intercept and slope recalibration resulted in minimal or no improvements in bias-indicating metrics within these subgroups. Our results exemplify the importance of integrating bias assessment early into the classifier development pipeline.

Introduction

An estimated 14 million United States adults met criteria for an alcohol use disorder in 2018, with nearly 1 in 10 adult alcohol users affected1. Unhealthy alcohol use represents a major economic burden and causal factor in cases of traumatic injury, liver disease, and other noncommunicable diseases resulting in death2,3. Further, alcohol-related disorders consistently rank in the top ten most common non-maternal diagnoses responsible for inpatient stays among adults under 44 years old4 and individuals with alcohol-related disorders are more likely to return to the hospital within two weeks of being discharged compared to unaffected individuals5. Screening tools for unhealthy alcohol use can effectively identify individuals who will benefit from interventions that decrease alcohol use-related morbidity and mortality6,7. Accordingly, the successful implementation of treatment depends on the availability and accuracy of such screening tools.

Unhealthy alcohol use screening in the hospital setting currently involves the use of a single screening question or a standardized questionnaire such as the Alcohol Use Disorders Identification Test (AUDIT)8. Adding self-report questionnaires into the clinical workflow requires additional time and resources that may limit their utility. Screening methods that utilize notes from the electronic health record (EHR) captured during routine care are promising alternative approaches to identify likely cases of unhealthy alcohol use9.

For clinical decision support tools, there is growing concern about the potential for bias in machine learning (ML)-based automated approaches. There have been several notable publications discussing unintended bias in ML tools across several fields, with consequences ranging from underprediction of health risk in Black patients by a widely used commercial insurance algorithm10 to increased error rate in speech recognition for Black speakers11 and undervaluing of female job candidates12. In medicine, minimizing bias in ML-based clinical decision support is critical to avoiding downstream harm and the exacerbation of existing healthcare disparities.

Our group previously applied methods in natural language processing (NLP) and ML to build a classifier for unhealthy alcohol use from notes collected in the EHR that offers adequate sensitivity for screening patients in the acute care setting9. The classifier was trained on EHR notes from patients with a primary admission for trauma and has since been validated using data from non-trauma inpatient hospitalizations13. In this study, we seek to evaluate and address bias through the use-case of our previously developed unhealthy alcohol use NLP classifier. Our aims are the following: (1) to assess for bias in the NLP classifier via examination of subgroups of age, sex, and race/ethnicity; and (2) to determine if recalibration among subgroups affected by model bias can mitigate the bias in the NLP classifier’s screening performance.
Methods

Unhealthy Alcohol Use Classifier

The unhealthy alcohol use NLP classifier previously published by our group\(^9\) was developed using concept unique identifiers (CUIs) derived from linguistic processing of clinical notes, with AUDIT scores ≥5 and ≥8 points as the reference standard for unhealthy alcohol use in women and men, respectively. Clinical notes available from within 24 hours of presentation to the Emergency Department were scanned for Unified Medical Language System entity mentions, which were mapped to CUIs. Hyperparameters were tuned to maximize the area under the receiver operating characteristic curve (AUC ROC) using 10-fold cross-validation. The final classifier retained 16 CUI features and achieved an average AUC ROC of 0.78 (95% CI 0.68-0.89).

Patient Setting and Data

Our data consisted of two cohorts: one from the original development paper using trauma patient encounters in the Emergency Department (n=1,326) and one from the validation cohort of an independent group of hospitalized patients in the medical/surgical wards (n=999).

Our trauma dataset included consecutive patients seen at Loyola University Medical Center’s (LUMC) Trauma Center who received screening for unhealthy alcohol use using the AUDIT questionnaire between April 2013 and November 2016. Results from the AUDIT were used as the reference standard for labeling cases of unhealthy alcohol use, with scores ≥5 and ≥8 points indicating unhealthy alcohol use in women and men, respectively\(^8\). The trauma cohort reflects the pooled training and internal validation data used for the initial development and validation of the unhealthy alcohol use NLP classifier\(^9\).

Our inpatient dataset consisted of a convenience sample of patients who presented to LUMC for non-trauma inpatient hospitalizations between January 2007 and September 2017. Unhealthy alcohol use was identified via chart review by a trained annotator following standardized criteria previously described\(^13\) with an oversampling of at-risk patients to provide a more balanced dataset for evaluating cases. The inpatient cohort reflect the data used for external validation of the NLP classifier\(^13\).

Predicted probabilities of unhealthy alcohol use were generated for all encounters in both cohorts, and the optimal cutoffs were determined using the Youden index maximization method. The optimal predicted probability cutoffs for identifying unhealthy alcohol use were ≥0.46 and ≥0.53 for the trauma and inpatient cohorts, respectively. In the trauma cohort, the classifier had a sensitivity and specificity of 61% (95% CI 56%-67%) and 78% (95% CI 75%-80%), respectively. In the external validation inpatient cohort, the classifier had a sensitivity and specificity of 86% (95% CI 83%-89%) and 82% (95% CI 78%-85%), respectively. Descriptive statistics for patient characteristics, including age, sex, ethnicity, and race, were presented for both cohorts. All analyses were performed using R version 3.6.0 (R Core Team, 2019).

Bias Assessment

We assessed for bias in the trauma and inpatient cohorts independently and by age group, sex, and race/ethnicity. For the purposes of bias assessment and correction, age was divided into two groups \textit{a priori} based on census age groups and sample sizes: 18 to 44 years old and 45 years and older. Race/ethnicity was divided into three groups: Hispanic, Non-Hispanic Black, and Non-Hispanic White. The reference standard labels and predicted labels for unhealthy alcohol use (present/absent) were used to calculate the number of false positives (FP), true positives (TP), false negatives (FN) and true negatives (TN) within each cohort and within subgroups of each cohort. We then calculated the bias assessment metrics of interest, which included false discovery rate (FDR; FP/[FP+TP]), false positive rate (FPR; FP/[FP+TN]), false omission rate (FOR; FN/[FN+TN]), and false negative rate (FNR; FN/[FN+TP]). All bias metrics were calculated as described by Saleiro, Kuester\(^14\) and 95% exact binomial confidence intervals were calculated for all metrics.

High FDR and/or FPR values were used as indicators of bias towards overestimation of risk within subgroups; high FOR and/or FNR values were used as indicators of bias towards underestimation of risk within subgroups. Combinations of high FDR and/or FPR values with high FOR and/or FNR values were interpreted as overall reduced model accuracy within subgroups.
Bias Correction

For the purposes of developing an adequate screening tool with the NLP classifier, we focused our bias correction efforts on maintaining high sensitivity with few false negative results, so subgroups with high FOR and/or FNR values were targeted. Model calibration of intercept and slope was assessed using calibration plots in accordance with the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis (TRIPOD) guidelines. Model recalibration was implemented for each cohort subgroup that had evidence of poor calibration. Predicted probabilities within affected subgroups were used to calculate linear predictors in a logistic regression classifier, which were subsequently used for model recalibration via intercept re-estimation, slope re-estimation, and concurrent intercept and slope re-estimation. These recalibration methods were chosen to minimize the number of re-estimated parameters, control familywise error rate, and to avoid overfitting given the relatively small sample sizes available among select subgroups within both cohorts. The original NLP classifier and all three recalibrated classifiers were compared via calibration plots and scaled Brier scores with bootstrapped 95% confidence intervals (1,000 iterations). A model's scaled Brier score reflects the mean square error of probability predictions, or Brier score, scaled by its maximum score such that values range from 0% to 100% and 100% indicates optimal performance. The bias-indicating metrics were also recalculated for affected subgroups using predicted probabilities and a predicted probability threshold determined via Youden index maximization from each of the three recalibration methods.

Results

Patient Characteristics

Our trauma cohort consisted of 1,326 encounters from 1,309 patients and our inpatient cohort consisted of 999 encounters from 856 patients. Age at first encounter, sex, ethnicity, and race distributions were similar in the trauma and inpatient cohorts (Table 1).

Trauma Cohort Bias Assessment

The case-rate of unhealthy alcohol use was 23% (n=305) across all encounters in the trauma cohort (Table 2). The FPR and FOR were higher among patients 18 to 44 years old compared to patients 45 years and older, indicating reduced model accuracy among adults 44 years and younger in the trauma cohort. The FPR and FOR were also higher among male patients compared to female patients, indicating reduced model accuracy among adult patients in the trauma cohort. The FOR was higher among Hispanic patients (FOR=0.22, 95% CI 0.16-0.30) compared to Non-Hispanic White patients (FOR=0.11, 95% CI 0.08-0.14), indicating biased underestimation of unhealthy alcohol use risk among Hispanic patients compared to Non-Hispanic White patients in the trauma cohort by the NLP classifier.

Inpatient Cohort Bias Assessment

The case-rate of unhealthy alcohol use was 58% (n=579) in the inpatient cohort (Table 3). The FOR and FNR were higher among patients 18 to 44 years old (FOR=0.32, 95% CI 0.25-0.40; FNR=0.20, 95% CI 0.15-0.26) compared to patients 45 years and older (FOR=0.12, 95% CI 0.09-0.17; FNR=0.10, 95% CI 0.07-0.14), indicating biased underestimation of unhealthy alcohol use risk among adults 44 years and younger compared to adults 45 years and older in the inpatient cohort. The FOR and FNR were also higher among Non-Hispanic Black patients (FOR=0.28,

**Trauma Cohort Bias Correction**

For the FOR and FNR metrics, the strongest bias in the trauma cohort with significant disparity was between the Hispanic and Non-Hispanic White subgroups. The original calibration primarily demonstrated overestimation of risk across the quintiles of predicted probabilities (Figure 1). Efforts at recalibration show improvement in movement towards the loess curve for perfect calibration. The concurrent intercept and slope re-estimation model resulted in the most significant improvement (Figure 1). The scaled Brier scores also reflected improvements in accuracy with intercept re-estimation (12%, 95% CI 9%-14%), slope re-estimation (15%, 95% CI 10%-21%), and concurrent intercept and slope re-estimation (17%, 95% CI 12%-21%) over the original model (7%, 95% CI 2%-10%).

The optimal predicted probability cutoffs were ≥0.33, ≥0.37, and ≥0.33 for the intercept re-estimation, slope re-estimation, and concurrent intercept and slope re-estimation models in the Hispanic subgroup, respectively. Despite improvements in model accuracy with recalibration, biased underestimation of unhealthy alcohol use risk (as indicated by a high FOR) persisted in the intercept re-estimation (FOR=0.21, 95% CI 0.15-0.29), slope re-estimation (FOR=0.21, 95% CI 0.15-0.28), and concurrent intercept and slope re-estimation (FOR=0.21, 95% CI 0.15-0.29) models compared to the original model (FOR=0.22, 95% CI 0.16-0.30). Minimal changes in FDR, FPR, and FNR were observed after recalibration.

![Figure 1](image.png)

**Figure 1.** Observed versus predicted probability of unhealthy alcohol use among Hispanic patients in the trauma cohort according to the (A) original versus intercept re-estimation model, (B) original versus slope re-estimation model, and (C) original versus concurrent intercept and slope re-estimation model. Five bins were used for each graph.

**Inpatient Cohort Bias Correction**

For the FOR and FNR metrics, the strongest bias in the inpatient cohort with significant disparity was between the age groups. Our recalibration methods failed to produce noticeable improvements in predictive accuracy of the NLP classifier within the 18- to 44-year-old subgroup of the inpatient cohort (Figure 2). The scaled Brier scores also indicated a lack of improvement in model accuracy with intercept re-estimation (41%, 95% CI 37%-44%), slope re-estimation (44%, 95% CI 40%-49%), and concurrent intercept and slope re-estimation (44%, 95% CI 40%-49%) over the original model (41%, 95% CI 37%-44%).

The optimal predicted probability cutoffs were ≥0.47, ≥0.43, and ≥0.43 for the intercept re-estimation, slope re-estimation, and concurrent intercept and slope re-estimation models in the 18- to 44-year-old subgroup, respectively. Using the recalibrated predicted probabilities and cutoffs, there was an equal, moderate decrease in FNR (FNR=0.12, 95% CI 0.08-0.17) across all recalibration methods when compared to the original model (FNR=0.20, 95% CI 0.15-0.26). We observed minimal changes in FDR, FPR, and FOR with recalibration.

As was the case in the 18- to 44-year-old subgroup, no noteworthy improvements in model accuracy were observed with model recalibration within the Non-Hispanic Black subgroup of the inpatient cohort (Figure 3). The scaled Brier scores similarly indicated a lack of improvement in model accuracy with intercept re-estimation (41%, 95% CI 37%-44%), slope re-estimation (43%, 95% CI 38%-48%), and concurrent intercept and slope re-estimation (43%, 95% CI 39%-48%) over the original model (40%, 95% CI 37%-44%).
Figure 2. Observed versus predicted probability of unhealthy alcohol use among 18- to 44-year-old patients in the inpatient cohort according to the (A) original versus intercept re-estimation model, (B) original versus slope re-estimation model, and (C) original versus concurrent intercept and slope re-estimation model. Five bins were used for each graph.

The optimal predicted probability cutoffs were $\geq 0.55$, $\geq 0.63$, and $\geq 0.59$ for the intercept re-estimation, slope re-estimation, and concurrent intercept and slope re-estimation models in the Non-Hispanic Black subgroup, respectively. We further found that biased underestimation of unhealthy alcohol use risk persisted across the recalibrated models with regards to both FOR and FNR compared to the original model. There were also minimal changes in FDR and FPR with recalibration.

Figure 3. Observed versus predicted probability of unhealthy alcohol use among Non-Hispanic Black patients in the inpatient cohort according to the (A) original versus intercept re-estimation model, (B) original versus slope re-estimation model, and (C) original versus concurrent intercept and slope re-estimation model. Five bins were used for each graph.

Discussion

Our study demonstrates biased underprediction of unhealthy alcohol use by our NLP classifier for Hispanic patients compared to Non-Hispanic White patients admitted for trauma. For non-trauma hospitalizations, we also demonstrate biased underprediction of unhealthy alcohol use for adult patients under 45 years old compared to adults 45 years and older and Non-Hispanic Black patients compared to Non-Hispanic White patients. Moreover, we show that the greatest improvement in classifier accuracy with recalibration is achieved via concurrent intercept and slope recalibration within the Hispanic subgroup of the trauma cohort. Finally, none of the recalibration methods we implemented adequately addressed the risk underprediction disparities seen across age groups and racial/ethnic identities.

Both of our study cohorts have a median age between 40 and 50 years old and are predominantly male and Non-Hispanic White. The demographic composition of the training cohort is likely responsible for some of the bias seen in our NLP classifier. Our trauma cohort represents all patients who presented to the LUMC Emergency Department for trauma over a span of three years and thus is a better representation of true unhealthy alcohol use prevalence than our inpatient cohort, which includes an oversampling of encounters with a high likelihood of associated unhealthy
alcohol use. Whole-cohort bias metrics are similar across the two cohorts except for the high FDR and FNR in the trauma cohort; these values are likely driven by the lower sensitivity and thus smaller number of TPs in the trauma cohort.

We were able to identify disparities in over- and underprediction of unhealthy alcohol use risk by examining FDR, FPR, FOR, and FNR resulting from our NLP classifier across demographic subgroups. Such algorithmic biases can be introduced in several places along the model development pipeline, including through the training data, model design, and threshold selection. The data used in the development of our NLP classifier resulted from a consecutive sample of patients seen over three years, though approximately half of the eligible patients in this time were not screened for unhealthy alcohol use via the AUDIT. Deviations from true consecutive sampling can result in selection bias due to underrepresentation of certain patient populations; this is particularly problematic when underrepresentation of minority groups is potentially involved. Measurement bias is also a concern when developing NLP tools, especially given existing evidence that implicit racial biases can influence physician language and the knowledge that biased physician language can be perpetuated through NLP features. Biases can further be perpetuated by using a single risk threshold, which can result in a lack of assistive measures for patient populations with systematic risk underprediction or an excess of punitive measures for patient populations with systematic risk overprediction.

Through our attempts to mitigate the biases identified in our unhealthy alcohol use classifier, we found that model recalibration was insufficient to address disparities in risk underprediction-indicating metrics across demographic subgroups. Alternative methods for minimizing bias in classification models can be used, starting with measures to reduce selection and measurement biases during data collection. Additional methods focus specifically on minimizing bias among minority populations through improvements in accuracy, including oversampling with subsequent weighting of minority population data and transfer learning. Our approach of post hoc recalibration within subgroups with biased risk underprediction resulted in some modest improvements in classifier accuracy. However, this method failed to produce improvements in FOR and FNR that would translate to positive effects in clinical practice. Our classifier in its current form stands to recommend assistive unhealthy alcohol use interventions to Hispanic trauma patients less frequently than to Non-Hispanic White trauma patients. Our results likewise demonstrate the value of bias assessment across patient subgroups rather than solely relying on global accuracy metrics of classifier models.

Our study has several limitations. We were unable to compare classifier bias between cohorts due to the use of two different gold standards for identifying unhealthy alcohol use. We were also unable to assess whether using different, sex-dependent AUDIT cutoffs for reference standard unhealthy alcohol use labeling in the trauma cohort introduced or masked classifier bias. Small sample sizes within some subgroups required us to collapse groups down, as in the age groups, or forego analysis altogether, as in the American Indian and Asian racial groups. Counts of FPs, TPs, FN, and TNs were also limited (<25) in four instances. Further, we were unable to assess for bias by gender identity as this data was not available.

We demonstrated the presence of biased unhealthy alcohol use risk underestimation by our NLP classifier among Hispanic compared to Non-Hispanic White trauma inpatients, 18- to 44-year-old compared to 45 years and older medical/surgical inpatients, and Non-Hispanic Black compared to Non-Hispanic White medical/surgical inpatients. We further showed that intercept, slope, and concurrent intercept and slope recalibration resulted in minimal or no improvements in bias-indicating metrics within these subgroups. In summary, we detected bias in our NLP classifier and were unable to adequately address this bias through post hoc recalibration methods. Our results exemplify the importance of integrating bias assessment early into the classifier algorithm development pipeline, ideally in collaboration with health equity researchers and with consideration of the complex nature of bias as it relates to structural health disparities.

Abstract

The management of personal health information (PHI) by older adults (OAs) takes place within a socio-technical context and requires the support of various stakeholders, including healthcare providers. This study investigates provider roles in supporting OA personal health information management (PHIM), barriers they face, and related design implications for health information technology (HIT). We interviewed 27 providers serving OAs in Seattle, WA. Providers support OA PHIM through medication management, interpreting HI, and providing resources. Barriers to OA PHIM described by providers include (1) challenges with communication between OAs, providers, and caregivers, (2) limited time and resources, and (3) limitations of tools such as secure messaging. Considering these barriers, provider roles, and the socio-technical context for HIT implementation, we recommend the design of HIT that facilitates communication across multiple provider types, integrates caregivers and patient-generated data, supports understanding of OA home environments, and offers credible health resources designed for OAs.

Introduction

The population of older adults (OAs), defined as individuals age 65 and above, is expected to increase from 49.2 million in 2016 to 95 million by 2060 in the United States.1 Aging is associated with greater utilization of healthcare services and more complex health issues,2 resulting in interactions with diverse healthcare providers and an increased amount of personal health information (PHI) to manage.3 Examples of PHI include medical history, tracked symptoms, medication lists, clinic visit summaries, and other information individuals keep about their health.4,5

The work of managing information related to one’s health has been called personal health information management (PHIM), and includes tasks and activities focused on finding, interpreting, using, organizing, and remembering one’s PHI.4,5 This work can help OAs to manage health conditions6 and support healthy aging,7 and is critical for developing systems of self-care, such as medication management. However, PHIM can be challenging for OAs, and is often compounded by conditions commonly seen in OAs, including memory loss or declines in physical health. In contrast to effective PHIM, a lack of accurate and complete information may contribute to poor quality care and health outcomes.8,9 Health information technology (HIT) is increasingly used to support and facilitate PHIM, but HIT design often overlooks the needs of OAs.10,11 Previous studies have demonstrated that utilizing sociotechnical models to examine patient work such as PHIM within organizational, physical, and social contexts can lead to development of HIT that takes into account OA needs.4,12-15

Our prior work from the Studying Older Adults and Researching their Information Needs and Goals (SOARING) project (soaringstudy.org) used a sociotechnical approach to investigate the work system of OA PHIM through extensive interviews with a diverse set of OAs and those involved with OA PHIM.16 Our research, along with others’, confirms that healthcare providers generate, gather, and transfer much of the health information (HI) sought and received by OAs,15,17 and therefore play a unique role in supporting OA PHIM. Further, when we asked OAs and their family and friends about key individuals important to health information management, they named health care providers, primarily physicians, but also pharmacists, social workers, and assisted living (AL) staff.15 As OAs age, others (family and friends and AL staff) provide increasing support for OA PHIM.15,17,19 A depiction of the network by which PHI is transferred in the context of OA PHIM is outlined in Figure 1.
Despite their importance in generating and providing HI, little is known about the role various health care providers play in OA PHIM. Prior research has examined physician and OA information needs in specific situations, such as hospital to home transitions or in shared decision-making. This study looks at a wider ecosystem of providers, seeking input from primary care physicians, gerontologists, medical residents, pharmacists, social workers, and assisted-living staff. We utilized the SEIPS 2.0 model, particularly the components of organization (communication, resources), and technologies and tools, to explore their collective and regular involvement in OA PHIM and the challenges they face, in an effort to help inform the design of HIT supportive of OA PHIM.

**Methods**

**Recruitment and Participant Characteristics**

We purposively sampled five provider types: primary care providers, specialists (including medical residents and gerontologists), social workers, pharmacists, and assisted living (AL) staff. Participants were initially recruited with emails to assisted living facilities, local hospitals, clinics, geriatric practitioner networks and local senior centers. Following initial recruitment, we recruited additional providers through snowball sampling. We continued to recruit and interview providers within each type until we reached data saturation, outlined by Saunders et al. as hearing similar information from participants. We interviewed 27 providers: eight family doctors and nurse practitioners, seven specialists (five geriatricians and two medical residents), four social workers, four pharmacists, and four AL staff. For the purposes of this paper, we grouped nurse practitioners, family doctors, specialists, and residents together as “medical practitioners,” as themes and roles were similar across these categories. Seventy percent of participants were female, 63% were non-Hispanic white and 96% held an advanced degree (Table 1). The percentage of OAs (>=65yrs) cared for ranged from 15 to 100%.

a. Unable to calculate mean and SD due to some participants providing a range, such as “20-30%” or “over 50%”. b. Medical practitioner = family practice/internal medicine physicians, geriatric specialists/fellows, medical residents, and primary care nurse practitioners. c. Social worker = clinical social workers and senior center social workers. d. Pharmacist = geriatric pharmacists, clinical pharmacists, and one pharmacist who coordinated between hospitals and temporary care units and assisted living facilities. e. Assisted living staff = a health services director, an assisted living administrator, a health information manager, and a nursing director.

Data Collection

The SOARING team developed an interview guide and pre-tested it with the team’s clinical advisors before finalizing it. The guide included structured questions about demographics, and a series of semi-structured questions concerning providers’ support of and perspectives on OA PHIM. We conducted in-person one-hour interviews with providers from June 2016 to January 2018. Experienced qualitative researchers (KO and AB) conducted the interviews at providers’ workplaces. Participants received a $50 honorarium. Interview recordings were transcribed verbatim by professional transcriptionists and uploaded to the qualitative online platform Dedoose (Dedoose, Manhattan Beach, CA). The University of Washington’s IRB approved all recruitment materials and procedures (IRB #: STUDY00000084).

Data Analysis

We analyzed interview transcripts using a thematic analysis process. Specifically, after reviewing transcripts, researchers (KO, AT, AB, SL) generated codes, making notes on patterns and insights relevant to OA PHIM. A preliminary codebook was created by one researcher (AB) in conjunction with the research team. Three researchers (KO, AB, SL) then independently applied the codebook to all transcripts and compared their application of the codes, resolving any discrepancies through discussion. After coding transcripts, the team met to discuss emerging themes. Codes fell under three categories: 1) providers’ roles in OA PHIM, 2) PHIM tasks that providers observed among OAs, and 3) the barriers to managing and sharing PHI between OAs and providers. We also examined codes within and across provider types to identify patterns unique to a provider type in each of these three categories. Recognizing parallels between the observations of providers and our prior work with OAs, we analyzed provider responses through the lens of OA PHIM tasks, identifying provider support of, and barriers or facilitators to, each task.

Results

Providers Types, Roles, and HI Exchanged with OAs

Providers described specific tasks they completed in support of OA PHIM, including providing health information (e.g., regarding medications, conditions, or treatments), interpreting or reconciling PHI with OAs and their caregiver, and sharing the OA’s PHI with other providers. Distinctions in the tasks performed by different providers in support of OA PHIM, and variations in the types of information needed, are summarized in Table 2 and detailed below.

257
Medical Practitioners

Medical practitioners spoke of documenting visits and collecting information (ex. medical histories, medications) from OAs and other providers. Many discussed the importance of gathering up-to-date histories, contact and medication lists to support the care team as well as OA PHIM. Medical practitioners frequently helped OAs interpret and understand PHI, such as test results and medical instructions, and encouraged OAs to use this information to reach their health goals. Some medical practitioners described the importance of sharing PHI (such as blood pressure logs) to help describe conditions, and facilitate shared decision-making about management strategies with OAs.

Pharmacists

Pharmacists’ support of OA PHIM often involved navigating between OAs and their medical doctors to clarify and update medications or interpret clinic visit summaries. Pharmacists in particular valued up-to-date medication lists:

*The number one thing is an accurate and up-to-date medication list that’s easily accessible to the individual and any key family members or caregivers, as well as something that can be shared easily with the healthcare team.* (P24, pharmacist)

Additionally, all pharmacists described supporting OA PHIM by helping OAs to create and maintain medication lists. For example, three interviewees made calendars to help OAs keep track of medications. One pharmacist even went to OAs’ homes to help reconcile and organize medications.

Social Workers

Social workers addressed a more holistic range of needs, focusing on understanding OAs’ social and emotional needs and connecting OAs with a variety of supportive resources (e.g., transportation, housing, mental healthcare, legal assistance, and power of attorney designation). Social workers had more opportunities to work with OAs in their homes, and communicated with doctors to provide contextual information about OAs’ mental health or home environment. One social worker described how communicating with doctors could help ensure consistency in the information provided to OAs and support adherence to care plans. A doctor similarly described the benefits of delivering messages to OAs through a team-based approach that included social workers.

Assisted Living (AL) Staff

AL staff in our study came from a range of backgrounds and had varied roles. In terms of supporting OA PHIM, AL staff first gathered information centered on admission to assess health status and level of support required:

*It’s always important to get a very clear and accurate picture of the person prior to their moving in…knowing exactly who they are, what their needs are, what their cognitive status is, and their mobility.* (P27, assisted living staff)

Once in the facility, AL staff often monitored and recorded information related to OAs’ health and functional status (e.g., fall incident reports, diagnoses, medication list, contact information of doctors, mobility issues, treatment for current illnesses) to determine needs and provide care. While AL staff often supported independent and collaborative PHIM, unlike other providers, AL staff sometimes took over PHIM tasks for OAs, or worked directly with OAs to collect, record, and track daily PHI. Their role often involved communicating with OAs’ family and friends, requesting information, providing updates about the OAs’ health status and care needs, and sharing records of health care services provided.

Observed OA PHIM

Descriptions of PHIM practices observed by providers fell into three key themes: 1) OAs have diverse PHI organizing and tracking behaviors, 2) OAs have varied medication management practices and 3) OAs seek HI from diverse sources.

Diverse HI organizing and tracking behaviors

Providers reported that OAs demonstrated a wide range of PHI organizing and tracking behaviors, from neatly arranged logs, to relying on memory or the memory of others. Fourteen providers described receiving patient logs from OAs, and had a positive opinion of such patient tracking. One AL staff commented that OAs’ active logging behavior reflected an interest in their health and helped her gauge their need for support.

Varied medication management practices
Twenty-one providers of all types stressed the importance of maintaining accurate and up-to-date medication lists. As with tracking, some OAs had highly organized medication management systems while others did not. Providers described a variety of medication management strategies including written lists, pictures of medications, medication dispensing devices, calling the pharmacist, and having adult children or the AL facility manage their medication. Some providers, however, reported that it was rare to see OAs having an organized medication list, and one commented that lists often did not include drug dosage and frequency.

HI sought from various sources

Twelve providers mentioned that OAs sought and received HI from outside sources including family, friends, the internet, television, advertisements, books, magazines, newspapers, community organizations, and support groups/classes. These observations are generally in line with our prior work exploring OA’s PHIM practices. In addition, our previously documented OA PHIM activities and tasks of seeking, sharing, organizing/tracking, and planning were supported in different ways by healthcare providers in this study. Table 3 highlights how OA activities and tasks were supported, along with some of the related barriers and facilitators to each activity and task. Barriers and facilitators are described in more detail in the section below.

Barriers to OA PHIM

We asked providers to identify barriers that they noticed OAs experiencing when practicing PHIM, and challenges to gathering and sharing health information in support of OA PHIM with both OAs and caregivers. Providers recognized a range of OA abilities and involvement with managing PHI, and often described positive experiences, including building trusting, long-term relationships and establishing regular communication electronically or otherwise. We focus on challenges below, but also highlight some of the key facilitators to OA PHIM that emerged from our conversations. Challenges are organized into elements of the socio-technical system that influence OA PHIM, including communication, resources, and PHIM tools.

Communication

Communication between providers and a) OAs, b) informal caregivers, and c) other providers, provided the context for supporting OA PHIM.

Communication with OAs: Nine providers of various types identified cognitive impairments as a barrier to communication. They noted that it was difficult for OAs with cognitive decline to recount medical history or current diagnoses, which made it challenging to determine the accuracy of the information. This hampered effective care-planning and support of OA PHIM. One social worker recommended initiating early conversations about care preferences and care transitions as a pre-emptive measure in case memory loss occurred.

I think nobody likes to have that conversation...about long-term-care planning. But it would be much easier to have a plan in place so that you're not taken by surprise. (P20, social worker)

Four providers described that physical impairments, such as visual or hearing difficulties, presented barriers for accessing and receiving PHI. Consequently, some providers offered information in a variety of formats (e.g., DVDs, phone calls, written information). Three providers, including a pharmacist and two medical practitioners expressed a desire to see OAs' home environments, in order to ensure safe medication management and provide context for management of other conditions.

Communication with Informal Caregivers: In general, providers described caregiver presence during a visit with an OA as helpful for communication and transfer of PHI between the provider and OA. Caregivers provided another ear in handling PHI, remembered things that OAs forgot, and filled in information gaps, particularly if OAs were experiencing cognitive decline.

...having caregivers and family in the room is extremely valuable for the information that they're able to provide that a lot of times the patient cannot. (P2, medical practitioner)

Although caregivers did facilitate communication of PHI, five providers described that it was difficult to contact busy caregivers to obtain and share relevant PHI. In other cases, family tensions created confusion around whether to contact caregivers or which caregiver to contact.

Communication Among Providers: Lack of communication between providers was a major barrier to PHI exchange across provider types. Issues with tools and technologies, such as limited interoperability between different electronic health record (EHR) systems, compounded communication barriers. All providers described spending time tracking down OA PHI by calling or faxing other providers. One medical practitioner described a process of gathering patient records from other healthcare systems, reviewing and entering them into their own systems. The task of gathering information was often done on the provider’s own time. When asked what would improve information exchange, this provider explained:

... [the] ability to get their [OAs'] data from other doctors and what meds they're on, just without having to go through so much rigamarole. I mean...something where everything's on the same system. (P4, medical practitioner)

Two of four pharmacists described not having access to current and complete HI from other facilities, such as hospital discharge notes that were needed to fill prescriptions, or data from other pharmacies to show if prescriptions had already been filled. For example, providers described a lack of clarity about whose responsibility it was to collect and share PHI. Because of these barriers to communication, some providers relied on OAs to bring along updated notes and medication lists to visits, thus increasing the burden for OA PHIM.

In contrast, teams of multiple provider types working collaboratively facilitated communications. One medical practitioner described the advantage of having a pharmacist available to ensure OAs were managing medications
appropriately. Additionally, one medical practitioner explained that having social workers integrated into the healthcare team facilitated communications and provided a more holistic picture of OA health and home environment.

**Resources**

*Time*: All types of providers expressed a desire to have more time with OAs to support PHIM. Several medical practitioners complained that current clinical workflows provide them with limited time to spend with patients. The lack of time limited the ability to collect critical PHI and provide individualized care.

One pharmacist expressed frustration that the system’s focus on the number of filled prescriptions did not allow time for understanding the patient’s needs and delivering quality care. Social workers described OAs who felt frustrated with the fast-paced healthcare system and the lack of human connection.

*Health Information Resources*: A frequently mentioned barrier to effective OA PHIM was the lack of access to plain language materials. Four medical practitioners expressed the need for simplified after-visit instructions and interpretations of lab results, and three pharmacists mentioned simplifying medication inserts so that the risks and benefits were easily understood.

> I think one of the worst things people can have is those darn printouts you get from the pharmacy that give you the gazillion list of possible side effects... nobody looks at them and anybody who does look at them gets terrified. (P23, pharmacist)

In addition, nine providers experienced challenges communicating with OAs who did not speak English, and expressed a need for HI resources in multiple languages. Six providers noted that some OAs had difficulty interpreting and judging the credibility of information gathered online and through other sources, and wanted tools to assist OAs in identifying quality HI sources.

**Tools**

*Patient Portals and Secure Messaging*: Providers were asked about the strengths and challenges of HIT with respect to OA PHIM. Much of their discussion focused on patient portals and secure messaging. Overall, providers felt that patient portals helped to facilitate care and allowed OAs to more easily manage their HI and communicate with providers. However, some providers also described challenges related to secure messaging. Five providers explained that with the introduction of secure messaging, there was an influx of questions from patients, and little time to respond. Four providers described confusion around the use of the portal for urgent messages. As one provider explained, the system had no way to flag messages that described urgent symptoms and should be triaged to a doctor immediately:

> ... I have gotten several symptom-based, “should I go to the emergency room?” type questions...that should have been answered much before they were. So it [the patient portal messaging system] doesn’t always flag urgency. (P14, medical practitioner)

Finally, four providers heard similar complaints from OAs about responses to messaging. OAs were concerned that their messages were not reaching the provider, as there was no confirmation of provider receipt, slow response times, or they received responses from nursing staff instead of their provider.

**Discussion**

We examined the role of different healthcare providers in OA PHIM and identified perceived barriers. Provider roles in supporting OA PHIM necessarily involved the exchange and flow of information, which providers used in unique ways to facilitate optimal OA health. Perceived barriers were best described within the sociotechnical contexts of communication (between OAs, providers, and caregivers), organizational resources (provider time, access to adequate health information, system interoperability), and PHIM related tools (patient portal technologies, secure messaging). Based on our findings, we recommend the following strategies to inform the design of HIT in a way that considers context, addresses barriers, and builds on existing facilitators:

1. **Include non-medical practitioner providers (pharmacists, social workers, assisted living staff) in data sharing agreements or in interoperable medical record systems.**

Consistent with existing literature, our providers identified limited system interoperability and lack of clarity around the responsibilities for transferring and sharing HI as barriers to communicating with other providers.22,27-29 In some cases, this placed more burden on OAs for managing their own PHI and sharing it with different providers. Lack of
access to accurate information between providers not only places additional burden on OAs but can lead to problems with OA safety and poor healthcare outcomes, particularly during transitions in care.29

There is a demonstrated need for improved information sharing between healthcare providers in different settings.22,28 Given the network of providers involved in OA healthcare, data sharing agreements or interoperable EHRs among different provider types could have a positive impact on OA PHIM.30 As supported by our interviews, coordinated approaches between providers such as social workers, pharmacists, and primary care physicians would provide a more holistic picture of OA health, and facilitate consistent information sharing more responsive to OA needs.

HIT that compiles relevant information from various providers would help to streamline the information gathering process, simulating a care team approach, in which multiple providers collaboratively support OA PHIM and healthcare. Time saved in gathering information and filling in information gaps could be invested in developing the patient-doctor relationship, supporting OA PHIM goals, and proactively identifying challenges.

b) **Incorporate options that allow providers to access the environments in which OAs are managing medications and other health issues.**

Another strategy to facilitate a more holistic understanding of OA health is to design HIT that facilitates insight into the context in which OAs manage their health and PHI. Specifically, in line with the desires of pharmacists and medical practitioners in our study, effective PHIM system could accommodate various media (video conferencing, photos, etc.) to allow providers, with the permission of OAs, to view and assess the safety of the home environment, ensure medication management, and identify lifestyle issues.

c) **Facilitate OAs’ understanding of HI through multiple sources and support the interpretation of these sources by trusted providers (creating provider-vetted resources outside of a clinical visit).**

Our findings confirm the difficulties that some OAs have in determining the credibility of online HI resources.15 Incorporating provider-vetted and delivered guides, with a variety of online and offline sources (e.g., request-by-mail articles and brochures) tailored to particular OA needs into HIT would address this need. HI delivered both through these guides, as well as through other mechanisms such as after-visit summaries and lab reports, should be presented in plain language form. In addition, it is important to ensure that information is available in multiple languages and tailored to the needs of OAs and others with visual, physical, or cognitive impairments.

d) **Explore mechanisms to provide formal access to HIT systems for informal caregivers.**

Communication between informal caregivers and providers can provide context for supporting OA PHIM, particularly for those who may experience functional or cognitive limitations over time.11,15 Therefore, it is important to explore a dyadic user experience that will facilitate information sharing and communication between caregivers and providers. However, HIT that supports sharing of HI between multiple stakeholders must take into consideration regulatory and personal barriers related to confidentiality and security.19,31 Allowing OAs to assign permissions and decide what information is shared is critical.

e) **Integrate OA generated data into formal HIT systems.**

As patients are being asked to play a more active role in their own health management, they generate their own data, whether these are logs like those commonly seen in our study, or reflections, preferences, or tracking of physiological variables through wearables or other monitoring devices. These tracking activities become a core aspect of PHIM and should become part of any HIT that is used to store and manage patient data. A HIT system that incorporates OAs’ own tracking and logging of daily behavior also facilitates provider support of PHIM, by allowing providers to generate trends and reports, and offer preventive care measures.30

**Strengths and Limitations**

Examination of multiple provider types and their role in OA PHIM offers a more complex and nuanced picture of OA PHIM. However, we interviewed a small number of providers from one metropolitan area, which may affect generalizability of the results. We did not include provider types such as physical therapists and naturopaths, that may also play a significant role in OA PHIM. While steps were taken to avoid bias, including having multiple researchers participate in coding, personal biases still may have influenced the themes we identified as salient.

**Conclusion**

Our work underscores the importance of the context in which HIT is implemented, including the communication, organizational structures, and tools that influence OA PHIM. Our results showcase the necessity of incorporating
multiple provider types into HIT design to support collaborative, patient-centered, and coordinated care that facilitates PHIM and improves the health of OAs. Although we have focused on HIT solutions, we recognize that our results have broader implications for OA PHIM. Our work revealed barriers in provider workflows, communication, and the allocation of time and resources. More work is needed to further examine barriers and related opportunities for policy and structural solutions to support OA PHIM.

Using Machine Learning to Support Transfer of Best Practices in Healthcare

Sebastian Caldas, M.Sc.¹, Jieshi Chen, M.Sc.¹, Artur Dubrawski, Ph.D.¹
¹Auton Lab, Carnegie Mellon University, Pittsburgh, PA, USA

Abstract
The adoption of best practices has been shown to increase performance in healthcare institutions and is consistently demanded by both patients, payers, and external overseers. Nevertheless, transferring practices between healthcare organizations is a challenging and underexplored task. In this paper, we take a step towards enabling the transfer of best practices by identifying the likely beneficial opportunities for such transfer. Specifically, we analyze the output of machine learning models trained at different organizations with the aims of (i) detecting the opportunity for the transfer of best practices, and (ii) providing a stop-gap solution while the actual transfer process takes place. We show the benefits of this methodology on a dataset of medical inpatient claims, demonstrating our ability to identify practice gaps and to support the transfer processes that address these gaps.

Introduction
When a set of practices an institution has developed over time is known to systematically lead to positive outcomes, it is an enticing target for implementation at other similar organizations. However, endeavors aimed at transferring such best practices can be inefficient and prone to failure, with common reasons being the difficulty to codify tacit knowledge and lack of adequate motivation for the transfer. Just as problematic is the inability to even identify a knowledge or practice gap between organizations, as it prevents the whole transfer process from taking place. In the context of healthcare, transferring best practices can be done to increase the efficiency and effectiveness of health services, and to improve patient outcomes: goals that healthcare organizations are under continuous pressure to pursue. Alas, because of the inherent complexity of healthcare facilities, it is also inherently complex to identify and share best practices among them.

Research into the transfer of best practices in healthcare has been overlooked, and thus the community has a limited understanding of which mechanisms could work best in practice. Previous work has focused on theoretically understanding the transfer mechanisms, mostly borrowing tools from other disciplines. For example, Guzman et al. combined tools from organizational learning and knowledge management with a practice-based perspective, laying down a theoretical framework that aligns the complexity of the practice to be transferred with appropriate transfer strategies. Meanwhile, Berta and Baker described the types of environments and knowledge where a transfer is possible. Finally, Elwyn et al. outlined different reasons that could make the transfer process fail in a hypothetical clinical setting using Szulanski’s sticky knowledge framework.

In this paper, we are interested in enabling the transfer of practices whose outcomes are reflected in the scores of Machine Learning (ML) models, particularly classification models. Given the escalating permeation of Artificial Intelligence in healthcare, examples of such models are numerous and diverse. Some of these include sepsis prediction, vital sign artifact alert adjudication, or the detection of abnormal lengths of hospital stays. In our proposed approach, we rely on multiple organizations having each trained an independent model from their operational data, and on an arbiter or advisory agency regulating the sharing of these models between the organizations.

We focus on the first stage of the transfer process as presented by Elwyn et al., the identification of a possible knowledge or practice gap, and on indirectly supporting the rest of the transfer process (implementation, ramp-up, until integration) by leveraging the knowledge gained from models trained at external organizations. For the former, we use the entropy of an ML model scores as a proxy for the consistency of the underlying practice, as illustrated in Figure 1. For the latter, we make use of novel transfer learning strategies to exploit the available knowledge from the external organizations while the actual best practice is successfully transferred.

We test our methodology on a dataset of medical inpatient claims, where our example ML task is to detect overly long lengths of stays. The proposed approach, however, can be broadly applied to other forms of data, such as Electronic Health Records, and other predictive tasks. In our example, we model selected hospital groups as different organizations, and different diagnosis related groups as different practices. We show that our proposed methodology can identify potential practice gaps that we can later support using transfer learning strategies.
Figure 1. Illustration of our proposed strategy to identify potential practice gaps. Consider two organizations, A and B, each one with its own classification model of some practice: model A and model B, respectively. When we use both models on the data from organization A, the resulting distribution of scores will have different entropies. We use this difference in entropy as a proxy to indicate a potential knowledge or practice gap. In this example, the entropy from model A is greater than the entropy from model B. Thus, we will consider organization B to have a more consistent practice than organization A, and we will recommend a transfer of B’s practice to A.

Motivation

In this section, we present an example to motivate our methodology. In this example, we work backwards from an existing transfer learning solution that proves useful, and arrive at the existence of a practice gap that can explain the apparent utility of the transfer algorithm. In our methodology, explained later in the Methods section, we can identify this gap before applying the transfer learning algorithm. The specific solution we consider was recently proposed by Caldas et al.\textsuperscript{11}. In their algorithm, a clinical organization, when assessing a particular data sample, e.g. a particular patient case, dynamically selects between a locally trained model and a model shared by an external organization. In this section, we focus on presenting and interpreting the results of applying the method on one particular Machine Learning (ML) task.

We consider the task of detecting long lengths of hospital stays in medical inpatient claims. Our claims data comes from the year 2016 Patient Discharge Database (PDD) from California’s Office of Statewide Health Planning and Development (OSHPD), and we solve our task using regularized logistic regression models. We define a long stay as one greater than the national average length of stay for the diagnosis related group (DRG) associated with the claim. We perform the analysis separately for each DRG and for two distinct hospital groups, treating each DRG as a different practice and each hospital group as a different organization. We refer to these organizations as Organization A and B. We provide more specific information about our data and ML models in our Results section.

For this motivating example, we focus on the DRG 291 associated with heart failure and shock with major complications or comorbidity. The results of our suggested dynamic classification algorithm\textsuperscript{11} for this DRG are shown in Table 1. As an example of how to interpret these results, consider Organization B: out of the 860 test cases where the external classifier (from Organization A) is used, 102 cases change predictions from incorrect when using the local classifier, to correct when using the external model. This represents 68% of the total count of hospital stays for which predictions of the two considered models differ, and thus we have enough evidence to discard the hypothesis that such difference is random.

The results in Table 1 indicate an asymmetrical relation between Organizations A and B in terms of knowledge sharing: Organization B observes significant gains from using Organization A’s model, but the reverse is not true. In light of this asymmetry, it is natural to inquire about possible causes of the apparent discrepancy. We explore three hypotheses that could explain it:

1. **Difference in sample sizes**: If Organization A were to have a larger data sample to train its model than Organization B, then we could explore the possibility that the observed asymmetry is due to this difference. However, for DRG 291, Organization B has ~20% more of these claims than Organization A, as seen in Table A.1. in the Appendix. As a result, we discard this hypothesis.

2. **Difference in model performance**: An inherent difference in model performance could explain the asymmetrical relationship observed in Table 1. If this hypothesis were to hold, we would expect the model trained in Organization A to outperform the model trained in B when evaluated on B’s data, and we should observe similar effects when evaluating these models on A’s data. In Figure 2, we see however that the Receiver Operating Characteristic (ROC) curve performances of these models are within each other’s error bands. For a more detailed analysis, we focus on comparing the true negative rates at a fixed 90% true positive rate and construct 95% confidence intervals for the difference in performance between models. Both intervals, which are plotted later on in Figure 5, end up containing 0, further indicating lack of evidence to support the hypothesis that the observed tradeoff in utility of these models can be attributed to difference in their predictive power.

3. **Difference in consistency and quality of care in patient treatment practice**: Having discarded perhaps the most obvious candidate explanations for the observed discrepancy, we turn our attention to the actual practice being modeled. With the available data we cannot directly evaluate consistency of clinical decisions, but we can rely on a proxy: the entropy of the distribution of scores produced by each classifier. We consider a higher entropy to be indicative of a more ambiguous practice in an organization - this happens when a model trained on operational data from this organization yields predictions that are less crisp at discriminating, for example, long and short stays in the hospital (to refer back to our working example). Such differences in the apparent crispness of the decision making process between organizations can exist even if the predictive performances of the models trained to automate such decisions do not differ when measured with common means such as ROC analysis.

We plot the score distributions for both models, evaluated on data from Organization B, in Figure 3. Here, we see that the entropy resulting from model A applied to data in B is indeed lower than the one resulting from applying model B to its own test data. We check that this difference is statistically significant by constructing 95% confidence intervals for the differences in entropy, which we’ll plot later on in Figure 6.

![Figure 2](image-url)  
**Figure 2.** ROC curves for our motivating example. We plot the false positive rate in logarithmic scale for visibility.

Not having insight into actual operations of each organization, we cannot definitely conclude that there indeed exists a knowledge or practice gap by just using medical claims records to support such judgement. But we propose that the presented result could motivate a thorough investigation and, if warranted, a properly designed intervention in organizations that show an opportunity for improving crispness of their practice, unless additional evidence could provide simpler explanations for the results in Table 1.

In our proposed methodology, we are interested in first identifying the apparent knowledge or practice gaps. These gaps will motivate organizational audits and adjustments to existing processes to align performance of the target
organization up to the apparent levels of their peers demonstrating a more consistent, crispier decision-making practice. Such organizational change may be, however, effortless and time consuming to prepare and implement. As a result, we also propose using a transfer learning method\textsuperscript{11} as a stop-gap solution. It will selectively apply the crispier decisions from a better-practice organization when assessing an opportunistically selected subset of all cases for which the external model is expected to confidently outperform the model trained on the local data. This strategy aligns with the transfer process steps outlined by Elwyn et al.,\textsuperscript{4} and it mitigates or at least postpones the effort of implementing a solution that may not be necessary if such algorithmic work-around is acceptable.

![Model A - Entropy: 7.45](image)

![Model B - Entropy: 7.48](image)

**Figure 3.** Score distributions for our motivating example. Model A is more confident in its predictions than model B when evaluating both models at Organization B. This is reflected in a lower entropy for model A.

**Methods**

In this section, we first describe our strategy for identifying possible knowledge or practice gaps between organizations, before sketching the transfer learning technique we recommend to support the transfer process.

*Analyzing model outputs to identify knowledge gaps*

Given a machine learning task, we propose that a well-performing and confident model is indicative of a robust and consistent practice. Consequently, if a model trained in an external organization shows a greater performance or confidence than a locally trained model, this suggests that there is a knowledge or application gap between the institutions. The models should be evaluated on the same set of data for conclusions to be valid. As such, we could imagine that organizations share their trained classifiers, perhaps through an arbiter, and then test and evaluate external models on their own local data. This way, the privacy of the individual organizations’ data can be preserved, a restriction often imposed in the healthcare industry\textsuperscript{12}. For example, in Figure 1, both models, A and B, are evaluated on data from organization A in order to draw conclusions about the state of organization A’s practices.

We outline two possible scenarios that can occur when comparing two models, one local and one external, on data from one organization of interest:

- The case in which one model dominates in terms of some performance metric (for example, Area Under the ROC Curve (ROC AUC), or recall rate at a fixed low false positive rate) is straightforward: if the local model dominates, no adverse gap exists; if the external model dominates, there is a possible knowledge or practice gap. The latter case, however, may not be very common in reality due to the usual degradation of clinical models whenever they are used outside of the institutions they were trained in\textsuperscript{13}.

- The case where the models are similarly well-performing, but show a different degree of confidence in their predictions. In this case, if Organization B produces a more confident model than A, as measured on data from A, then this could be indicative of a more consistent practice implemented in organization B. This is the case we encounter the most often in our experiments. To tackle these situations, we quantify model confidence through the entropy of the distribution of scores generated by the model. This is the same proxy we used in our motivating example to quantify consistency of practice. Note that alternative proxies of quality of practice can also be used instead without changing the proposed framework.

Regardless of the scenario that led to the identification of the potential knowledge or practice gap, it is important to verify that this conclusion is not the product of statistical artifacts. In particular, one should be aware of whether the organizations have different amounts of data to work with. More data is usually associated with better-performing
models, so it is crucial to control for this effect before making any recommendations that will consume resources and impact organizations in the long-term.

*Using transfer learning as a stop-gap solution*

Once an organization has identified a potential local knowledge or practice gap with respect to an external institution, it is natural to look into the adoption of the external practice. However, implementing a new or modifying the existing practice can be a long, time-consuming process. While the structural and organizational efforts towards such adoption are planned and gradually implemented, the local practice is known to be sub-optimal, and thus in detriment to both the institution and some of its patients.

To reap benefits while waiting for the organizational changes to yield actual utility, we suggest using a temporary solution in which the local organization exploits the external model within their current practice. We propose the use of a dynamic classification framework, through which the local organization will select the most appropriate model, local or external, for each new sample. This framework proceeds in two stages:

1. **Estimation of the models’ loss**: Once a new, previously unseen by the model sample arrives, we do not have an associated label for it. To estimate the loss that the local and the external classifiers will incur on it, we make use of the *k*-nearest neighboring samples available in the training data set. Our estimate is the mean of the losses that are incurred on these neighbors. Notice *k* is a hyperparameter we may need to tune via, e.g., cross-validation.

2. **Selection of the most competent model**: Having the loss estimates for the local and the external models, we take the ratio of the estimate for the local classifier over the estimate for the external. This way, *r* will be higher whenever the external classifier seems to be more favorable. Hence, we use the external classifier if *r > r*₀, where the *r*₀ threshold can be optimized on the training or validation set of data to maximize the utility of the framework. In more technical terms, *r*₀ can be chosen to minimize the p-value of a statistical test whose null hypothesis states that using the local classifier on samples where *r > r*₀ provides a better or equal utility than using the external one. We can measure the utility in terms of, e.g., correct predictions.

Another strategy would completely replace the local model with the external one while the practice is being transferred. However, this strategy entails forgoing all the knowledge codified in the local model. It may also not yield any benefits if the performance of both models was judged to be similar from the start. On the other hand, because the proposed dynamic framework is based on the comparative analysis of the local behavior of both models, the local organization can yield benefits from the external model selectively on a subset of their samples, even when global performance metrics of the considered models are comparable.

**Results**

**Data Description**

We use the data from the year 2016 Patient Discharge Database (PDD) from California’s Office of Statewide Health Planning and Development (OSHPD). This dataset consists of over 3.8 million inpatient medical claims, with associated information about the diagnoses and procedures reported in each claim. We limit our study to the top 20 diagnosis related groups (DRGs) with the highest volume of claims, which we model separately as different practices that could be improved. Out of these, we exclude DRGs relevant to newborns to further focus our analysis.

Moreover, for clarity of presentation, we focus on data pertaining to only two hospital groups. Nevertheless, our analyses can be directly applied to larger numbers of organizations, and to entities at different levels of organizational granularity, for instance individual hospitals or practices within a hospital system. Throughout the rest of this text, we refer to these selected hospital groups as Organization A and Organization B. We are left with 14 DRGs representing over 240 thousand inpatient claims. Table A.1. in the Appendix shows descriptions of the considered DRGs as well as sample sizes for each DRG in each organization.

**Machine learning models**

To demonstrate our method, we propose a machine learning task that predicts whether a claim will be associated with an unusually long length of hospital stay. To fulfill this task, we binarize the traditional length of stay prediction task, using the national average length of stay of each DRG as a threshold to determine the labels: a positive label represents a stay longer than the national average while a negative label represents a shorter stay. We do not consider a scenario in which our defined organizations could share their data, replicating the realistic setting in which
institutions are constrained by patient confidentiality and other data privacy considerations\textsuperscript{3}. We end up with one model per DRG, per organization.

We solve the task using regularized logistic regression, but our methodology admits any type of model with an ability to estimate loss of predictions made on individual query data samples. We use 5-way cross-validation to pick the regularization hyperparameter, performing a grid-search over 1,000 settings. We train our models using 70% of available data, and report our results on the remaining 30% held out for testing. We use the true negative rate at a fixed 90% true positive rate (TNR @ 90% TPR) as our evaluation metric. This performance indicator quantifies the desired trade-off between predicting lengths of stay in a normal range while maintaining high sensitivity, but alternative performance metrics can surely be used in its stead as well. We present the performance of the resulting models in Figure 4. We refer to the model trained at Organization A as model A, and similarly for model B.

![Figure 4](image)

**Figure 4.** TNR @ 90% TPR for the trained models. Each model is tested on data from the organization where it was trained. The error bars reflect 95% bootstrap confidence intervals, for which we performed 1,000 resamplings. Note that except for a couple of DRGs, results of these models on their own data are not statistically discernible.

**Identification of knowledge gaps**

We begin by observing the differences in performance between model A and model B once both models are used in the same organization. We plot these differences in Figure 5. We observe that most of our confidence intervals include zero difference, and in these cases we cannot claim the prevalence of one model over another. We see only two intervals that do not contain zero: DRG 392, Organization A and DRG 765, Organization B. Both of these are composed exclusively of positive differences, which indicates that the local model outperforms the external. For these cases, we have enough evidence to discard a possible existence of a knowledge or practice gap, as it is defined in our approach.

Next, we proceed to identify models that are similarly performant on data from a given organization, as seen in Figure 5, but show a difference in entropy of the distribution of their prediction scores. Figure 6 shows these results. Here, we are interested in intervals composed exclusively of positive differences, as they indicate that the entropy of the local model is greater than the entropy of the external one, and a sought-after gap may indeed exist. Table 2 summarizes the DRGs and organizations where we have identified potential knowledge or practice gaps.

**Inspection of statistical artifacts**

As previously mentioned, we need to verify that the potential gaps we identified are not products of statistical artifacts. In particular, we want to make sure that they are not by-products of the differing sample sizes between organizations. To do this, for each DRG, we subsample the training dataset in the organization with the most data until it has the same volume as the other organization. We repeat this random subsampling process ten times and train a completely new model each time. The results of this exercise are shown in Figure 7.

Controlling for size, we see some of our conclusions change: some performance differences we thought were negligible, i.e., the confidence interval contained zero, turn out not to be. This happens for Organization A, DRGs
603, 774 and 775. In these cases, our confidence intervals are composed exclusively of positive differences. We take this as evidence to discard a knowledge gap.

**Figure 5.** Differences in performance when model A and model B are used in the same organization. The presented differences correspond to the performance of the local model minus the performance of the external one. Error bars correspond to bootstrap confidence intervals. We maintain an overall confidence coefficient of 95%, using Bonferroni’s method to correct for making multiple comparisons.

**Figure 6.** Confidence intervals for difference in entropy. The presented differences correspond to the entropy of the local model minus the entropy of the external one. Error bars were drawn in a similar fashion as in Figure 5. We do not plot DRG 392 - Organization A nor DRG 765 - Organization B, as we had already discarded the potential existence of a knowledge gap for these cases due to a difference in model performance.

**Table 2.** Conclusions before inspecting for statistical artifacts. A star (*) indicates a potential knowledge or practice gap, as defined by our framework. A “P” indicates the evidence to discard the potential gap came from the difference in model performance, while an “E” indicates the evidence came from the difference in score entropies.

Figure 7. Differences in performance and differences in entropy when controlling for sample size. Differences shown correspond to the output of the local model minus the output of the external one. Error bars correspond to confidence intervals where we maintain an overall confidence coefficient of 95% and apply a Bonferroni correction. We construct these intervals by assuming normality in the distribution of the differences. We only plot those DRGs and organizations for which we had identified a potential knowledge or practice gap, as shown in Table 2.

**Evaluation of the proposed transfer learning approach**

We evaluate our transfer learning framework by looking at the samples where the algorithm decides to use the external model, specifically those for which the external model changed the prediction with respect to the local one. We call these flipped samples. If the new prediction of these flipped samples is correct, then we consider it a successful flip. Moreover, if the percentage of flipped samples over all flips is greater than 50%, then we consider the method successful.

Table 3 shows our results for the DRGs and organizations where we identified a knowledge gap. We pay close attention to the columns Train $p$-value and Test $p$-value. They both relate to how confident we are that the percentage of correct flips is lower than 50%, but the latter is only available after evaluation. It follows that if Train $p$-value is too large, we will be discouraged from using this framework at test time, recommending the use of only the local model instead. This happens for three of our identified scenarios: DRG 470, 690 and 766, all for Organization B. As a confidence threshold we used an alpha of 0.05 and corrected for multiple comparisons using Bonferroni’s method. For all other scenarios, we observe both a statistically significant Train $p$-value and Test $p$-value. This means we are both confident about using the method and have enough evidence to claim the method is beneficial on our test data.

**Discussion**

We discuss four axes of our work: our results on the inpatient claims dataset, how this work fits within the broader scope of Machine Learning (ML) techniques, and our limitations and possible future work.

**ML-aided practice transfer for inpatient claims:** Table 3 enumerates the nine DRGs and organizations where our methodology identified a potential practice gap. If these organizations were to undertake transfer processes for these practices, our suggested transfer learning stop-gap solution could support six of these processes, allowing the local organization to reap benefits from the external knowledge, codified through the external model, sooner. In the other three cases (DRG 470, 690 and 766, all for Organization B), our suggested solution recommended using only the local model. All these three cases had a difference in entropy that suggested a more ambiguous local practice, but had some of the lowest absolute differences identified, as observed most clearly in Figure 7. A more robust approach could establish a threshold for the difference in entropy, but this threshold may end up being application dependent.

**New avenues for federated learning:** Federated learning is a novel distributed learning paradigm that allows clinical institutions to collaborate in the training of machine learning models without sharing patient data. The transfer algorithm we leverage was developed in the context of federated learning, exploiting model sharing instead of data sharing between institutions. This work shows a new promising avenue for the application of federated learning: supporting practice transfer processes. This can be done by understanding the contributions the local organization makes to the collaborative model vs. those made by external institutions, as we did in our motivating example.

Limitations and future work: There exist other other possible differences between institutions, besides those explored in this work, that can explain apparent practice gaps. Two in particular come to mind: (1) inter-center population heterogeneity, and (2) differing ML capabilities, in terms of the adoption and incorporation of ML practices. Future research efforts should be made to develop and test methods that differentiate between differences in these axes and knowledge gaps.

Future work can also validate the generalizability of the proposed approach by extending it to new multi-source datasets. A more ambitious next step would, ideally, observe the identified practices and validate both the existence of a gap and the utility of the stop-gap solution. Such a research study could be impractical, requiring coordination from multiple institutions and the undertaking of an actual transfer process, which is resource-intensive. Another avenue with a more restricted scope is the identification of more desirable model qualities correlated with best practices attributes that have been identified in theoretical work, beyond high performance and low entropy.

Conclusion

We presented a new approach to identifying opportunities and supporting the transfer of best practices in healthcare using a machine learning methodology tailored to this task. To illustrate this approach, we focused on groups of organizations with practices that can be codified into classification models. By sharing these models and comparing their performance and consistency, we draw conclusions about whether there exist potential discrepancies in the robustness of the underlying practices. If we identify such gaps, we propose using a dynamic classification framework as an immediately available stop-gap solution until the proper organizational investigation and improvement plans to address the apparent gaps are developed and completed.

Broken down by bias: Healthcare biases experienced by BIPOC and LGBTQ+ patients

Reggie Casanova-Perez, MS1, Calvin Apodaca1, Emily Bascom1, Deepthi Mohanraj1, Cezanne Lane1, Dhrishi Vidyarthi1, Erin Beneteau, MS, Janice Sabin, PhD, MSW1, Wanda Pratt, PhD1, Nadir Weibel, PhD2, Andrea L. Hartzler, PhD1

Abstract

Bias toward historically marginalized patients affects patient-provider interactions and can lead to lower quality of care and poor health outcomes for patients who are Black, Indigenous, People of Color (BIPOC) and Lesbian, Gay, Bisexual, Transgender and Gender Diverse (LGBTQ+). We gathered experiences with biased healthcare interactions and suggested solutions from 25 BIPOC and LGBTQ+ people. Through qualitative thematic analysis of interviews, we identified ten themes. Eight themes reflect the experience of bias: Transactional Care, Power Inequity, Communication Casualties, Bias-Embedded Medicine, System-level problems, Bigotry in Disguise, Fight or Flight, and The Aftermath. The remaining two themes reflect strategies for improving those experiences: Solutions and Good Experiences. Characterizing these themes and their interconnections is crucial to design effective informatics solutions that can address biases operating in clinical interactions with BIPOC and LGBTQ+ patients, improve the quality of patient-provider interactions, and ultimately promote health equity.

Introduction

Implicit bias shapes healthcare providers' behavior and can result in health disparities based on race, ethnicity, gender, and sexual orientation.1,2,3,4 These biases reflect prejudices and stereotypes that may be subtle and unintentional, and lead to well-recognized inequities in health and healthcare for patients who are Black, Indigenous, People of Color (BIPOC) and Lesbian, Gay, Bisexual, Transgender and Gender Diverse (LGBTQ+).3,4,5 For example, Black patients are prescribed less pain medication,6 receive less aggressive heart attack treatments,7 receive fewer cardiovascular referrals,8 achieve poorer reproductive outcomes,9 experience less patient-centered communication, and rate care quality worse than White patients.9 Similarly, bias towards LGBTQ+ people can result in poor quality of care related to discrimination based on sexual orientation and/or gender identity.10 Avoiding seeking care,11,12 lack of provider knowledge and training about LGBTQ+ health care needs,13 a preference among heterosexual providers towards heterosexual patients,14 and insufficient research about the health of LGBTQ+ populations.15 Implicit biases towards these historically marginalized groups negatively impact patient-provider interactions and produce unnecessary health inequities.

Although many have recognized and attempted to mitigate implicit bias,16 evidence suggests that this bias continues to influence clinical interactions.17 This ongoing problem exposes the need for a deeper understanding of how marginalized and underserved patients experience unfair treatment related to perceived bias and discrimination,18 which can help inform mitigating strategies in the future,19 including informatics solutions. As a first step in the design of automated technology to identify biases operating in patient provider interactions, this qualitative study investigated healthcare biases experienced by BIPOC and LGBTQ+ people and elicited their ideas for improving those experiences in future interactions with healthcare providers. We describe themes that emerged from our qualitative analysis of interviews with BIPOC and LGBTQ+ people, including their experiences of bias, their responses, the consequences, and their ideas for solutions. The research questions this study addresses are:

RQ1. How do BIPOC and LGBTQ+ patients experience biases in healthcare?
RQ2. What solutions do BIPOC and LGBTQ+ patients suggest for improving those experiences in the future?

Methods

Study Design
Data collection included an online survey and a semi-structured interview conducted remotely through Zoom. The University of Washington Institutional Review Board approved this study.
**Participant Recruitment**

Inclusion criteria for participant recruitment were: (1) to be BIPOC and/or LGBTQ+, (2) be 18 years of age or older, and (3) reside in the United States. The research team distributed recruitment flyers through institutional mailing lists, social media, and “community champions” who are patient representatives from BIPOC and LGBTQ+ communities who serve on our project’s advisory board. Those who consented to participate completed the online survey and interview. Recruitment ended when the interviews reached thematic saturation.

**Online survey**

The online survey collected demographics information, including age, gender, race, ethnicity, education, and self-identification as BIPOC and/or LGBTQ+, and experiences of discrimination through the standardized 10-item Day-to-Day Unfair Treatment Scale. This widely used scale collects the frequency of experiencing situations considered to be unfair, such as being treated with less courtesy or respect than other people or being called names, harassed or followed around in stores. Response options were “Never”, “Once”, “2-3 times”, and “4 or more times.” For example, if the respondent answered something other than “Never” to the question “Have you been followed around in stores?”, an additional question asked about the main reason for it with the following options: Ancestry, gender, race, age, religion, height or weight, shade or skin color, sexual orientation, education or income level, physical disability, or other. We did not recruit information about participants’ socio-economic status or insurance coverage.

**Interviews**

Interviews occurred between June and November 2020 via Zoom and lasted one-hour. Except for one interview, two researchers interviewed each participant, one as the primary interviewer following the interview guide and the other one asking clarifying questions. During the first half of the interview, we asked participants to “Tell us about a time when you had an interaction with a doctor where you felt not heard, disrespected, or made uncomfortable?” (RQ1. Experiences). The second half of the interview asked them “If you had the power to change the experience you described, what would you change?” (RQ2. Strategies). After each interview, the researchers made notes summarizing the participants’ experiences and solutions. Interviews were recorded and transcribed for qualitative analysis.

**Data Analysis**

Survey data was summarized with descriptive statistics, and qualitative data was summarized using thematic analysis. Thematic analysis involved developing and refining a codebook and transcript coding. Codebook development started with three researchers (RCP, CL & DV) inductively creating a preliminary codebook with the key themes identified from the initial transcript review. RCP incorporated relevant codes from existing literature and advice from co-authors. Next, two new coders (DM & EB) and an interviewer (CA) familiarized themselves with the data and refined the codebook. The analysis team was composed of four coders (RCP, DM, EB, CA). Two were female (DM & EB), one male (CA), and one non-binary (RCP). Two coders identify as Hispanic/Latino (CA & RCP), one as Asian American (DM) and one as White (EB). The analysis team read two transcripts weekly for codebook refinement and iterated until they reached a consensus. With the refined codebook, the researchers had two sessions of consensus coding where they coded individually two transcripts in Atlas.TI v.9 and manually reviewed the applied codes as a team. After making small adjustments to the codebook for addressing remaining discrepancies, the analysis team coded transcripts in pairs in Atlas.TI until completion.

**Research Context**

In early 2020, the WHO declared a pandemic due to the COVID-19 disease, which forced states and countries to go into lockdown, requiring this study work to take place remotely. COVID-19 brought to light long existing health disparities towards marginalized communities who were disproportionately exposed to the virus because of their ‘essential’ job category which prohibited them from staying home. Additionally, the Black Lives Matter (BLM) movement gained massive support after graphic videos depicting police brutality against Black people went viral on social media. Simultaneously, the American political environment and media was frequently filled with discriminatory comments. These three aspects may have influenced BIPOC or LGBTQ+ people to be more willing to share their negative experiences and how those experiences impacted their life. Collecting the data in these unprecedented circumstances presented a unique opportunity to understand patients’ experiences of bias and discrimination during clinical interactions.

**Results**

**Participants**

Twenty-five participants completed the survey and the interview. Table 1 summarizes their characteristics. Participants ranged in age from 19-60 and were racially diverse. The majority were women, not Hispanic/Latino, and
college educated. Eleven participants were BIPOC, ten reported were BIPOC & LGBTQ+, and three were LGBTQ+. One participant did not report to be BIPOC or LGBTQ+ but described themself as an “older Asian woman.”

**Experience of day-to-day unfair treatment**

Table 2 summarizes participants’ responses to the 10-item Day-to-Day Unfair Treatment Scale. Overall, participants reported experiencing substantial levels of unfair treatment. For example, all participants reported receiving poorer service than others and experiencing people acting as if they are superior. Eighty-seven percent of participants reported being treated with less respect and courtesy than others, 83% reported being called names or insulted, and 91% reported experiencing other people ‘acting as if they think you are not smart’. Seventy-five percent of participants said they had been followed around in stores because of racial bias. Of those, 70% reported this was due to race, 10% due to sexual orientation or gender, and the remaining 20% chose other reasons such as height or weight, and shade of skin color.

**Interview themes**

Participants talked about their experiences of bias in the healthcare system, their reaction, and its consequences. They described experiences in different healthcare settings during the entire process for care-seeking, from scheduling the appointment to picking up their medications; explaining why their experiences involved different types of healthcare providers (Physicians, Nurses, Pharmacists). Although participants were not prompted, they organically mentioned healthcare system problems that made them feel not being taken care of and contrasted their negative experiences with positive ones. We identified two types of themes: (A) Experience and (B) Strategy. Experience themes refer to the biased healthcare experiences that contributed to feelings of not being taken care of. We identified and named eight Experience themes: Transactional Care, Power Inequity, Communication Casualties, Bias-Embedded Medicine, System-level problems, Bigotry in Disguise, Fight or Flight, The Aftermath. We also report on interconnections among these themes. Strategy themes refer to insights for mitigating experiences of bias in healthcare. We identified two Strategy themes: Good Experiences and Solutions.

A. Experience with bias in healthcare

1. Transactional care

Transactional care refers to a provider treating an appointment as a job rather than an opportunity to look after the patient’s well-being. This theme refers to the patients’ experience of the appointment. Participants told us about incidents regarding providers rushing the appointment, not being thorough enough or only treating symptoms, refusing to take care of more than one medical concern in one appointment, and being uninformative with the patient about their medical reasoning, diagnoses, treatments, or alternatives. Participants expressed feeling unseen in transactions:

“I talked about being at the hospital and feeling I was just like, an assignment or some sort... of just one thing to do, like, 'okay, this is what you have to check the vitals, and this is where you need to give him this specific thing.' But not really being felt like I was really being seen.” – PT18, BIPOC & LGBTQ+ Non-binary.

“That's what I always hear from my previous PCP is, 'Oh, we'll see if it gets better or take some over-the-counter medication for this' or, 'Oh, you know, just change your diet or exercise more.' But I didn't feel like he was really paying attention to, you know, what I actually was going through.” – PT01, BIPOC & LGBTQ+ Man

2. Power Inequity

Power Inequity refers to the power imbalance between patients and providers that affected rapport building. This imbalance was often described as due to a knowledge difference between patients and providers. This imbalance made some participants feel that the provider judged them not to be smart enough to understand medical information, identify valid medical concerns, or make the best medical decisions. This judgment made some participants feel powerless and have no say in their own health or how they want to manage it. For example, one participant told us:

“I do think that it also comes with that power dynamic of like having more control as a doctor. As a professional you can say like 'I have all these degrees and have all these years of experience, and you're just a patient’ ... you don't have as much power in the situation, so they can kind of have control.” – PT08, BIPOC & LGBTQ+ Woman.

Incidents for this theme involve providers making all the medical decisions without including the patient in the process, not building rapport with the patient, dismissing the patient without giving them an explanation, and making the patient feel that they do not have the qualifications for making medical decisions. For example, PT13 felt dismissed:

“I was asking the doctor what he thought would be like the cause of my symptoms. I suggested something, and he just kind of brushed it off. I feel like I wish he would have just explained why that wouldn't have been the case, rather than brushing it off. It kind of left me wondering why did he brush it off? was it a dumb reason or something?” – PT13, BIPOC Woman.

3. Communication Casualties

Communication Casualties refers to verbal or non-verbal cues that the patient identified as uncomfortable, awkward, or inappropriate. These negative cues made the patient feel unwelcomed, judged, or not taken care of. Participants described how some providers’ comments negatively impacted their ability to receive care. Negative verbal cues refer to providers saying inappropriate comments to the patient, scolding them, or verbally judging their actions. Non-verbal cues refer to behaviors that made the patient feel that the physician was not paying attention to them, wanted the appointment to be over, or is did not understand their needs; these nonverbal cues included lack of eye contact, approaching the door when the patient was speaking, or having a judgmental tone of voice. For example, PT15 described negative cues expressed by a healthcare provider:

“I was seated, she was standing above me hands on her hips, literally lecturing me as if she was my mother. And flat out said 'if you were my son, this is what I would say to you’” – PT15, BIPOC & LGBTQ+ Man.

Several participants talked about the provider transmitting a ‘vibe’ that made them not trust the providers even if they could not explain the communication cue explicitly in words. PT14 describes the “vibe” of a negative interaction:

“I told (the provider) about my issue and (they) don't really offer any suggestions, and it was so tough. You can't explain vibes, right? There's no definition, it just felt awkward and weird” – PT14, BIPOC & LGBTQ+ Woman.

4. Bias-Embedded Medicine

Bias-Embedded Medicine refers to instances in which the patient felt they were treated unfairly because of their personal characteristics, such as race, ethnicity, gender identity, sexual orientation, or physical characteristics (e.g., weight). Because of these possible assumptions, patients had a hard time accessing tests, treatment, or obtaining a diagnosis. Incidents for this theme are misunderstanding of pain, BIPOC & LGBTQ+ stereotyping, and other types of
situations, such as weight or age. Misunderstanding of pain was when providers were thought to assume that the patient (BIPOC patients usually) was exaggerating their pain to get pain medication. For example, PT21 told us:

“I said, ‘Could you please do that [MRI] because I’m a movement performance artist. So, I would jeopardize my entire well-being, career, and financial status if I injured myself further. It's really, really important I treat myself for the exact condition.’ He said, well, ‘we are deeming it medically unnecessary because we do not feel it’s necessary for you to have an MRI because we feel this information is good enough’” – PT21, BIPOC Woman.

BIPOC & LGBTQ+ stereotyping is when the provider adopts certain behaviors and characteristics after making assumptions related to the patient’s demographic. Other types of stereotyping included assumptions based on reasons, like age or weight. For example, one participant described an experience of stereotyping:

“I saw written down ‘high-risk homosexual behavior’. She asked me if I ever had sex with men. She didn’t ask me the last time I had sex with men, and it couldn’t have been because I hadn’t had sex in like months, (…) I just dislike for her to make that assumption, that I was out there having unprotected sex” – PT23, BIPOC & LGBTQ+ Non-binary.

5. System-level problems
System-level problems refer to the patient feeling that the healthcare system is unwelcoming and difficult to navigate. Incidents in this theme related to the medical record, such as trouble accessing their records, or problems like confusing insurance systems, non-inclusive medical forms, and the lack of diversity in the medical workforce. For example, one participant described inaccurate medical records:

“After discharging me, (the physician) wrote in the chart notes that I had refused care. And I said, ‘That’s not true, this is what he told me, and I wasn’t going to stay there for things to get worse’” – PT06, BIPOC & LGBTQ+ Woman.

Another participant describes the lack of diversity they perceive in the healthcare workforce:

“There’s a real issue with supporting doctors who look like their patients. The only people of color are the ones cleaning, or in the cafeteria. I think diversity is such a huge part of it... I’m not saying that all doctors need to be people of color but, maybe seeing more people who just aren’t in that standard mold that we’ve created healthcare to follow.” - PT14, BIPOC & LGBTQ+ Woman.

6. Bigotry in Disguise
Bigotry in Disguise refers to when participants perceived providers to have implicit discriminatory attitudes or behaviors towards BIPOC and LGBTQ+ patients. Examples are the provider not knowing how to talk or take care of gender-diverse patients or appearing unaware of important needs for BIPOC patients, such as the prevalence of specific conditions among certain races/ethnicities. Participants understood that providers are not supposed to know everything but wanted providers to be honest about being unknowable. For example, PT21 describes perceptions of a provider’s disregard for her South Asian ancestry:

“I said, ‘There’s a British study done on South Asians and cardiovascular disease and metabolic syndrome. There should be specifications as to what is healthy (for South Asians)’. He dismissed me and said ‘all that matters is you do x, y, and z, which is not only for South Asians, just start, just do this’. And I said, ‘okay, you don’t know about the South Asian Studies’. And he said, ‘I’ve never heard of any of this, and it doesn’t matter’” – PT21, BIPOC Woman.

Another incident is when patients feel ‘othered’ by providers, meaning that the provider makes a rigid distinction between the provider’s and the patient’s community. These distinctions peaked when BIPOC participants saw providers treating White patients better than them (i.e., racial favoritism). These discriminatory attitudes were also experienced by LGBTQ+ participants. For example, PT25 describes a provider’s bias toward their girlfriend:

“I said, “My partner has a penis. Does that affect this or that?” And he laughed and said, “Oh, well, I’m sure your boyfriend, yada, yada, yada.” It made me so angry, because not only was he… I guess, for my body, I can justify it, and I can understand not everybody is super educated about trans issues or pronouns, whatever. I can excuse that even if it’s not right, to help me get through the process and minimize my discomfort, but as soon as he disrespected my girlfriend, I got mad, and I just stopped talking, started giving very short, to-the-point answers, because I didn’t wanna get angry and I wasn’t going to explain everything in a hospital gown.” – PT25, LGBTQ+ Multi-gender.

7. Fight or Flight
Fight or Flight refers to responses in which the patient realized they were being treated unfairly. There were two distinctly different types of responses: Active and Passive. The active response is when the patient self-advocates and demands to be treated with respect (i.e., fight). The passive response is when the patient says nothing and waits until the interaction is over (i.e., flight) for fear of repercussions. For example, PT21 described her “fight” response:
"I was so angry, and I told him 'I'm extremely upset with how you treated me, the difference in statistics for a South Asian person and a white person are very, very different. You're dismissing me. You're just dismissing me because I'm young and I'm brown, and you don't think my statistics are bad enough, and you've already told me that you think I'm fat, so I'm not going to see you again.'" – PT21, BIPOC Woman.

Surprisingly, several participants, independent of whether they had an active or passive response, justified the providers’ behavior for treating them unfairly. For example, PT04 told us:

“Okay, giving them the benefit of the doubt, they were probably just following protocol. That's where I think that maybe healthcare procedures need to account for looking more like situation alliance.” – PT04, BIPOC Woman.

8. The Aftermath

The Aftermath refers to the consequences that biased experiences had in patients’ lives. The most serious was the health-related consequences, where a patient’s conditions got worse following a provider’s dismissal. Other serious consequences were the patient self-medicating, delayed or avoided healthcare unless it was an emergency, or simply mistrusted the healthcare system altogether. For example, PT11 describes consequences of such dismissal:

"I was overweight but active, I complained about knee pain all the time, and doctors always said 'lose weight.' Well, one time on vacation, I got injured and had to go get X-rays done on my knee. When the X-rays came back, the doctor was, like, “you have arthritis, and also your kneecap is misaligned.” My first reaction was 'I'm not even 30, and I have arthritis?' and then it was anger because I have been dismissed for like a decade". - PT11, BIPOC & LGBTQ+.

Other consequences were changing providers searching for one who would treat them fairly, or start having “covering” behaviors, where the patient would change their physical presentation in the hope that providers will treat them better:

"This is another thing too that I have to do - I'll make sure that I'm suited that day. Like head to toe. Because even that sometimes can help the experience. Let me put on my professional attire. Sadly, it still doesn't work... I actually have to prepare myself in that way and be selective about what I choose to wear that day. Like I wouldn't want to go in like my leggings." – PT16, BIPOC Woman. Quote about covering behaviors

Interconnections among themes related to participants’ experiences with bias in healthcare

Identified themes are intrinsically connected. Figure 1 is a visual representation of interconnection among themes within three nested dimensions: the healthcare system (purple rectangle), the appointment (yellow rectangle), and the patient-provider interaction (green). The eight Experience themes are in bold. The first dimension, the healthcare system, includes the ‘System-level problems’ since participants mentioned structural problems as a challenge when visiting the provider. In the appointment dimension, we found ‘Transactional Care’ since it refers to problems during appointments. In the appointment dimension, we found two entities (in blue), the provider and the patient, connected within the patient-provider interaction dimension. The provider can bring the ‘Bias-Embedded Medicine’ and ‘Bigotry in Disguise’ into the interaction which the patient can perceive as ‘Power Inequity’ and ‘Communication Casualties,’ leaving the decision of “Fight or Flight” to the patient. After the appointment, ‘The Aftermath’ could result in the patient choosing to leave the healthcare system altogether, so it sits halfway outside the healthcare system dimension.

![Figure 1. Interconnections among themes related to participants’ experiences of bias in healthcare](image-url)
B. Strategies to mitigate the experience of bias in healthcare

The second half of the interview focused on the participants’ suggested solutions about how to prevent these biased healthcare experiences from repeating. Many participants organically contrasted their negative experiences with good experiences. We report both participant-generated solutions along with those good experiences since they can display well-received providers’ actions and could help guide mitigating strategies.

1. Solutions

Solutions refer to the participants’ ideas about what could help prevent the biased interactions from repeating. Participants’ ideas include having patient advocates accompany them to feel more comfortable at the providers’ office, providing feedback to the provider to let them know what went wrong during the interaction, enhance provider training on interpersonal skills and cultural competence towards BIPOC and LGBTQ+ patients, and promote diversity in the healthcare workforce. For example, PT16 describes providing feedback:

“The goal, hopefully, from the doctor's perspective, would be to have this honest feedback that they could grow from and implement changes for. It's tough, but you know it's a necessity.” – PT16, BIPOC Woman.

Participants mostly referred to non-technological solutions, but some mentioned the use of technology to address the solutions. For example, PT02 proposed using technology for patient advocacy:

“I think it would be useful in the doctor's office if there was a robot that could be like 'wait, doctor, let the patient talk' because I feel like doctors are always in a rush” – PT02, BIPOC Woman.

2. Good experiences with healthcare

When talking about negative experiences with providers, most participants organically compared those experiences with good experiences they had with other providers. For BIPOC patients, good experiences were the ones when the provider did not doubt their symptoms. For LGBTQ+ patients, good experiences happened when the provider validated their identity and did not make assumptions about them or their partner. For both groups, good experiences were when the provider treated them with respect, carefully listened, took their needs into consideration, gave a thorough explanation of the diagnosis and treatment, genuinely worked in rapport building, and were noticeably interested in reducing the power differences (e.g., sitting at the patients’ eye level, looked them in the eyes). For example, PT22 describe feeling respected by the provider:

“I think it was that my first doctor, he respected that I wouldn't have been there if I hadn't done a ton of research, and he also respected the fact that I had been working in the medical field for 11 years. That I wasn't just an internet researcher. So, he wasn't wasting time trying to dumb things down, and he explained what needed to happen and why it needed to happen” – PT22, LGBTQ Transgender Woman

PT16 describes feeling a warm welcome from a provider:

“He spent time with us, like he wanted to know what I was doing for my well-being, and I talked to him about my arthritis and using CBD, and I went there for my lungs (laugh). And that was a cool experience. And my daughter had just turned 18, so we were in separate rooms, and he was 'if you guys are cool with it, we can sit together.' It was really warm, and this is a walk-in clinic.” – PT16, BIPOC Woman

Discussion

As a critical first step to inform design of automated technology to identify how biases operate in patient provider clinical interactions, we interviewed 25 BIPOC and/or LGBTQ+ participants about biased healthcare experiences. We found eight themes related to the experiences and two themes about the strategies to mitigate bias in the future. Experience themes were Transactional Care, Power Inequity, Communication Casualties, Bias-Embedded Medicine, System-level problems, Bigotry in Disguise, Fight or Flight, and The Aftermath. We presented a visual representation on the interconnections among the eight experience themes. Strategy themes were Solutions and Good Experiences. The ten themes presented in this study contribute to the understanding of biased healthcare experiences from the perspective of BIPOC and LGBTQ+ patients. Although prior research examines impacts of implicit bias on healthcare (1)(3)(4) we are contributing to filling the gap that exists surrounding how to apply the perspectives of BIPOC and LGBTQ+ patients on biased healthcare experiences and gathers their ideas for designing informatics solutions. Health informatics researchers and practitioners can leverage our findings to inform the development of technological innovations that improve the quality of patient-provider interaction by addressing implicit bias.

The experiences we heard from both groups support prior work related to not being heard22 and being dismissed by providers.23 BIPOC participants experiences related to racial discrimination in healthcare,24 measurements of
perceived racial/ethnic discrimination, its impact on health and well-being, physical and mental health outcomes, the perpetuation of health inequities, and its impact to patient-provider communication. Experiences from LGBTQ+ participants are consistent with literature reporting poor quality of care due to discrimination based on sexual orientation or gender identity, lack of provider knowledge about LGBTQ+ health care needs, and a preference towards heterosexual patients. We corroborated that institutional racism and homo-/transphobia remain problems in healthcare. Themes related to the patients’ response and consequences from a biased interaction, support prior work about medical mistrust originating from perceived discrimination experiences. This understanding of the “Fight or Flight” and “The Aftermath” themes can inform a better healthcare service design for improving patients’ experiences in the healthcare system. These themes and their interconnection allowed us to understand how BIPOC and LGBTQ+ patients experience biases in healthcare, our RQ1.

The “Good Experiences” that participants shared demonstrated that some healthcare providers may have noted these problems and contributed to enhancing the experiences of patients from marginalized groups. Simple non-technical solutions might go a long way to help patients feel validated and cared for, such as a questionnaire for the patient to fill out their sexual orientation and gender identity. Thus, health informatics researchers and practitioners can leverage simple and familiar technologies (e.g., electronic questionnaires) to improve patient-provider interactions. Solutions that aim to enhance providers’ training reflect the need for medical education curriculum with a strong, fully integrated, culturally competent component and content on the medical needs of the BIPOC and LGBTQ+ community. Diversifying the healthcare workforce is another priority in the quest for more equitable care and strategic use of technology in healthcare to achieve health equity (i.e., “TechQuity”). The themes we identified allow us to understand how BIPOC and LGBTQ+ patients want to improve healthcare experiences, which provides critical guidance for all of these potential solutions.

This study has a number of limitations and strengths. One significant limitation is sampling bias. Due to COVID-19 restrictions, we were only able to recruit through virtual means which skewed our sample to be younger and college educated, and potentially socioeconomically advantaged. Our sample was likely limited due to the technological requirements for participating in the interview (e.g., device compatible with Zoom software with a microphone, stable internet connection), which could have prevented people with non-technical backgrounds from participating. Another limitation is recall bias, which could have impacted the experiences the participants reported. Our use of recently minted terminology such as “BIPOC” could also have had an impact on the age of participants because this term may have been more familiar to younger people. Finally, we only interviewed three participants who were LGBTQ+ only, which limits the transferability of findings for this population. However, we captured perspectives from ten participants who were both BIPOC and LGBTQ+, which offered important insights on intersectional experiences.

We demonstrate that there is an opportunity for the biomedical informatics community to establish a more collaborative environment between patients and informaticians for solutions on how to improve the patient-provider interaction, provide better patient-centered care, and incorporate marginalized patients’ needs. Patients’ perspectives about biased healthcare experiences have laid the groundwork for using these patient reported themes in a range of future work to promote TechQuity. In particular, we are using findings to inform co-design work with patients and providers inform automated assessment tools that raise awareness of hidden bias in patient-provider communication. Future work should also examine experiences of intersectional individuals in greater depth and how this intersectionality can be represented and incorporated into technological solutions.

Conclusion

We interviewed 25 BIPOC and/or LGBTQ+ participants who described biased healthcare experiences when visiting a healthcare provider. Through qualitative thematic analysis, we describe ten themes that describe their experiences and suggested solutions to mitigate those experiences in the future. Characterizing these themes and their interconnections lays a foundation for understanding lived experiences of patients from marginalized groups that can critically guide the design of informatics solutions to mitigate those biases, improve the quality of patient-provider interactions, and ultimately promote health equity.

Unpacking the Drop in COVID-19 Case Fatality Rates:
A Study of National and Florida Line-Level Data

Carnegie Mellon University, Pittsburgh, PA, USA

Abstract  Since the COVID-19 pandemic began, the United States’s case fatality rate (CFR) has plummeted. Using national and Florida data, we unpack the drop in CFR between April and December 2020, accounting for such confounders as expanded testing, age distribution shift, and detection-to-death lags. Guided by the insight that treatment improvements in this period should correspond to decreases in hospitalization fatality rate (HFR), and using a block-bootstrapping procedure to quantify uncertainty, we find that although treatment improvements do not follow the same trajectory in Florida and nationally (with Florida undergoing a comparatively severe second peak), by December, significant improvements are observed both in Florida and nationally (at least 17% and 55% respectively). These estimates paint a more realistic picture of improvements than the drop in aggregate CFR (70.8%–91.1%). We publish a website where users can apply our analyses to selected demographics, regions, and dates of interest.

Introduction
Over the past year, the coronavirus (COVID-19) pandemic has continually evolved, with disease outbreaks expanding and contracting; lockdown measures tightening and loosening; testing capacity (mostly) increasing; and treatments protocols evolving. Decision-makers trying to maintain a grasp of the rapidly unfolding situation face a few key questions (among others): Have new treatment protocols improved outcomes over time? Is COVID-19 fatality decreasing? How does the actual infection rate compare to at previous dates? To what extent are rising case counts artifacts of expanded testing?

The most widely reported statistics for monitoring the pandemic are confirmed cases and deaths. At first glance, the two appear to tell divergent stories about the trajectory of the pandemic over time. Confirmed cases peak for the first time in April (with a 7-day average of nearly 32,000 daily cases), peak again with more than twice as many cases in a second wave in July (nearly 67,000), and yet again in a much larger third wave in December (nearly 230,000) (Figure 1, left panel). However, reported deaths appear to tell a contradictory story concerning the relative severity of the three waves (Figure 1, middle panel). Dividing deaths by cases, we observe that the reported case fatality rate has fallen dramatically after the first wave, from nearly 7.9% at the height of the first wave in mid-April to the 0.7%–2.3% range since July. (Figure 1, right panel). There are several plausible explanations for this decline, each with significant policy implications. Thus far, academic and public discourse has centered around the following hypotheses:

(H1) The age distribution of infected patients has shifted, altering the CFR due to the higher risk among the elderly.1–4
(H2) Increases in testing capacity have driven down the CFR due to a rising number of tests catching milder cases.5–7
(H3) Apparent shifts in case fatality rate, are artifacts due to the delay between detection and fatality.1,7,8
(H4) Treatment has improved as doctors grow more experienced and new therapeutics become available.3,9–12
(H5) The disease itself is mutating, leading to changes in the actual infection fatality rate over time.5,13
(H6) Social distancing has reduced the viral load that individuals are exposed to, resulting in milder infections.13–15

Note that H1–H3 can be misleading if not sufficiently accounted for. Due to Simpson’s paradox, since there are large differences in fatality between different age groups, if the age distribution shifts (H1) we could easily observe an overall decrease in CFR despite increasing CFRs in every age group (or vice versa). Additionally, testing ramp-up (H2) and delays between detection and fatality (H3) can cause the behavior of case fatality rate to diverge substantially from the behavior of the true infection fatality rate. Thus, CFR can be a poor proxy for actual infection fatality rate (IFR).

On the other hand, the last three phenomena—improved treatments, disease mutation, and changing viral load—correspond to actual reductions in mortality and could be grounds for policy changes. This work demonstrates how

*Equal contribution.
While these clinical trials have evaluated the effects of specific treatments in their identified target populations, our work studies the broader impacts of treatment improvements over time at a larger national scale. As far as we are aware, this is the largest national-scale (588,126 hospitalizations, 10.3 million cases) data-driven visualization, and analytical code pipeline for both the CDC and Florida COVID-19 line-level public datasets.

In particular, we argue that complete and accurate age-stratified, line-level hospitalization data is pivotal for distinguishing true improvements from artifacts. Hospitalizations should be less influenced by testing capacity than confirmed cases, and less influenced by treatment efficacy than deaths. While there may have been changes in admitting criteria at the very worst moments, for example, when New York hospital demand exceeded capacity in late March, for the most part, criteria for inpatient hospitalization is relatively consistent across time periods. Additionally, in the study time period (April 1st to December 1st), treatment improvements mostly targeted hospitalized COVID-19 patients.

Importantly, this analysis yields several important observations: (i) large increases in testing do occur between the waves but do not explain them away; (ii) since age distributions shifted substantially between the first and second waves, age must be accounted for in order to separate out the effects of treatment from age shift; (iii) between the first and second waves age-stratified HFRs improved substantially in the national data (with HFR decreasing by as little as 27% in the 80+ age group and as much as 37% in the 30-39 age group), but were relatively unchanged in Florida (with a slight increase in HFR by as little as 2.9% in the 80+ age group and as much as 13% in the 60-69 age group); (iv) by December 1st, both Florida and national data suggest significant decreases in HFR since April 1st—at least 17% in Florida and at least 55% nationally in every age group; and (v) comprehensive age-stratified hospitalization data is of central importance to providing situational awareness during the COVID-19 pandemic.

As far as we are aware, this is the largest national-scale (588,126 hospitalizations, 10.3 million cases) data-driven analysis to quantify and account for all three artifacts (age distribution shift, increased testing, and detection-to-fatality delay) when estimating treatment improvements. To allow users to apply our analyses to time ranges, states, and demographics of interest, we publicly release an interactive web application. Finally, we release a full pre-processing, visualization, and analytical code pipeline for both the CDC and Florida COVID-19 line-level public datasets.

Related Work
Several COVID-19 treatments were developed over the study time range (April 1st to December 1st), and each underwent randomized controlled trials testing for its individual efficacy. Dexamethosone resulted in a lower 28-day mortality when estimating treatment improvements. To allow users to apply our analyses to time ranges, states, and demographics of interest, we publicly release an interactive web application. Finally, we release a full pre-processing, visualization, and analytical code pipeline for both the CDC and Florida COVID-19 line-level public datasets.
To get a holistic sense of improvements over time several studies have examined CFRs. In a study of 53 countries, all but ten were found to have lower CFRs in the second wave compared to the first. However, as delineated in our introduction, confounding factors such as shifting age distribution (H1), testing capacity (H2), and detection-to-death lags (H3) can lead to misleading interpretations of the CFR. For example, when comparing CFR by age group in Italy and China, Onder et. al. suggested variation in testing strategies as a possible explanation for discrepancies. In study of COVID-19 cases in Germany, an apparent discrepancy between cases and deaths was attributed to shifting age distribution, testing capacity, or true effectiveness of government-issued directives. While these country-level studies identify the three “artifacts” (H1-H3) as limitations of interpreting the CFR, none explicitly account for them.

To account for changes in testing capacity, we examine hospitalization data. While (as far as we are aware) no nation-wide studies in the U.S. account for all three artifacts, some hospital systems have controlled for them by conducting age-stratified cohort studies. Among 5,121 hospitalized COVID-19 patients in a single New York health system, Horwitz et. al. demonstrated that after adjusting for age, sex, ethnicity, and other clinical factors, HFR between March 1st and June 20th decreased but not as much as observed before adjusting for these factors. In another New York hospital system, Mehta et. al. demonstrated that cancer and older age were associated with increased risk of case fatality, finding no significant associations between race and mortality or gender and mortality. In a study conducted among 21,082 COVID-19 patients admitted to 108 English critical care units between March 1st and June 27th, mortality risk in mid-April and May was found markedly lower than earlier in the pandemic even after adjusting for age, sex, ethnicity, comorbidities, and geographic region. While these studies provide thorough estimates of mortality for their respective regions during their specific time periods, we analyze data over a longer time range and larger scale (588,126 hospitalizations, 10.3 million cases) that purportedly captures all of Florida and most of the United States.

Our data does not contain information about viral mutations and viral loads (H5 and H6). However, a few studies have begun to investigate their impact. The B.1.1.7 and B.1.351 variants of COVID-19 were first reported in the U.S. at the end of December 2020 and January 2021, respectively. While it is unclear how these variants will ultimately impact HFRs, recent studies indicate that vaccines may be more effective against the B.1.1.7 variant than the B.1.351 variant. Regarding social distancing precautions reducing viral load, in a study across seven countries, declining CFR was found to be correlated with strict lockdown policies and widespread PCR testing. At a hospital system in northern Italy, Piubelli et. al. found that among patients diagnosed with COVID-19 in their emergency room, the proportion of patients requiring intensive care decreased over time, also having lower viral load. Our analysis does not attempt to separate out the effects of viral mutations (H5) and changing viral loads (H6), but we note that these are factors that can affect the true infection fatality rate, and therefore can be reflected in our estimates as well.

Methodologically, prior studies on the COVID-19 fatality have employed logistic regression, Cox proportional hazards, and propensity matching to adjust for age and other comorbidities. While logistic regression and propensity matching can quantify risk of death averaged over their study time period, we are interested in the evolution of fatality risk over time. While the standard Cox proportional hazards does model risk over time, it assumes a simple linear form between the covariates and the log hazard. Without making this assumption, we leverage techniques in time series literature to reduce noise in the raw signal, and compute uncertainty around the estimates at any given time. Assuming smoothness in the true underlying trend, the moving average can obtain a better estimate of the trend than the raw signal. To quantify uncertainty in time series, the moving block bootstrap technique was developed in lieu of standard bootstrapping targeting independent and identically distributed observations. In this technique, the time series is chunked into blocks to reduce dependence among them. This reduced dependence is hard to ensure, however, thereby suggesting a strategy between model-based and block resampling. To reduce much of the dependence between original observations, one can “pre-whiten” the data by fitting a model to the data, and computing the residuals. Instead of block resampling the original dependent series, the residuals can be resampled, and added back to the model estimates. This intermediate solution, termed post-blackening, has been shown to work more consistently in practice.

Materials and Methods

Data Description We center our analysis on (1) state-level COVID-19 Case Line Data made available by the Florida Department of Health (FDOH) and (2) national-level COVID-19 Case Surveillance Data made available by the United States Centers for Disease Control and Prevention (CDC). Both datasets are line-level, including date of detection, demographics (including age and gender), and indicators of eventual outcomes for each case (Table 1). In our defined
cohorts, all COVID-19 cases are confirmed with a positive PCR lab result. Each FDOH case is marked with the date it was confirmed, and each CDC case is marked with the date it was reported. Overall, there are 1,004,818 confirmed cases in the FDOH data, and 10,332,725 in the CDC data.

Signal Smoothing To smooth out daily fluctuations in data reporting, for each date, we compute the 7-day lagged averages for COVID-19 cases, hospitalizations, and deaths. From this point onward, any discussion of these quantities or fatality rates based on them, unless otherwise stated, refers to the smoothed signal. Thus, in both FDOH and CDC data, we collect data extending back to March 26th in order to analyze the April 1st to December 1st time range.

Separating Artifacts from True Improvements. We argue that three main phenomena fuel an “artificial” decrease in CFR: increased testing capacity (H1), shifting age distributions (H2), and delays between detection and fatality (H3).

Since testing (H1) is not included in the FDOH or CDC data, we pull in data from The COVID Tracking Project to quantify increased testing capacity in Florida and nationally. We plot 7-day lagged averages of tests administered and the positive test rates. To avoid artifacts from increased testing, we examine changes in HFRs rather than CFRs.

To establish and account for shifting age distributions (H2), we examine cases, hospitalizations, and deaths stratified by age groups: 0-9, 10-19, 20-29, 30-39, 40-49, 50-59, 60-69, 70-79, and 80+. Naturally, age stratification reduces the amount of data for each estimate, so we omit HFR estimates that are based on fewer than two deaths.

Finally, to account for delays between detection and fatality (H3), we take advantage of the line-level nature of the data in order to perform a cohort-based analysis. For each date, we extract the cohort of individuals confirmed positive on that date, as well as whether those individuals eventually died or were hospitalized. By contrast, publicly reported case fatality rates are typically not cohort-based—the patients whose deaths are reported in the numerator are not in general the same patients whose confirmed infections show up in the denominator. Because case confirmation tends to precede reported deaths, these signals tend to be misaligned and are subject to fluctuation, even if the actual case fatality rate were fixed (so long as incidence does change). Line-level data enables us to circumvent this problem.

Taking the above three adjustments into account, our primary quantity of interest for treatment improvements is the age-stratified HFR. For the rest of the paper, we define CFR and HFR at day \( t \) as follows:

\[
\text{CFR}_t = \frac{\text{cases at day } t \text{ that eventually die}}{\text{cases at day } t}, \quad \text{HFR}_t = \frac{\text{cases at day } t \text{ that eventually get hospitalized and die}}{\text{cases at day } t \text{ that eventually get hospitalized}}
\]

Quantifying True Improvements Thus far, news and academic sources have highlighted three main “true improvements”: improvements in treatment (H4), disease mutations (H5), and reduced viral loads due to social distancing (H6). We seek to quantify treatment improvements (H4) by computing the drop in HFR.
Estimation using Block-Bootstrap and Cubic Splines. We use a cubic spline to fit the trend of the 7-day lagged average HFRs, and use a moving block-bootstrapping technique with post-blackening to estimate uncertainty around this trend. As described in the related work, 7-day lagged averages provide better estimate of trend by assuming smoothness rather than a specific functional form. Block-bootstrapping with post-blackening enables us to estimate uncertainty around this trend, with a weaker assumption than the standard i.i.d. assumption. We use a 7-day block size, based on the length of the time series and our observations that reporting follows a weekly cadence. After block-bootstrap resampling the residuals, the residuals are added back to the cubic spline, creating the replicates needed for estimating HFR with uncertainty. A visual walkthrough of this procedure is in the “HFR estimation” section of our web tool.

Visualization Tool. We publish an interactive web tool, available at acmilab.org/unpack_cfr, for dynamically applying our analyses to any demographic or date range of interest. On both FDOH data and CDC data, it displays plots for aggregate and age-stratified cases, hospitalizations, and deaths over time (Figure 3); plots for age distributions of cases, hospitalizations, and deaths over time (Figure 5); and estimates of age-stratified HFR as well as the change between two user-provided dates (Table 2 and 3). The user can select gender, race/ethnicity, and state to form cohorts of interest. For HFR estimates, the user can use a date selector to obtain new estimates for their date range of interest.

Results

Cases, Hospitalizations, and Deaths
In both the FDOH and the CDC data, one can discern three waves of COVID-19 cases. The first wave peaks in mid-April, the second wave peaks in mid-July, and cases leading up to December indicate a third wave (Figure 3).

Increased Testing. Between April 1st and December 1st, testing increases significantly, by approximately 964% in Florida and 1080% nationally (Figure 2). Florida observes a spike in testing near the second peak, whereas national testing rises more smoothly. We note that although peaks in Florida testing (Figure 2, left) coincide with spikes in Florida cases (Figure 3a, left), these spikes in cases cannot be entirely attributed to increased testing because there are also rises in positive test rates in April, July, and December (Figure 2, right).

Cases. Across all age strata, as measured by cases, Florida’s second wave is the most severe (Figure 3a, left) out of the three waves. In aggregate, it has approximately 1153% more cases than in the first peak and 46% more cases than in the ongoing third wave (Figure 3a, left). In contrast, nationally the third wave has substantially more cases than the first two peaks—392% more than the first peak and 150% more than the second peak (Figure 3b, left). Also, note that the relative jump in cases between the first two peaks is 96%, much less than the 1153% jump seen in Florida. This could be due to a combination of the spike in Florida’s testing in the second peak, as well as variation in the trajectories of different states (e.g. the populous state of New York was particularly hard-hit in the first wave).

Hospitalizations and Deaths. Overall, hospitalizations and deaths corroborate the story told by positive test rate (Figure 3a, center and right). In Florida, hospitalizations and deaths indicate a more severe second peak than first peak, though the contrast in peak size is not as dramatic as in the plot of cases. By contrast, in the national data, the second peak is smaller than the first. Much of the discrepancies of trends seen in cases versus in hospitalizations and deaths are likely attributable to increases in testing (Figure 2). Towards the third wave in December, Florida hospitalizations and deaths are at similar levels to that of the first wave. Nationally, the third wave appears to be worse than the second.

![Figure 2: COVID-19 positive test rates (right) and tests (left and middle) for Florida and the United States, calculated using 7-day trailing averages and pulled from the COVID Tracking Project. Positive test rate is calculated by dividing new positives by total new tests on each day. Data outside the April 1st to December 1st time range considered in this study is grayed out.](image-url)
Figure 3: Age-stratified cases, (eventual) deaths, and (eventual) hospitalizations in Florida and in the U.S., by the date of first positive test result (Florida) and date of report to the CDC (U.S.). Note that the x axis is not the date of death or date of hospitalization.

Figure 4: Aggregate case fatality rate (left) and hospitalization fatality rate (right) in Florida and in the U.S., by the date of first positive test result (Florida) or date of report to the CDC (U.S.).

Aggregate Fatality Rates. As expected, aggregate CFRs are lower than aggregate HFRs both in Florida and nationally (Figure 4). Unlike the national CFR which primarily decreases across the time range, the Florida HFR oscillates and reaches similar levels in both April and July. A deeper analysis of age-stratified fatality follows in later sections.

Confounding Due to Demographic Shift

Age. Between the first two peaks, the age distribution of cases shifts substantially, with the median age in Florida falling from 51 to 40, and the median national age group, from 50-59 to 30-39. After the second peak, the age distributions continue to fluctuate. In September, younger cases increase, possibly related to the start of the school year (Figure 5, left). By December 1st, the Florida median age remains at 40 but the national median age group rises to 40-49. Older individuals comprise a disproportionate share of hospitalization and death counts (Figure 5, middle and right).

Gender. The gender ratios in each age group’s cases, hospitalizations, and deaths appear relatively flat over time. Thus, in this paper we choose not to stratify by gender due to the reasonably small shift in the gender distribution over time, and practically to have more support in each group. However, we do provide this option in our web tool.

Age-stratified HFR

Consistent with prior literature, we find that as the age group increases so does the corresponding HFR (Tables 2 and 3). Measuring treatment improvements by HFR drop (computed as $\frac{HFR_{new} - HFR_{old}}{HFR_{old}}$), we observe larger treatment
Figure 5: Age distributions among Florida and national cases, (eventual) hospitalizations, and (eventual) deaths, by the date of first positive test result (Florida) and date of report to the CDC (U.S.), respectively.

Table 2: Estimates of HFR and drop in HFR on peak dates. Median and 95% confidence intervals are computed using block bootstrapping. Results with inadequate support are omitted.

improvements between April and December to be correlated with younger age (Table 3). Note, however, that the younger groups have small HFRs to begin with, so the opposite trend might appear when considering absolute rather than relative improvements. Additionally, the confidence intervals for HFR drops are wider for younger age groups.

Between the first two peaks (Table 2), the national age-stratified HFR estimates from block bootstrapping decrease by as little as 27% in the 80+ age group, and as much as 37% in the 30-39 age group. On the other hand, in Florida the age-stratified HFR actually increases in each age group by as little as 2.9% in the 80+ age group, and as much as 13% in the 60-69 age group. Note that the HFR changes between peak dates in Florida are an example of Simpson’s paradox, where in each age group the HFR increase, but the aggregate HFR actually decreases by 2.3%.

Compared to peak-to-peak changes, across the entire time range (Table 3) we observe a more dramatic decrease in HFR. In Florida, the HFR drops by as little as 17% in the 80+ age range, and as much as 42% in the 60-69 age range. Nationally, the HFR drops by as little as 55% in the 80+ age groups, and as much as 73% in the 20-29 age group.

While this paper presents estimates at the two peaks and the endpoints of the study time range, we can easily read off similar estimates with uncertainty for all dates between April 1st and December 1st. This type of interactive functionality is available in our web tool. In our web tool, when stratifying by gender in addition to age, the conclusions surrounding drops in HFR are similar to those when just stratifying by age.
Table 3: Estimates of HFR and drop in HFR between April 1st and December 1st. Median and 95% confidence intervals are computed using block bootstrapping. Results with inadequate support are omitted.

Discussion

We unpack the drop in CFR to quantify improvements reasonably attributable to advances in treatment, accounting for shifting age distributions (H1) by age-stratifying, increased testing capacity (H2) by focusing on the hospitalized, and the detection-to-fatality delay (H3) by conducting a cohort-based analysis. We find that increased testing does not explain away the three waves due to corresponding peaks in hospitalizations, deaths, and positive test rates. We visualize the shifting age distributions, and quantify the decrease in age-stratified HFRs between the first two peaks and across the entire study time range. Combining all these analyses, we arrive at the following narrative:

At the beginning of April, testing was relatively sparse (Figure 2). Cases, hospitalizations, and deaths were rising, and reached peak levels circa April 15th (Figure 3). Roughly one in every ten tests came back positive in Florida, and one in every five tests, nationally. In Florida, the aggregate HFR was approximately 23%, with age-stratified HFRs ranging between 9.2% for the 50-59 age group to 46% for the 80+ age group (Table 2). Nationally, the aggregate HFR was approximately 29%, with the age-stratified HFRs ranging between 21.1% for the 20-29 age group and 57% for the 80+ age group (Table 2). In each age group, the national HFR was higher than the Florida HFR, possibly due to overwhelmed hospital systems in states hit hard during the first wave. In fact, our web tool indicates that 34.5% of national CDC cases between April 1st and April 15th were recorded in New York alone.

Over the next three months, the proportion of younger individuals with COVID-19 grew steadily (Figure 5). Testing continued to rise nationally, and spiked in Florida as it approached a heavier second peak around July 15, with positive test rates also at an all-time high (Figure 2). Florida experienced record hospitalizations and deaths, and the age-stratified HFRs were at least as high as in the first wave (Table 2). While Bill Gates had publicly attributed “a factor-of-two improvement in hospital outcomes” to dexamethosone and remdesivir, this did not yet appear to be true in Florida. (Alternatively, treatment improvements might have been counterbalanced by strain on the hospital system.) On the other hand, cases in New York had diminished (shown in our web tool) and were starting to surge in other states, forming a smaller second peak nationally (as measured by hospitalizations and deaths). Between the first two peaks, the national HFR had dropped by 41% in aggregate, with age-stratified HFRs dropping as much as 37% in the 30-39 age group and as little as 27% in the 80+ age group. The different stories told here by Florida and the national aggregate data underscore the importance of state-level rather than national analysis.

Finally, come December 1st, a third wave is underway. Approximately 31% of all national cases since April were confirmed in the last month alone (Figure 3b). In terms of hospitalizations, deaths, and positive test rate, this third wave has already surpassed the second wave. For Florida, the third wave is already at least as severe as the first wave. Fortunately, age-stratified HFRs in both Florida and the national aggregate data appear to have dropped significantly since the start of the pandemic, likely indicating treatment improvements (though possibly confounded by H5 and H6). Since April 1st, the age-stratified HFR in Florida has decreased by as much as 42% in the 60-69 age group and as little as 17% in the 80+ age group. Nationally, the age-stratified HFR has decreased by as much as 73% in the 20-29 age group and as little as 55% in the 80+ group. Regarding the CFR, on July 27, former President Donald Trump stated in a press briefing that “Due to the medical advances we’ve already achieved and our increased knowledge in how to treat the virus, the mortality rate for patients over the age of 18 is 85 percent lower than it was in April.”

Note, however, that none of our estimates of treatment improvements are as large as the 85% touted by Trump. In summary, CFR can be misleading if age distribution shift, increased testing, and detection-to-death delay are unaccounted for.
Limitations

We aim to quantify treatment improvements (H4) in Florida and the U.S. by estimating changes in the age-stratified HFR, but H4 could also be influenced by disease mutation (H5) and changing viral loads (H6). To distinguish their effects in future work, we need additional data. Furthermore, while we listed the six hypotheses we found in literature review, possible alternative explanations may arise in the future as pandemic evolves.

We assume that treatment improvements will be reflected in the HFR because over our study’s time range, major treatment improvements (e.g., dexamethosone and remdesivir) targeted hospitalized patients. While the first U.S. vaccination was administered outside of our study time range, vaccines take effects before hospitalization, and so their treatment improvements may not be reflected in the HFR for future studies. While our method could still quantify post-hospitalization treatment improvements, we note that vaccination roll-out criteria (e.g. occupation, age) and other characteristics (e.g. socioeconomic background) could influence who gets hospitalized in the first place.

Other limitations arise from data quality issues. In both the FDOH and CDC data, hospitalization and death are highly missing (Table 1), possibly introducing bias in the HFR estimates if the data are not missing at random. States have different patterns when reporting data to the CDC (seen by filtering for any state in our web tool). The reported CDC cases appear to be incomplete. For instance, the CDC cases reported from Florida only account for 67% of the cases provided by the FDOH, they are reported sporadically even after smoothing, and no death is reported since October. Cross-referencing with the COVIDcast API, we find that in the CDC data reported from Texas, only 4.9% of the cases and 0.01% of the deaths are accounted for, and only 14 hospitalizations were recorded. Thus, in our national analysis, we are making the assumption that in aggregate the signal will outweigh the noise. Despite the data limitations, the CDC data appears to be the best available source of line-level cases needed for cohort-based analysis across the United States. We note that in the Florida FDOH data, on the other hand, we use the positive test confirmed date which is not missing at all in this data, making the Florida HFR estimates more reliable than those from the national data.

Transitions of Care: Completeness of the Interoperability Data Standard for Communication from Home Health Care to Primary Care

Edgar Chou, MD, MBA, FACP\textsuperscript{1}; Paulina S. Sockelow, DrPH, MS, MBA\textsuperscript{2}
\textsuperscript{1} Thomas Jefferson University, Philadelphia, PA; \textsuperscript{2} Drexel University, Philadelphia, PA

Abstract

Data sharing is necessary to address communication deficits along the transitions of care among community settings. Evidence-based practice supports home healthcare (HHC) patients to see their primary care team within the first two weeks of hospital discharge to reduce rehospitalization risk. A small subset of patient data collected at HHC admission is mandated to be transmitted to primary care, predominantly by fax. Using qualitative analysis, we assessed completeness of the United States Core Data for Interoperability (USCDI) interoperability standard, as compared to the patient data collected by the primary care team (topics) and HHC (classes) during the initial visit; and offer interoperability recommendations. Findings indicate the USCDI does not cover 74\% of the 19 faxed HHC classes that mapped to the primary care topics, and 95\% of the 38 not-faxed HHC classes. We offer USCDI recommendations to address these interoperability gaps.

Keywords: communication, home health care nursing, home health nursing, primary health care, continuity of patient care/standards, transition of care, nursing informatics, documentation

Introduction

Data sharing across transitions of care is necessary to address fragmented care delivery along the health care continuum. Much of the patient care is provided in community settings where, due to information silos and lack of interoperability, data communication deficits exist along the transition of care among community settings. These deficits are becoming more apparent as health care organizations move towards value-based care where hospitalizations and readmissions are key quality and cost drivers. To support data sharing, the United States Core Data for Interoperability (USCDI) replaces the Common Clinical Data Set (CCDS)\textsuperscript{1} as a data standard in transitions of care.\textsuperscript{2} USCDI support for data communication among community settings warrants investigation.

Home healthcare services (HHC)\textsuperscript{3} and a primary care team visit are transition-in-care components for over one million Medicare patients annually discharged from hospital to home. Evidence-based practice supports HHC patients seeing their primary care team within the first two weeks of hospital discharge\textsuperscript{4,5} which has been shown to reduce rehospitalization risk in patients with heart failure\textsuperscript{6} and sepsis.\textsuperscript{7} Accordingly, the Centers for Medicare and Medicaid (CMS) reimburses providers for a patient office visit within 14 days of hospital discharge, the Transition of Care (TOC) visit.\textsuperscript{8} Patients with medical and/or psychosocial problems requiring at least moderate medical decision-making receive services\textsuperscript{9} which results in lower mortality and cost of care.\textsuperscript{8} Evidence and CMS regulations highlight TOC visit importance. Left unsaid are the specifics of what information is needed for the TOC visit – for medical decision-making and prospective analysis e.g., re-hospitalization risk.

A rich set of information relevant to TOC clinical decision-making is collected during the HHC visit as structured data yet little of this data is transmitted to the primary care team. During the first (admission) visit HHC clinicians conduct medication reconciliation, assessment, and documentation of patient cognitive and functional capabilities and patient safety in the CMS Outcome and Assessment Information Set (OASIS\textsuperscript{10}). To finalize the admission, a minimal OASIS data subset is faxed to the primary care physician to request clinician order sign-off for HHC reimbursement. The faxed form (the ‘485’) is difficult to interpret due to the paucity of structured data, preponderance of narrative text, and asynchronicity of receipt in relation to the TOC patient visit. The brevity of the typically 20-minute TOC visit limits the information physicians can gather as they address acute and chronic illnesses. Yet important information is in the OASIS. For example, a recent literature review identified OASIS data that predicts re-hospitalization risk.\textsuperscript{11} Another example is HHC identifies a patient living with cognitive deficits which affect medication ingestion. This information could inform the primary care team of the need for additional resources to ensure the patient’s safe pill consumption. This communication occurs verbally, if at all: No formatted or structured documentation of this information, paper or electronic, reaches the physician office.

Lack of HHC and primary care EHR interoperability promulgates information siloes. The result is potential missed clinical opportunities (not having information in the right place at the right time) and lack of data for research such as re-hospitalization risk predictive analytics. Data flow deficits between HHC and primary care can impact patient
outcomes, and hospital and practice CMS reimbursement. The USCDI may address the needed interoperability from HHC to primary care. We undertook an investigation of USCDI completeness as compared to HHC patient information (a) currently communicated to primary care through the 485 form and mapped to the TOC; and (b) which could be communicated from OASIS for the TOC visit. From this analysis we seek to provide HHC-to-primary care interoperability recommendations.

Methods

The authors conducted deductive qualitative analysis to meet the objectives in two steps. First, they assessed the extent to which HHC patient data currently communicated on the 485 provides the information needed for the TOC, and the completeness of the USCDI relative to the 485 data that mapped to the TOC. Second, they mapped OASIS data not communicated on the 485 to the TOC, and assessed completeness of the USCDI relative to the OASIS data that mapped to the TOC. The current version of OASIS, Version D, was used in the analysis. The authors’ perspective was that of a primary care physician knowledgeable about HHC OASIS data who was considering the HHC information the primary care team might need. The perspective was not that of a physician more narrowly interpreting the TOC topics as it is currently implemented. An example of the former is medication self-administration issues, and example of the latter is medication list. The chosen perspective was selected to provide insight into the potential value of HHC data to the primary care team.

Completeness of USCDI coverage of 485 data mapped to the TOC

In the absence of a CMS TOC document, we used a primary care medical society TOC. It contained information descriptions (referred herein as topics) and lacked structured data fields. This analysis focused on TOC activities or decisions which require data (e.g., Obtain and Review Discharge Information). TOC topics could be interpreted as having some overlap, for example, implying review of the same data (e.g., Obtain and Review Discharge Information, and Review Need for Follow-up on Pending Testing or Treatment both include review of clinical status). The TOC contained 9 clinical information topics distributed among 3 domains as follows. The four clinical status topics were:

- Obtain and Review Discharge Information
- Review Need for Follow-up on Pending Testing or Treatment
- Interact with Other Clinicians who will Assume or Resume Care of the Patient’s System-specific Conditions
- Establish or Re-establish Referrals for Specialized Care

The two functional status topics were:

- Educate the Patient and/or Caregiver to Support Self Management, and Activities of Daily Living (ADL)
- Provide Assessment and Support for Treatment Adherence and Medication Management

The three service needs topics were:

- Identify Available Community and Health Resources
- Facilitate Access to Services Needed by the Patient and/or Caregivers
- Assist in Scheduling Follow-up with Other Health Services

The topic, Communicate with Agencies and Community Services Used by the Beneficiary, was excluded from the analysis as it is not currently interpreted as referring to 485 information due to the asynchronicity.

The 485 communicates 19 specified structured and unstructured data (classes). Information sources are 13 OASIS classes for the structured data, and unstructured, non-OASIS EHR data for 10 classes. Some 485 classes have multiple OASIS classes as data sources. The classes are in 3 domains: clinical status, functional status, and safety. The thirteen 485 clinical status classes include 9 OASIS-sourced classes (i.e., Primary Diagnosis/Other Diagnoses [3 questions], Cognitive, Behavioral and Psychiatric Symptoms [4 questions], Living Arrangements [1 question], Hospitalization Risk [1 question]) and 5 EHR-sourced classes (i.e., Orders for Discipline and Treatments, Prognosis, Medications List, Allergies, Nutritional Requirements). The 5 functional status classes include 4 OASIS-sourced classes (i.e., Goals/Rehabilitation Potential/Discharge Plans) and 4 EHR-sourced classes (i.e., Mental Status, Functional Limitations, Activities Permitted, Durable Medical Equipment [DME] and Supplies). Note that Goals are not specified as to whether patient or clinician goal. The single safety class was from EHR data (i.e., Safety Measures).

The USCDI contains standards at incremental levels of adoption: Version 1, Draft Version 2, Level 2, Level 1 and Comments. Version 2 is the focus of this analysis as it is the most current proposed standard and incorporates Version 1 which has been adopted. Levels suggest data elements that are in discussion to be incorporated in subsequent
versions. Comments contain data elements that have adoption hurdles, including insufficiently defined use cases and implementation or development burdens.\textsuperscript{13} Excluded from the analysis, but of note, Comments includes functional class (e.g., Mental, Mobility, Self Care, and Instrumental ADL [IADL]). The USCDI contains data classes and elements. Elements which were qualifiers for classes (e.g., dosage as a qualifier for medication) were excluded from the analysis. Referring to ONC documentation,\textsuperscript{13} the authors reviewed classes to identify those relevant to HHC and TOC patient information. Excluded USCDI classes were: Provenance, Implantable Device Identifier, and Patient Demographics. The retained USCDI classes were 14 structured classes, all in the clinical domain, including Medications List, Problems, Procedures, (Patient) Goals, and Care Team Member.

The authors independently extracted topics (TOC) and classes present on the 485 form and used an Excel spreadsheet (Microsoft Corporation, Redmond, WA) for organization. The authors compared their extractions and resolved differences. They decided to avoid redundant mapping due to overlapping TOC topics by mapping 485 data to the more closely mapped TOC topic. Drawing on the physician author’s clinical expertise and working collaboratively, the authors categorized the extracted topics and classes from each source into domains present on either source (i.e., clinical status, functional status, home safety) and classes within each domain (e.g., for clinical status: Medications List, Problems). For example, the domain clinical status included the following classes within the topic of medications from the designated sources: TOC- provide assessment and support for treatment adherence and medication management; 485- medications; USCDI- medications. The class/element hierarchy is consistent with that of the USCDI. The authors also characterized each class from each source as structured or unstructured.

The authors, in partnership, identified topics and classes that mapped or did not map between the TOC and the 485. The working description of mapping was if a class was included fully or partially in a topic. An example of a partial mapping is that discharge information includes many classes. Therefore, instead of a single class, many classes (e.g., medication issues, fall risk, ADLs) provide information to the TOC topic, Obtain and Review Discharge Information. Each 485 class was reviewed for mapping to one or more TOC topic which shared the underlying concept. For example, the 485 class ‘Medications List’ mapped to the TOC topic Obtain and Review Discharge Information which infers inclusion of problems, medications, and allergies. The analysis produced a list of topics and classes, each characterized as mapped or unmapped, and tagged with data source (TOC, 485), domain, and structured/unstructured.

Working together, the authors mapped the listed topics and classes to the USCDI. The mapping indicated completeness of the data standard relative to the TOC information and the currently faxed HHC information. Incompleteness of the standard indicated areas for development of USCDI transitions of care interoperability recommendations.

Completeness of USCDI coverage of OASIS data mapped to the TOC

The OASIS contains 68 questions related to the admission. The authors eliminated 16 demographic and insurance questions, and 1 question lacking clinical relevance (inpatient discharge date). Retained were 51 patient health classes (questions) to assess the patient in domains including clinical status, functional status, home safety, and service needs.\textsuperscript{10} All OASIS data is structured. Most question responses are categorical, typically with 3-to-6-point scales. The 34 clinical status classes include Medication Issues, body systems (including emotional and behavioral), and Hospitalization Risk. The 13 functional status classes include ADL/IADL, and Self Management. The 2 home safety classes are Living Arrangements (regarding presence of other people) and Falls Risk. The 2 service needs classes focus on care management related to supervision needed for safety.

Together the authors compared the 485 and OASIS classes, retaining classes unique to OASIS (non-unique classes were mapped above). The examination of retained classes followed the data collection and analysis process described above to identify classes that mapped (fully or partially) and did not map between the TOC and OASIS. For example, the OASIS class Medication Issues did not appear on the 485 and mapped to the TOC topic Obtain and Review Discharge Information. Mapping to the USCDI indicated completeness of the USCDI relative to HHC OASIS data available and not communicated to primary care, suggesting areas for USCDI recommendation development.

Results

The comparison of TOC topics, 485 classes, and USCDI classes is shown in Table 1. Results of the comparison are described below.

Completeness of USCDI coverage of 485 data mapped to the TOC

Comparison of TOC topics and 485 classes indicated all 19 of the 485 classes mapped to 6 TOC topics, and 3 TOC topics were unmapped. Nine 485 classes mapped to multiple TOC topics, and 4 TOC topics had multiple 485 classes which mapped to them. The nine 485 classes that mapped to multiple TOC topics were: Goals/Rehabilitation

297
Potential/Discharge Plans, Medications List, Hospitalization Risk, Living Arrangements, Orders for Discipline and Treatments, Functional Limitations, Activities Permitted, DME and Supplies, and Safety Measures. The 4 TOC topics with multiple 485 classes were: Obtain and Review Discharge Information (all 485 classes); Establish or Reestablish Referrals for Specialized Care (3 classes); Educate the Patient and/or Caregiver to Support Self Management and ADL (5 classes); and Identify Available Community and Health Resources (3 classes). Two TOC topics each had a single 485 class which mapped to it: Review Need for Follow-up on Pending Testing or Treatment, and Provide Assessment and Support for Treatment Adherence and Medication Management. The 3 unmapped TOC topics were: Interact with Other Clinicians who will Assume or Resume Care of the Patient’s System-specific Conditions, Assist in Scheduling Follow-up with Other Health Services, and Facilitate Access to Services Needed by the Patient and/or Caregivers.

Contrasting TOC topics and USCDI classes indicated all 14 USCDI classes mapped to 5 TOC topics, and 4 TOC topics were unmapped. Eight USCDI classes mapped to multiple TOC topics, and 3 TOC topics had multiple USCDI classes which mapped to them. The 8 USCDI classes that mapped to multiple TOC topics were: Clinical Notes, Medications List, Assessment and Plan of Treatment, Laboratory, Procedures, Diagnostic Imaging, Health Concerns, and (Patient) Goals. The 3 TOC topics with multiple USCDI classes were: Obtain and Review Discharge Information (all USCDI classes); Review Need for Follow-up on Pending Testing or Treatment (6 classes); and Establish or Reestablish Referrals for Specialized Care (6 classes). The two TOC topics with a single mapped USCDI class were: Provide Assessment and Support for Treatment Adherence and Medication Management; and Educate the Patient and/or Caregiver to Support Self-Management and ADL. The 4 unmapped TOC topics were: Interact with Other Clinicians who will Assume or Resume Care of the Patient’s System-specific Conditions, and all the service needs topics: Identify Available Community and Health Resources, Facilitate Access to Services Needed by the Patient and/or Caregivers, and Assist in Scheduling Follow-up with Other Health Services.

Looking across the TOC, 485, and USCDI mappings, the single TOC topic to which the 485 classes mapped, but remained unmapped by USCDI classes, was Identify Available Community and Health Resources. While all the 485 classes mapped to the TOC, only 5 of 19 classes (26%) mapped to the USCDI. Four of these five 485 classes directly overlapped with the USCDI classes of Goals, Problems, Medications List, and Allergies. The 485 class Goals/Rehabilitation Potential/Discharge Plans provided additional data beyond the USCDI class Goals. Fourteen 485 classes did not map to the USCDI: 13 were structured and 1 was unstructured (Orders for Discipline and Treatments). The structured classes spanned the clinical (9), functional (4), and safety (1) domains. The unstructured class was in the clinical domain.

Completeness of USCDI coverage of OASIS data mapped to the TOC

Examination of the OASIS and the 485 indicated that of the 51 OASIS classes, 13 (25%) mapped to the 485. The mapped classes were distributed in the following domains: clinical (8), functional (4) and safety (1).

Comparison of TOC topics and the remaining 38 OASIS classes indicated all remaining OASIS classes mapped to 6 TOC topics, and 3 TOC topics were unmapped. Nineteen OASIS classes (50% of remaining classes) mapped to multiple TOC topics, and four TOC topics had multiple OASIS classes which mapped to them. Herein we refer to related OASIS codes classes groupings, e.g., the 5 medication related classes are referred to as Medication Issues. The number of OASIS classes related to a grouping is noted in parentheses. The 8 groupings of the 19 OASIS classes that mapped to multiple TOC topics were: History and Physical (1 OASIS class); Home Therapies (1 class); ADL/IADLs (9 classes); Falls Risk (1 class); Medication Issues (5 classes); Care Management (1 class); and Therapy Need (1 class). The 5 TOC topics with multiple OASIS classes were: Obtain and Review Discharge Information (all OASIS classes); Establish or Re-establish Referrals for Specialized Care (4 classes); Educate the Patient and/or Caregiver to Support Self Management and ADL (9 classes); Provide Assessment and Support for Treatment Adherence and Medication Management (6 classes); and Identify Available Community and Health Resources (4 classes). One TOC topic had a single OASIS class which mapped to it: Review Need for Follow-up on Pending Testing or Treatment. The 3 TOC topics that were unmapped in the 485 analysis remained unmapped in the OASIS analysis.

Looking at the possible data flow of OASIS classes to the TOC through the USCDI indicated two findings. Of the 38 OASIS classes not on the 485, two (5%, i.e., History & Physical, Height & Weight) mapped to USCDI classes (i.e., Clinical Notes, Vital Signs). For example, the History & Physical class in OASIS is one component of the Clinical Notes class in the USCDI. In total, 42 OASIS classes (83% of all OASIS classes) did not map to USCDI. They spanned the clinical (29; 57% of all classes), functional (9; 18%), service needs (2; 4%) and safety (2; 4%) domains. All classes are structured.

**Discussion**

We examined transitions of care patient data needed in patient-centered primary care (TOC), available in home health care (OASIS) and communicated from HHC to primary care (485) to assess the completeness of the transitions of care.
data standard (USCDI). This analysis is operationally relevant: Conducting the TOC evaluation within the first two weeks of the HHC patient’s hospital discharge is a CMS requirement associated with reduced re-hospitalizations.\textsuperscript{8}

Findings indicate a deficit in the information needed for decision-making during the TOC visit. Data faxed from HHC did not map to three of the nine TOC topics. Furthermore, HHC data is unlikely to be available in the primary care TOC visit workflow. HHC information is not communicated electronically as structured data and can be sent days before and even after the TOC visit.

Our analysis also suggests a paucity of structured HHC patient data – likely to be informative to the primary care team – is currently communicated to primary care. Thirty-eight OASIS classes not currently faxed to primary care mapped to TOC topics. This result suggests the prescribed data flow from HHC to primary care (i.e., 485) could be enhanced with important information on topics including living arrangements, falls risk, and medication issues such as self-administration capability. In addition, OASIS has categorical assessment measures which could provide rich information for the primary care team, for example, types and degree of functional limitations. Future research would investigate whether communication of additional structured OASIS data for the TOC would be perceived as useful by the primary care team.

The finding that not all information on the TOC mapped to OASIS (e.g., Medications List) indicates OASIS data was a necessary but not sufficient data source for the TOC. This mismatch suggests an opportunity for future research in other standardized data sources which could provide structured data to the TOC.

The overlap of TOC and HHC patient information reveals opportunities for data sharing, especially in this era of value-based care. Furthermore, promoting interoperability is an aspect of CMS’s Value-Based Care program.\textsuperscript{14}

Comparison of the transitions of care interoperability standard (USCDI) with TOC and HHC patient data indicates the USCDI is incomplete in regards to inclusion of HHC information.

The standard maps either fully or partially to a minority (26\%) of HHC classes faxed to primary care. We recommend the USCDI be expanded to include all structured HHC data currently faxed to primary care. Accordingly, we suggest the USCDI, which specifies the Goals class as patient goals, include a class for clinician goals to align with the TOC and 485. We also propose that HHC agencies use the USCDI to electronically transmit data which is currently faxed. However, a barrier to HHC and primary care interoperability is that USCDI use is premised on Health Information Exchanges (HIE) participation, which is hampered by HHC technical and financial resource constraints.

The USCDI mapped either fully or partially to only 5\% of HHC classes captured in the OASIS and not faxed to primary care. Further studies are needed to understand the importance to primary care clinicians of HHC data that mapped to the TOC yet not currently contained in the USCDI. The importance of the HHC data may include informing about timely access to additional services, identification of additional resources that may aid in the care of the patient, or additional accommodations that may be needed given the current mental state of the individual. We recommend USCDI expansion to incorporate structured OASIS data not currently faxed and perceived as important by primary care.

Ingesting HHC information into primary care EHRs as standardized, structured data could enable presentation of the information in the TOC at the right time and allow application of data management tools thereby supporting clinician decision-making. Improved transition of care data interoperability could benefit patients in addressing their individual needs with this patient-centered approach, while benefiting health care organizations financially as they apply these approaches to mitigate hospitalizations and hospital readmissions. Improved transmission from HHC to primary care would enable data analytics: decision support, machine learning, and predictive modeling. These capabilities would support development of additional insights, further informing the data capture process, the interpretations generated from the system, and their subsequent presentation to the clinical care team in addressing patient outcomes. Future research is warranted to assess the feasibility of this recommendation, and the impact on primary care workflow and patient outcomes.

This study has limitations related to the information sources. The TOC guidance used in this analysis contained information topics which tend to be broader than data elements, requiring interpretation by the authors. Future work would incorporate in the analysis TOCs from diverse settings to improve specificity of TOC data elements. Similarly, the USCDI Version 2 contains data elements which are open to author interpretation. For example, Assessment and Plan of Treatment does not specify which discipline is the focus, a consideration as physician information content differs from that of nurses. Also, the 485 analysis was limited to structured HHC data and excluded narrative data. It is possible that the excluded text data could contain information needed for the TOC, as EHRs in HHC contain information in addition to that captured in the OASIS.\textsuperscript{15,16}
We illustrate the gaps in communication that can be addressed through interoperability. Current approaches in data analytics have been applied towards calculating hospital risk for individual patients. By incorporating this information into the primary care EHR, additional insights can be developed, further informing the data capture process, the interpretations generated from the system, and its subsequent presentation to the clinical care team in addressing patient outcomes.

Conclusions

The national move towards value-based care with hospitalizations and readmissions as key quality and cost drivers underscores the importance of interoperability along transitions in care. The important primary care TOC visit during the transition from hospital to home has information deficits despite the rich structured patient data collected in home health care. Implementation of USCDI between HHC and primary care could bridge the information silos. Study findings indicate that addressing the inadequate USCDI coverage of HHC data is warranted.

Consolidated Environmental and Social Data Facilitates Neighborhood-Level Health Studies in Philadelphia

Colin Christie, Sherrie Xie, Avantika R. Diwadkar, Rebecca E. Greenblatt, Alexandra Rizaldi, Blanca E. Himes
Department of Biostatistics, Epidemiology and Informatics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Abstract
A wide range of datasets containing geographically distributed measures of the environment and social factors is currently available, and as low-cost sensors and other devices become increasingly used, the volume of these data will continue to grow. Because such factors influence many health outcomes, researchers with varied interests often repeat tasks related to gathering and preparing these data for studies. We created Sensor-based Analysis of Pollution in the Philadelphia Region with Information on Neighborhoods and the Environment (SAPPHIRINE), offered as a web application and R package, to integrate pollution, crime, social disadvantage, and traffic data relevant to investigators, citizen scientists, and policy makers in the Greater Philadelphia Area. SAPPHIRINE’s capabilities include providing interactive maps and customizable data retrieval to aid in the visual identification of pollution and other factor hotspots, as well as hypothesis generation regarding relationships among these factors and health outcomes.

Introduction
Epidemiologic and Electronic Health Record (EHR) data can be enhanced for the study of conditions in which social and economic variables play a prominent role by linking them to sources of external information via person-specific geocodes. For example, air pollution, a well-established global health hazard consisting of particulate matter (PM) and gaseous chemicals that is associated with increased rates of hospitalization for asthma, COPD, pneumonia, and cardiovascular disease as well as with increased all-cause mortality, can be linked to other datasets to understand its influence on health. Similarly, the Area Deprivation Index (ADI), a validated score of socioeconomic deprivation derived from factors including education, employment, income, and housing quality, can be assigned to individual persons in the U.S. via their residential geocodes to obtain estimates of their socioeconomic status. ADI has been correlated with all-cause, cardiovascular, cancer, and childhood mortality. Although area-level information may not adequately substitute for individual-level information in all cases, its use can still capture important relationships.

In the U.S., air pollution levels are monitored by the Environmental Protection Agency (EPA) to ensure state and local compliance with the Clean Air Act. Specifically, six criteria pollutants are monitored: PM10, which are particles with diameter less than 10 μm, PM2.5, or fine particles with diameter less than 2.5 μm, SO2, NO2, O3, and CO. Regulatory monitors operated by the EPA are highly accurate but are stationed at fixed locations with limited spatial coverage. Pollutant concentrations at locations outside of regulatory stations can be estimated using interpolation methods such as inverse-distance-weighting, which can be inaccurate compared to direct measurement. EPA pollution data is also limited in terms of its temporal resolution: measurements are only available as temporal averages over multi-hour periods.

Concern for pollution’s effects on health along with broad demand for accessible environmental monitoring have led researchers and manufacturers to develop low-cost, portable pollution sensors in recent years. These sensors are able to take measurements anywhere and at any time. PM sensors, such as those offered by HabitatMap and PurpleAir, can be used in conjunction with mobile devices to upload PM measurements to crowdsourced databases in real-time. In Philadelphia, HabitatMap and PurpleAir sensors have been utilized by citizen scientists, researchers, and the Clean Air Council, an environmental non-profit, to assess neighborhood-level exposures to air pollution. Other health-related variables, including neighborhood socioeconomic status, crime incidence, and exposure to vehicular traffic, exhibit high geospatial variability in Philadelphia and have been linked to negative health outcomes such as asthma exacerbations. Understanding the drivers of geospatially varying health disparities in Philadelphia thus requires fine-scale, neighborhood-level data on the physical and social environments.

We created Sensor-based Analysis of Pollution in the Philadelphia Region with Information on Neighborhoods and the Environment (SAPPHIRINE), a web application and R package, to integrate sensor-based pollution data, EPA
regulatory monitor data, and other social data on Philadelphia neighborhoods in an interactive, versatile tool that facilitates the conduct of local environmental health studies.

Methods

Data Sources and Processing

Geographic boundaries and study time-period

The Greater Philadelphia Area was defined as the Philadelphia-Reading-Camden Combined Statistical Area, which includes Berks, Bucks, Chester, Delaware, Montgomery, and Philadelphia Counties in Pennsylvania; Atlantic, Burlington, Cape May, Camden, Cumberland, Gloucester, and Salem Counties in New Jersey; Kent and New Castle Counties in Delaware; and Cecil County in Maryland20. A shapefile of this region was created based on a U.S. counties borders dataset available online21. The date range for measures of interest was selected as June 1, 2015 to December 31, 2019.

AirBeam data

HabitatMap offers the portable sensors AirBeam and AirBeam2, which measure PM$_{2.5}$ concentration, temperature, and humidity. AirBeam2 additionally measures PM$_{1}$ and PM$_{10}$ concentrations. Location data corresponding to these measures is recorded via paired smartphone GPS recordings. AirBeam and AirBeam2 data were downloaded from HabitatMap’s website22 as tabular datasets of measurements uploaded by any user within the greater Philadelphia area. To ensure SAPPHIRENE included only mobile and stationary outdoor measures, AirBeam data was flagged if it: 1) spanned a region of less than 0.0001 degree of latitude or longitude, 2) included PM$_{2.5}$ values greater than 150 µg/m$^3$, or 3) contained the strings inside, indoor, or fixed in the title. After manual review of geospatial and temporal plots from these sessions, those determined to be indoor and stationary were excluded. Additional AirBeam data taken by members of our lab between October 23, 2017, and July 26, 2018 were incorporated into the final dataset.

PurpleAir data

PurpleAir offers low-cost stationary sensors that continuously record PM$_{2.5}$, PM$_{1}$, and PM$_{10}$ measurements and automatically upload them to a linked website. We downloaded PurpleAir data23 as 15-minute average measures for all sensors located in the Greater Philadelphia Area. Simultaneous data points from each PurpleAir sensor’s “A” and “B” channels were compared. The two measures were averaged if greater than 30 units and within 10% agreement or if less than 30 and within agreement to 3 units. Otherwise, the data points were excluded.

Sensor data processing

Sensor-based data were processed in R$^{24}$. First, data were summarized in data frames according to measurement type (i.e., temperature, humidity, PM$_{1}$, PM$_{2.5}$, PM$_{10}$). Each data frame included the timestamp, latitude, longitude, measurement value, and sensor ID for each data point. Data frames were then joined by timestamp, latitude, longitude, and sensor ID into one data frame. AirBeam or PurpleAir PM$_{2.5}$ measurements were excluded when a synchronous humidity value of 80% or greater was recorded, as hygroscopic growth of particulate matter occurs at approximately 80% humidity and leads to errant measurements in optical sensors$^{25}$. PM measurements from AirBeam2 sensors were included regardless of humidity because AirBeam2 sensors include a particle drying mechanism to avoid hygroscopic error. AirBeam and AirBeam2 data points were consolidated into 10s averages.

Crime

Tabular data capturing all crime incidents that occurred in Philadelphia during the study period as reported to the Philadelphia Police Department was downloaded from OpenDataPhilly$^{26}$. The data was processed into a data frame that included the timestamp, latitude, and longitude of each incident.

Area Deprivation Index (ADI)

2018 ADI national percentile rankings at the block group level were sourced from the Neighborhood Atlas data portal$^8$ which calculated ADI from the American Community Survey 5-year estimates for 2014-2018 and assigned percentile rankings, with 1 indicating the lowest level of disadvantage and 100 indicating the highest level of disadvantage. The R package censusapi was used to gather the specific GEOIDs of the study area’s block groups to be joined with the ADI data and block group geometries from the US Census Bureau’s 2019 cartographic boundary file. National ADI rank data, geocoded by block group, were then saved as a shapefile.
Traffic

Annual Average Daily Traffic (AADT) is the typical daily traffic volume of a segment of road calculated by dividing the total number of vehicles traveling across a road segment in a year by 365\(^2\). Traffic volume line data containing the AADT of all road segments in Pennsylvania was downloaded from the Pennsylvania Department of Transportation Open Data Portal\(^{28}\) and subsetted to the six Greater Philadelphia Area counties in Pennsylvania (Berks, Bucks, Chester, Delaware, Montgomery, and Philadelphia). The traffic data was not subject to temporal subsetting because the AADT for each road segment was measured over a different time period and was not predicted to have fluctuated substantially given that all measurements were recorded in or after the year 2012. The traffic data was rendered as a raster layer in R by resampling the AADT values for all road segments to a high-resolution grid using the “mean” function in the raster library\(^{29}\).

EPA data

Daily-averaged measurements of PM\(_{2.5}\), PM\(_{10}\), SO\(_2\), NO\(_2\), O\(_3\), and CO concentrations from EPA monitors were downloaded from the EPA Air Data Portal\(^{16}\) for the study time period and the Greater Philadelphia Area. Data describing the EPA monitors was downloaded from the EPA Interactive Map of Air Quality Monitors\(^{30}\). For each pollutant, the measurement data frame was joined to the corresponding monitor data frame by Air Quality System (AQS) site ID and parameter occurrence code. These frames were then joined by date, latitude, longitude, and all site information (AQS ID, name, city, state, start date, and end date).

**SAPPHIRINE Design**

SAPPHIRINE was created using the RStudio R shiny library, which facilitates creation of interactive web apps from R\(^{31}\). The app consists of interactive Leaflet maps\(^{32}\) for various environmental variables plotted using the following approaches: average temperature in °C, average relative humidity as a percentage, average PM\(_1\) concentration in \(\mu g/m^3\), average PM\(_{2.5}\) concentration in \(\mu g/m^3\), average PM\(_{10}\) concentration in \(\mu g/m^3\), average SO\(_2\) concentration in ppb, average NO\(_2\) concentration in ppb, average O\(_3\) concentration in ppb, average CO concentration in ppm, total number of reported crimes, estimated average ADI, and estimated average AADT. For sensor-based measures (temperature, humidity, PM), the average value for each bin is calculated from all available data points falling within the bin, given user-specified parameters. Similarly, the ADIs of all block groups whose geocoordinates fall within each bin are averaged. Crime incidents are summed within each bin. For traffic, the pre-existing raster layer is resampled to fit the user-specified grid of bins using bilinear interpolation, which produces an estimated geospatially averaged AADT value for the region covered by each bin. Measurement densities for sensor-based data types are plotted as log-transformed sums of counts for all available data points for a given measurement type that fall within the bin. Raster layers for EPA data are rendered with inverse-distance-weighted interpolation at 1km\(^2\) resolution using the five nearest stations to each point. Code used to create the app, links to the data sources used, and the R package are available at https://github.com/HimesGroup/sapphirine. The app can be accessed at http://sapphirine.org.

**Using SAPPHIRINE to Explore Potential Relationships Between Environmental Variables**

To illustrate how SAPPHIRINE can be used to explore associations between different geospatial variables, we used the app to visualize the distribution of PM\(_{2.5}\) concentrations and traffic near Interstate 676, a major freeway that travels east-west through downtown Philadelphia. To highlight the app’s unique feature of temporal subsetting, we compared a plot of PM\(_{2.5}\) concentrations generated from all available sensor measurements to a plot generated from measurements taken between 4pm-6pm, produced using app controls to capture approximately the evening rush hour. To illustrate how SAPPHIRINE can help identify pollution hotspots and generate hypotheses, we visually identified regions with greatest EPA PM\(_{2.5}\) measurements and contrasted them with other available environmental measures.

**Results**

**SAPPHIRINE Web App Features**

The user interface is shown in Figure 1. On the “Main Map” tab, a custom map of PM\(_1\), PM\(_{2.5}\), PM\(_{10}\), temperature, humidity, crime, ADI, or traffic can be displayed as a color-scaled raster layer based on the selected variable and user-specified criteria (Figure 1A). Users can select specific sensors from which to display data, dates and times of measurements taken, and a range of latitude and longitude coordinates. Additionally, users can select the resolution of the data displayed by choosing the number of rows and columns by which to partition the selected geographic area. Interactive features of the map include the abilities to navigate and zoom in/out on the map, to open an interactive tool for measuring physical distances on the map, to select whether a map should display measurement values or density of measures for a given variable, and to click on the map to open a popup window that lists all available data types for
the bin corresponding to the clicked location, along with measurement values for all data types. Users can download csv files of 1) the subset of original data points used to create the customized map or 2) the geospatial averages corresponding to the bin values on the map. In the former case, the csv contains measurement and crime data, and in the latter case, all variables, including measurement densities. An alternative view of the data is provided in the “Map Grid” tab which displays maps of multiple variables for their side-by-side comparison, which facilitates hypothesis generation via visual exploration (Figure 1B). Under “EPA Map,” users can select a variable for which to display an interpolated raster layer of EPA data over the specified date range. Users can click on blue dots corresponding to monitor locations to display information about the monitoring site and can click on any location in the raster to retrieve the interpolated pollution estimate. The EPA data used to create the map can be downloaded as a csv file.

**Figure 1.** SAPPHIRINE web app screenshots. A) Main Map displays a single variable at one time. B) Map Grid with PM$_{2.5}$ sensor measurements, crime, ADI, and interpolated EPA PM$_{2.5}$ map layers displayed.

**SAPPHIRINE R Package**

The R package saphirine includes objects and functions allowing for similar data visualization and retrieval directly within R. The comprehensive sensor and crime data frame are included as “local.data”, and the EPA data frame as “EPA.data”. The pre-processed poverty and traffic raster layers are included as “poverty.raster” and “traffic.raster.” “GPA_counties” provides the shapefile of the boundaries of the Greater Philadelphia Area counties. “GPA_counties” is easily subsettable with the function “selectGPACounties”, which allows users to select desired counties by providing their names. For reference, correct county names are accessible in “GPACountyNames”. Similarly, “sensor.list” provides the list of sensors included in the dataset. The package defines a new class of object, “EPA_RasterBrick”, similar to “RasterBrick” with an added slot for corresponding monitor data.

The function “customLocalData” allows users to retrieve subsets of “local.data” according to the geographical region, date range, times of day, variables, and sensors they specify. For the geographical region, users can supply their own shapefile, use a subset of “GPA_counties”, or define a square region using latitude and longitude extrema. By default, all variables are included and all of “GPA_counties” is covered. Similarly, “customEPAData” allows users to retrieve data from the EPA frame, subsetted by date range, region, and variables. “localRaster” accepts a subset of “local.data”, ideally an output of “customLocalData”, and generates a brick of raster layers corresponding to the included variables. Users specify the region of coverage and numbers of rows and columns in each raster as well as the variables to be included in the brick. By default, all sensor variables and crime are included, as are poverty and traffic, which are resampled from “poverty.raster” and “traffic.raster”. Furthermore, users can toggle the addition of measurement density layers for sensor-based variables. “intEPARaster,” similarly, accepts an output of “customEPAData” and generates a raster brick for specified variables over a specified region. The rasters are rendered using inverse-distance-weighted interpolation at 1km$^2$ resolution using the five nearest stations. Users can adjust the inverse distance exponent if desired. Finally, “localMap” and “EPAMap” accept outputs of “localRaster” and “intEPARaster”, respectively, and integrate them into interactive Leaflet maps analogous to those on the web app. Users 1) can choose whether to include descriptive popups, 2) can supply a shapefile for customized display boundaries, and 3) can customize colors for the raster displays.
SAPPHIRINE uses a total 4,355,563 data points, of which 3,606,899 (~82.8%) correspond to environmental variable measures (temperature, humidity, and PM concentrations) collected by low-cost sensors, and 734,616 (~16.9%) are crime incidents reported by the Philadelphia Police Department (Table 1).

**Table 1.** Number of data points used to develop SAPPHIRINE by data source and type.

**Exploring the Low-Cost Sensor Data at Varying Spatial Resolutions**

Figure 2 demonstrates how users can compare low-cost sensor measurements at different spatial resolutions to understand them better. In Figure 2A, a PM$_{2.5}$ hotspot is apparent in the upper right-hand corner. Figure 2B shows this same region rendered at increased resolution via zooming, which permits interactively determining that the bin concentration is approximately 44 µg/m$^3$ taken over 42 data points. The user can increase the resolution further by adjusting the bin size and spatial coverage, which yields a map such as that displayed in Figure 2C, where it becomes clearer that the hotspot was due to walks along a multi-blocked loop in the Fox Chase neighborhood of Northeast Philadelphia. By changing dates, it becomes apparent that the high measures were taken on a single day: December 3, 2017. Thus, an isolated phenomenon was most likely responsible for a higher PM$_{2.5}$ concentration this particular day.

![Figure 2. Low-Cost Sensor Data at Varying Spatial Resolutions. A) Low-cost sensor measures averaged over full study period. B) Zoomed-in area that has hotspot (boxed region in Figure 2A) with the summary data of one bin displayed. C) high resolution rendering shows that hotspot resulted from a single set of measures along a specific walk.](image-url)
Exploring the Relationship between Low-Cost Sensor PM$_{2.5}$ Measures and Traffic Volume

Figure 3 shows plots produced by SAPPHIRINE of PM$_{2.5}$ concentrations and traffic volumes near I-676. As expected, traffic volume is highest along major freeways (I-676 running east-west, I-76 running north-south in the west, and I-95 running north-south in the east; Figure 3C). While there is little apparent correlation between traffic volume and PM$_{2.5}$ concentrations when PM$_{2.5}$ is estimated from all available sensor data (compare Figure 3B and 3C), such a relationship is patent when PM$_{2.5}$ is estimated from only measurements taken between 4pm and 6pm (compare Figure 3A and 3C). During the evening rush hour, sensor measures of PM$_{2.5}$ recorded near highly trafficked roads tend to appear higher than sensor measures recorded further away (Figure 3A and 3C). This finding may be expected because traffic volume is highest during peak commute times, when highly trafficked roads are most likely to contribute to local pollution levels. PM$_{2.5}$ estimated using all available sensor data include copious measurements recorded during low-traffic times, during which non-traffic sources of pollution are likely to make relatively greater contributions to local PM concentrations. These results confirm the well-established relationship between traffic volume and high PM pollution levels near roadways.$^{33,34}$

![Figure 3](image3.png)

**Figure 3.** Plots of PM$_{2.5}$ concentrations estimated using sensor measures taken A) between 4pm-6pm and B) at all times of day. C) Average traffic volume expressed as average annual average daily traffic (AADT).

Exploring a Regulatory Monitor PM$_{2.5}$ Hotspot versus ADI

Figure 4 shows plots produced by SAPPHIRINE of EPA PM$_{2.5}$ measures and ADI. Visual inspection of the pollution plot shows areas of higher PM$_{2.5}$ concentration, with the blue arrow pointing to Chester, PA, an Environmental Justice area where residents are exposed to pollution from a trash incinerator, a sewage incinerator, chemical plants, and toxic waste sites. On the ADI map, one can readily observe that this region has values near the 100th percentile, indicating high socioeconomic disadvantage. These observations confirm an expected local relationship, demonstrating that SAPPHIRINE can be used to uncover novel hypotheses by linking environmental data types.

![Figure 4](image4.png)

**Figure 4.** Plots of A) interpolated EPA-measured PM$_{2.5}$ concentration and B) ADI. Arrows highlight a PM$_{2.5}$ hotspot in Chester, PA with high socioeconomic disadvantage.
Discussion

We created the SAPPHIRINE web app and R package to integrate geospatially varying environmental and social data in the Greater Philadelphia Area. SAPPHIRINE allows users quickly to identify potential pollution hotspots and explore relationships between environmental and social variables, as well as consider these variables for health studies. Researchers can download data according to their preferences for use in more extensive analyses. Concerned citizens can visualize pollution levels near home or along a commuter route and investigate their source. While there are national- and state-level environmental datasets available, we restricted the geographic region covered by SAPPHIRINE to the Greater Philadelphia Area because local stakeholders lack a resource like it that includes unique local datasets (e.g., crime data) and for which local action can be taken (e.g., deploying low-cost sensors at specific locations). For example, local environmental organizations such as the Clean Air Council can more easily explore the social and environmental issues that impact Philadelphia’s neighborhoods.

SAPPHIRINE is novel in its inclusion of low-cost pollution sensor data and social data alongside more conventional environmental datasets. With the rise in personal sensor use, there has been a concurrent rise in crowdsourced online databases offering visualization tools, but these existing web apps are limited to data generated by specific brands of sensors. Thus, SAPPHIRINE contains a greater quantity and variety of data that can be used to gain insights.

There are limitations to the datasets included in SAPPHIRINE. While EPA monitors measure PM continuously using highly accurate regulatory equipment, low-cost sensors like AirBeam are less reliable, are not as accurate, and are deployed only when researchers or citizen scientists choose to use them. PM estimates derived from portable sensors may be informed by few sessions and not reflect average levels over longer time periods. Fixed-location sensors, such as PurpleAir, tend to be operated continuously, and thus, while they can provide greater temporal resolution, they have limited spatial coverage. While the multiplicity of data layers in SAPPHIRINE provides a unique opportunity for easy hypothesis generation, disparities in data coverage among different variables limit the ability of researchers to address some questions. Low-cost sensor data nonetheless provides high granularity helpful for hypothesis generation and complements data from regulatory monitors.

As advances in technology increase the accuracy and usability of low-cost pollution sensors, we expect a notable increase in crowd-sourced pollution data coverage and reliability. For example, some sensors have been rendered compact enough to attach to a smartphone case, and microchip-sized sensors promise easy auxiliary attachment to personal devices such as smartphones or smartwatches in the future. Such developments will help resolve the data coverage disparities among variables in SAPPHIRINE, thus increasing data interpretability and application utility.

Maintaining SAPPHIRINE up to date with its current data types is straightforward because all data processing scripts are highly automated. In ongoing work, we are updating SAPPHIRINE to include additional environmental datasets including tree cover, green spaces, and neighborhood cohesion. Additionally, we may expand the geographical scope of our application beyond the Greater Philadelphia Area.

Conclusion

We created SAPPHIRINE, an online web application and R package, that integrates geospatially varying environmental and social data in the Greater Philadelphia Area to facilitate their use for research, policy, and citizen-science efforts. Data available in SAPPHIRINE can be customized according to several user-defined parameters and then downloaded, which facilitates its inclusion into EHR-derived and epidemiologic datasets for studies that seek to better understand the role of environmental and social factors on health outcomes.

Racial Disparity in Clinical Alert Overrides

James J. Cimino, MD
Informatics Institute, University of Alabama at Birmingham, Birmingham, Alabama

Abstract

The existence of systemic racism in US health care is widely recognized, but the role that informatics plays has received little attention. Clinical guidelines, which can incorporate implicit racial bias or be adhered to in racially disparate ways, are often the basis for clinical alerting systems. It is also possible that clinicians might be discriminatory in their response to alerts (for example, by deciding whether to agree or override the alert). We sought to study whether alert logic in our hospital uses patient race as part of its criteria and if alert override rates show any racial disparities. We obtained data on 5,120,114 alert events at the University of Alabama at Birmingham (UAB) Hospital and examined override the rates and reasons with respect to patient race. We found override rates of 82.27% and 81.30% for Black or African American patients and White patients, respectively. Some differences by alert were statistically significant but generally small. Override patterns varied by clinician but reasons given were generally not disparate, suggesting that if racist behavior is present, it is not widely systemic. However, the great variability in individual clinician behavior suggests that deeper analysis is warranted to determine whether disparities are indeed racist in nature.

Introduction

The existence of systemic racism in US health care is widely recognized, with increasing study and discussion in the medical literature (see Figure 1). Guidelines for publishing papers discussing health inequities due to racism have been published. Despite the important role that informatics plays in health care systems and structures, relatively little has been published relating informatics to systemic racism. As part of a larger program to achieve anti-racist health informatics, we seek to study ways in which health information systems might abet or mitigate discriminatory practices, including racist, sexist, and ageist, by looking for evidence of disparate activity.

Clinical guidelines, intended to support unbiased, evidence-based care, often treat race as a clinically relevant factor in risk estimation or treatment selection. This inclusion of race may unintentionally result in discriminatory medical practice, for example by steering minority patients away from needed medical procedures. Even when guidelines do not explicitly include racial factors, clinicians with conscious or unconscious (implicit) bias, may apply them in a discriminatory manner, for example by withholding pain medications from Black patients because of beliefs about pain tolerance or tendency towards opiate use disorder.

Electronic health records (EHRs) frequently employ computerized alerts and reminders (collectively referred to in this paper as “alerts”) to help assure adherence with clinical guidelines. Depending on the alerting logic, clinicians may be given an opportunity to choose whether to accept or override the alert. Thus, the same racial disparities that occur with guideline adherence might be replicated by users of health information systems. It is also possible that clinicians might be discriminatory in their response to alerts (for example, by deciding whether to agree or override the alert). Indeed, recent research using machine learning to predict clinician overrides showed some preliminary data suggesting that patient race might correlate with override rate.

Figure 1: Annual publications cited in PubMed, mentioning systemic racism, based on a search of PubMed on March 9, 2021 (https://pubmed.ncbi.nlm.nih.gov/).

Electronic health records (EHRs) frequently employ computerized alerts and reminders (collectively referred to in this paper as “alerts”) to help assure adherence with clinical guidelines. Depending on the alerting logic, clinicians may be given an opportunity to choose whether to accept or override the alert. Thus, the same racial disparities that occur with guideline adherence might be replicated by users of health information systems. It is also possible that clinicians might be discriminatory in their response to alerts (for example, by deciding whether to agree or override the alert). Indeed, recent research using machine learning to predict clinician overrides showed some preliminary data suggesting that patient race might correlate with override rate.

---

1 Related terms, often used interchangeably, are “systematic racism” and “structural racism”.
2 Of the 470 citations found by searching PubMed for “systemic racism” or ‘systematic racism’ or 'structural racism’ on March 7th, 2021, only two include the word “informatics”.
In light of recent raised awareness of the need for proactive antiracism, we sought to study whether alert logic in our hospital uses patient race as part of its criteria and if alert override rates show any racial disparities. Where disparities were noted, we examined individual clinician behavior and the reasons given for overriding alerts.

**Methods**

**Setting**

The University of Alabama at Birmingham (UAB) Hospital is a 1,157-bed tertiary hospital and academic health science center located in Birmingham, Alabama. The hospital has installed Millennium (Cerner Corporation, Kansas City, MO) as its inpatient and outpatient EHR. Millennium provides a capability for systems personnel to define logic for issuing alerts to users when events (such as orders and procedures) do or do not occur. Some alerts simply deliver a message to the user and possibly block the user from carrying out an activity until a preventing state is corrected or removed. Other alerts allow clinicians to provide a reason for overriding the warning message and then allow them to proceed with the activity that triggered the alert.

**Dataset**

We obtained data on all instances of automated alerts issued by the UAB Hospital EHR for the 2019 calendar year for all clinical settings (e.g., in-patient, ICU, clinic, emergency room, etc.). All data were obtained in “limited data set” form with an exemption of oversight from the UAB Institutional Review Board and were subsequently rendered anonymous through removal of date information. Small racial categories were eliminated from analysis. Alerts that did not allow override were excluded. Alerts have obscure names that generally have meaning to system developers; those important to this study have been given more “user-friendly” names by the author. Data included patient race and gender (provided by patients at time of their registration into the health system), a unique (but deidentified) code for the clinicians receiving the alerts, whether the alerts were accepted or overridden and, if overridden, the reason for the override, chosen by the clinician from a standard list. Multiple alerts occur for most patients. Race of the clinicians is not available.

**Analysis**

Total alerts and percent overrides were calculated by race for the total data set and by each alert. Statistical significance of override rate differences were obtained using an “N-1” Chi-squared calculator (MedCalc; https://www.medcalc.org/calc/comparison_of_proportions.php). For those alerts that occurred frequently, reasons given for overrides compared by race. The override rates for frequent alerts were calculated for individual clinicians.

**Results**

**Dataset**

Overall, 169 types of alerts were triggered 5,120,114 times. Of the 35 alerts that allow overrides, 939,472 alert events occurred, of which 764,166 were overridden (81.34%). Eight race classes with relatively few alerts (American Indian or Alaska Native, 1,607; Asian 11,280; Hispanic or Latino, 9,397; Native Hawaiian/Other Pacific Islander 87; Other, 79; Multiple, 1,410; Decline/Refuse 12,857; and blank, 279;) accounted for 3.94% of all alert events and were excluded from further analysis.

Remaining race classes were “Black or African American” (321,055 events; 82.27% override rate) and “White” (581,410 events; 81.30% override rate). The difference between these override rates (0.97%; 95% CI 0.80% to 1.14%; P<0.0001) corresponded to an excess of 3,114 overrides for Black patients over what would be expected if the rate was the same as for White patients. Table 1 shows the comparisons of override rates for each alert. Differences were generally small (less than 6%), especially for alerts that occurred frequently. Figure 2 shows the actual number of alert overrides for Black patients and the expected number for each alert based on the override rate for White patients. Visible differences are apparent for only the most infrequent alerts (Figure 2D).

We selected the two most frequent alerts (200,000 times or more) and three alerts that occurred very frequently (30,000 or more) and had a rate difference greater than 0.05% for further study. Table 2 shows statistics on numbers of unique clinicians and alert events for these five alerts. The percentage of clinicians who overrode all alert events (and thus had no racial disparities) for each of these five alerts ranged from 41.3% to 93.7%. For clinicians whose override rate was less than 100% for all patients (“mixed response”), the numbers of agreements and overrides are shown in Figure 3. Alert event for patients whose gender is “unknown” are therefore excluded. Override patterns vary greatly by clinician, in part due to differences in the populations of patients for whom the alerts are generated and in part due to
the response to the alerts by the clinician. For example, Clinicians 6, 8 and 9 in Figure 3A only had alerts generated for white female patients. In Figure 3B, Clinician 9 agreed with alerts about half the time for all demographic subgroups, while all other clinicians favored overrides 90% of the time for all demographic subgroups.

Override reasons provided by clinicians are shown in Table 3. Racial differences in the rates for reasons given are all below 9%, with the vast majority being below 1%. Despite their small absolute size, many are significantly different statistically.

**Discussion**

Analysis of data from the UAB Hospital’s clinical alerting system show differences in override rates associated with race that while small in absolute terms, do not appear ascribable to chance alone. The data neither support nor exclude the possibility that some of these differences are due to implicit bias or inappropriate discriminatory processes. Individual clinician patient populations and override behavior vary greatly, and the apparent disparities may warrant
further investigation. However, the reasons given for overrides show strong disparities, suggesting that racist behavior may be present. Given the variable nature of the clinical issues addressed by the collection of alerts, statistics alone cannot tell the whole story. An examination of the alert logic itself is also warranted.

The first question to ask, after Vyas and colleagues,[4] is whether alert logic includes consideration of race in a way that might abet explicit or implicit bias. A review of the 35 alerts in this study shows no explicit inclusion of race in the alert logic. However, three alerts related to use of sulfonylurea (Alert 16, from Table 1), radiocontrast dye (Alert 26) and meperidine (Alert 33) do use an estimated glomerular filtration rate (eGFR) calculation that is adjusted for Black race. As noted by Vyas, although such calculations are considered “standard”, they might induce discrimination based on either over-estimation or under-estimation in renal function. In our data, the override rates were slightly

Figure 3: Override counts of five alerts of interests from Table 1 (Graphs A to E – numbers in parentheses correspond to alert numbers in Table 1) for the top 10 most frequent overriding clinicians (numbers 1 to 10) in each alert. Clinician 3 in Graph B is also Clinician 9 in Graph C. Otherwise, clinicians are unique across all five graphs.

3 UAB_EKM!UAB_RULE111_SULF_UREA_ALT, UAB_EKM!UAB_RULE355_RADONC_CREATI and UAB_EKM!UAB_RULE62_MEPERIDINECRL, respectively.
lower for Black patients for one alert (accounting for 7 fewer overrides) and essentially indistinguishable for the other two. If the eGFR calculation is having an effect, it is small, infrequent and, in any case, may still be appropriate.

A second question to ask is whether known discriminatory practices that affect guideline adherence are reflected in alert override activity, such as withholding expensive treatments or delaying decision making. Discriminatory practices related to opioid use, for example, are more than theoretical.[4] Only one of the alerts studied – the meperidine alert (Alert 33) – involves administration of opioid therapy (a warning about the use of meperidine in patients with decreased creatinine clearance). This alert was triggered only 203 times with an override rate difference of less than 0.4%, or less than one fewer overrides for Black patients than would be expected for the same number of alerts for White patients. While the number of alert events is small, it is reassuring to find that alert override behavior does not appear to recapitulate clinician biases seen that have been reported in opioid guideline adherence.

More detailed study of causes for alert override disparities will be difficult, likely involving chart review and interviews to better understand the clinical justification in each case. Information such as clinician race and gender could be collected at that time. The good news is that the racial disparities found, while statistically significant, seem clinically insignificant. The rate differences in the top three alerts in Table 1, correspond to a total of 1,760 excess overrides in Black patients out of a total of 109,931 alerts (1.6%), while the single most frequent alert (Alert 13, “Patient Has Allergy to Drug Being Ordered”[4]) shows 273 fewer overrides (0.2%) than would be expected by chance. Thus, more in-depth study may have difficulty finding sufficient numbers of inappropriate acceptances or overrides for meaningful analyses. And although systemic racial bias should always be a concern, there may very well be excellent reasons for overrides that do have a justifiable correlation with race, for example if decisions differ based on an underlying disease that is itself correlated with race independent of social determinants of health and disease (e.g., ignoring a drug-allergy interaction in a life-threatening situation such as sickle cell crisis).

This study is limited in several ways. First, it involves a single institution – one that is actively involved in addressing systemic racism in healthcare.[9] Because clinician behavior at other institutions may vary, this study should be replicated elsewhere. Second, this study only examined clinical decisions based on alerts implemented with override capabilities. Therefore, it does not attempt to discover racial disparities in other types of decision making or decision support systems. Third, the clinical context of the alert occurrences is not included in this analysis. Alerts occurring in different settings (for example the maternity ward, cancer center, emergency department or medical clinic) may have different patient demographics and may also have different reasons for alert overrides. Fourth, the reasons for override are chosen from a list that may subject to inaccuracies, the list may not contain the desired reason, or the clinician may not choose carefully.[10] Finally, the results of the analysis are only as good as the data themselves. In particular, patient race data in EHRs are frequently inaccurate.[11] Although UAB has special interests in collecting accurate race data[9] and appears to do so based on our anecdotal experience in clinical settings with patients and their EHRs, no formal study has been conducted. If Black patients are being labeled as White by default (that is, in the absence of accurate information), the size of disparities might be being masked, favoring the null hypothesis.

Conclusions

Mitigation of unconscious human bias in clinical decision making requires constant vigilance. Clinical informaticians, being human, must also be vigilant against the transference of their biases into the systems they build. The current study provides a method with the potential for detecting such bias and, at least in this case, suggests that systemic bias is minimal or absent. However, the great variability in individual clinician behavior suggests that deeper analysis is warranted to determine whether disparities that are indeed racist in nature.

Acknowledgments

This study was initiated by discussions with Dr. Tim Kennell, whose work on alert override prediction raised concerns about racial disparity, with Dr. Suzanne Bakken, who encouraged the analysis that informed this paper, and Andria Cimino, who provided editorial and scientific advice. Additional discussions with Drs. Tiffani Brite, Kevin Johnson, Enieda Mendonca, Umberto Tachinardi and Casey Overby Taylor provide additional insight into data analysis. The author is supported in part by the UAB Informatics Institute and by the Center for Clinical and Translational Science, under grant 1TL1TR001418-01 from the National Center for the Advancement of Translational Science (NCATS). The author thanks Ms. Ayme Miles for assistance in obtaining the data used in this study.

Abstract Family planning is a crucial component of sustainable global development and is essential for achieving universal health coverage. Specifically, contraceptive use improves the health of women and children in several ways, including reducing maternal mortality risks, increasing child survival rates through birth spacing, and improving the nutritional status of both mother and children. This paper presents a data-driven approach to study the dynamics of contraceptive use and discontinuation in Sub-Saharan African (SSA) countries. We aim to provide policymakers with discriminating contraceptive use patterns under different discontinuation reasons, contraceptive uptake distributions, and transition information across contraceptive types. We used Demographic Health Survey (DHS) Calendar data from five SSA countries. One recurrent pattern found was that continuous usage of injectables resulted in discontinuation due to health concerns in four out of five countries studied. This type of temporal analysis can aid intervention development to support sustainable development goals in Family Planning.

Introduction

The World Health Organization (WHO) defines Family Planning (FP) as a means to allow individuals and couples to anticipate and attain their desired number of children and the spacing and timing of their births. The effective use of contraceptives can significantly improve the health of women and children, and it has been shown to reduce maternal mortality risks, and improve child survival through birth spacing, as well as improve the nutritional status of both mother and child¹. Contraceptive discontinuation (CD) occurs when the use of a contraceptive is stopped for any reason while the woman is still at risk of an unintended pregnancy. It is estimated that between 20-40% of users discontinue a contraceptive method for reasons other than a desire to become pregnant or no longer needing a method (e.g., post-menopausal)². While a portion of women would switch to a different contraceptive method after discontinuation, many do not, leaving them at risk of an unintended pregnancy. Thus, CD may signal a dissatisfaction with the contraceptive used, and hence it remains an important topic for domain-experts and policy makers in order to improve the efficiency of FP³–⁷. While there are multiple studies on FP and contraception, focusing on measuring fertility rates⁸, childbirth spacing⁹, modelling prevalence of modern methods¹⁰, and grouping of calendar episodes by long and short-term contraceptive methods¹¹, not many studies were conducted to identify temporal patterns that lead to discontinuation over time. Our work aims to uncover temporal patterns of contraceptive discontinuation and reasons for discontinuation across countries and subpopulations of women. Such patterns can lead to further research questions regarding the demand and supply chain issues of contraceptives or how to develop robust educational interventions to provide information regarding contraceptive methods and their side-effects.

This work was done in partnership with the Bill & Melinda Gates Foundation (BMGF), specifically with their Family Planning team who advised on research questions of interest, data sources, and provided feedback on proposed methods and evaluation of results. In this paper, we explore two questions regarding contraception use and discontinuation episodes¹: (Q1) Are there any recurrent sequences of contraceptive use and discontinuation across countries? (Q2) What do women transition to when they discontinue or switch between contraceptive methods? To address these questions, a series of events are analyzed in a time window of 12 months using contraceptive calendar data from the Demographic and Health Surveys Program (DHS)¹². Specifically, in each month, DHS provides 1) the type of contraceptive method being used, if any, 2) the events that occurred in that month such as pregnancy, birth, termination, and

¹A discontinuation episode refers to an event that occurs in a specific month when a contraceptive method is not used for any reason.
3) the reason for discontinuation (if it occurs). While the DHS data provided longitudinal calendar data (for five years) on women’s contraceptive use, the latest 12 months were used to reduce the impact of recall bias. Pattern mining was performed to check for common patterns of events among women that discontinue their contraceptive uptake. In this paper, two major scientific contributions are provided in line with addressing the above research questions. First, discriminatory subsequences are detected and characterized, along with the extent of their discriminatory power, for different types of discontinuation reasons (Q1). Second, we provide an analytic tool to visualize uptake distributions and transition between contraceptive methods in various subpopulations (Q2). The tool enables domain experts to easily visualize contraceptive switching patterns and interact with the obtained results. For the first time, this allows us to automatically compare subgroups of interest using patterns that are unique to a subgroup. Such patterns are valuable to a practitioner to gain a notion into contraceptive uptake time-based patterns and discontinuation trends. The analysis shows that patterns of continuous usage of injectables were a precursor to contraceptive discontinuation due to health concerns in four out of five Sub-Sahara African (SSA) countries studied. Additionally, we observed that such sequences for DHS Kenya (2014), DHS Ghana (2014), DHS Nigeria (2013) and DHS Burkina Faso (2010) are discriminant i.e. statistically unique to women who used injectables.

To the best of our knowledge, this is the first presentation of data-driven and automatic subsequence mining used to understand patterns of contraceptive use in various subpopulations. Furthermore, the proposed dashboard-based interactive and visual analytic tool enables policymakers to explore longitudinal contraceptive dynamics and discontinuation reason via its interface that allows interactive exploration of contraceptive use, distribution, and pattern uptake trends across different countries.

Related Work

Previous studies in this field of research mainly used traditional models, such as decision trees and logistic regressions, to perform stratified analysis to understand the correlations between contraceptive uptake and pre-determined covariates \(^3\text{-}^\text{7,13}\). The majority of these studies are focused on India (the second most populous Asian country) \(^7\) and Nigeria (the most populous African country) \(^3\text{-}^\text{5}\). A few studies were also able to understand the determinants of contraceptive use across multiple countries, particularly Sub-Saharan African (SSA) countries \(^5\text{-}^\text{14}\) and Cahill et al. \(^6\) analysed the prevalence rate across multiple countries in the world. A summary table is provided in Table 1.

Table 1: Summary of related works on contraceptive use. Countries: Kenya (KE), Malawi (MA), Madagascar (MD), Rwanda (RW), Cameroon (CA), Chad (CH), Zambia (ZA), Zimbabwe (ZI), Ghana (GH) and Mali (MI). LARC: long-acting reversible contraceptive; LR: Logistic Regression. Data source: Demographic and Health Surveys (DHS).

Figure 1: Overview of the proposed framework that takes temporal data, such as contraceptive calendar data available in DHS datasets, for a given country $C_n$. There are two main modules that feed the analytics of the dashboard in the framework. First, the Discriminatory pattern mining module is in charge of extracting the top $k$ discriminatory subsequences between two classes defined by discontinuation reason $R_{m}$ to display on the dashboard. Second, the transition extractor handles preprocessing episode data and probability distribution uptake estimation. This module returns a pair of a probability ($\text{Prob}_n^i$), transition ($\text{Transitions}_n^i$) for each contraceptive method $CM_k$ for $C_n$.

Most existing works on the analysis of FP programs and identifying key determinants of contraceptive use tend to employ simple modeling techniques, such as regressions. These studies largely ignored the time-based calendar data, which we believe may reveal novel patterns on contraceptive use in different groups. In contrast to these prior studies, we employ sequence mining methods to provide data-driven patterns into contraceptive discontinuation, using the sequential calendar data to mine uptake patterns.

Materials and Methods

In this section, the dataset used for the analyses and the extension of PrefixSpan to analyze contraceptive discontinuation is described. An overview of the proposed approach is shown in Figure 1.

The dataset

The DHS program\(^2\) has collected, analyzed and disseminated representative data on population, health, HIV and nutrition through more than 300 surveys in over 90 different countries. Nationally representative surveys are designed to collect data on monitoring and impact evaluation indicators important for individual countries and for cross-country comparisons. The DHS calendar\(^12\) dataset contains monthly history of certain key events in the life of the respondent. The calendar collects a complete history of women’s reproduction and contraceptive use for a period of between five and seven years prior to the survey. The exact length of the period covered by the contraceptive calendar varies depending on the duration of data collection, whether the survey overlapped two years and the month in which the respondent was interviewed\(^12\). In the current standard DHS-7 questionnaire for the calendar consists of two values per episode. The first value represent events such as: births, pregnancies, terminations and contraceptive use (twenty six different types of episodes are considered). The second value represents the reason for discontinuation of contraceptive use (nineteen different reasons are considered). For this study, 95,855 calendars were processed, spanning five SSA

Data-driven Discriminatory Sequence Mining

Sequential pattern mining is a data mining technique that discovers frequent subsequences in a sequence database, such as DHS Contraceptive Calendar data. PrefixSpan\textsuperscript{15} is one of such pattern mining techniques and it employs a projection-based, sequential pattern-growth approach for efficient mining of temporal patterns is used. In this approach, a sequence database is recursively projected onto a set of smaller projected databases, and sequential patterns are grown in each projected database by exploring locally frequent fragments only. Several notations for the contraceptive pattern mining problem being investigated are defined below.

Definition 1

Let \( B = \{ e_1, e_2, \ldots, e_m \} \) be an item base consisting of items, in this case, different types of contraceptive episodes. An itemset is a subset of items if \( I \subseteq B \). A sequence is an ordered list of itemsets, in our case a series of monthly ordered episodes from calendar data. A sequence \( T = (t_1 \rightarrow t_2 \rightarrow \cdots \rightarrow t_n) \) with \( \forall k 1 \leq k \leq n : t_k \subseteq B \).

Definition 2

Let \( I \subseteq B \) be an itemset and \( T \) a sequence over \( B \), the cover of \( I \) is defined as the set:

\[
K_T(I) = k \in 1, \cdots, n | I \subseteq t_k
\]

The cover of an itemset is the index set of sequences that contain all items in \( I \). The value \( \sigma_T = \frac{1}{n} |K_T(I)| \) is called relative support of \( I \). The support of \( I \) is the fraction of sequences that contain it.

Definition 3

Given the minimum support \( \sigma_{\text{min}} \in \mathbb{R}, 0 < \sigma_{\text{min}} \leq 1 \), the set of frequent itemsets is defined as:

\[
\Phi_T(\sigma_{\text{min}}) = I \subseteq B | \sigma_T(I) \geq \sigma_{\text{min}}
\]

Definition 4

A sequence \( s = (s_1, s_2, \cdots, s_n) \) matches a sequence \( s' = (s'_1, s'_2, \cdots, s'_m) \) if there exists \( j_1 < j_2 < \cdots < j_n \) such that \( s_i = s'_j \), the function is defined as \( \text{match}(s, s') \).

In this study, the goal of using sequence mining is to identify contraceptive uptake patterns that may be unique to one cohort of women (e.g., women that discontinued due to health concerns). Extracting such sequences do not only shed information regarding uptake patterns to domain experts, but can also have predictive power —i.e., be able to predict that a discontinuation may occur in \( k \) steps if a particular pattern is being observed. To identify such unique or “discriminatory” sequences, the PrefixSpan\textsuperscript{15} is extended in several ways. First, we need to look for differentiating sequences between two classes, namely women who discontinued due to health concerns and those who did not discontinue. To address this, PrefixSpan was extended to mine for patterns that are different between the two classes of interest. There are two parameters that need to be set, namely \( \sigma_{\text{min}} \) (Def. 3) and \( w_{\text{max}} \). The first parameter expresses a threshold on how often a particular pattern occurs, in terms of the minimum percentage across all the sequences in DHS calendar data for a given country. The patterns identified are sequential in nature and are subsequences of the contraceptive uptake patterns. \( w_{\text{max}} \) defines the time window to be analyzed. PrefixSpan reporting method is extended such that each pattern is tagged with various metrics. While these are familiar concepts in association rule mining, their definitions to mine sequences with discriminatory power are slightly modified in this work. The two key metrics are support and lift. Support left and right, is the support \( \sigma_T \) (Def 2) of a pattern \( T \), for left and right datasets, respectively. Lift(\( T, left, right \)) is the ratio of \( \frac{Pr(\text{match}(s,S_1))}{Pr(\text{match}(s,S_2))} \), defining how often a pattern occurs in the left dataset compared to the right. When this number is very large, it indicates that the pattern is unique to the left dataset. With these definitions, the problem of finding discriminatory patterns can be formalised as follows: Let \( p_s = \frac{Pr(\text{match}(s,S_1))}{Pr(\text{match}(s,S_2))} \) the ratio of finding a given pattern, where \( S_1 \) and \( S_2 \) are two collections of sequences (e.g., those that continue contraceptive use vs. those that don’t). Let \( d_s = \max(p_s, \frac{1}{p_s}) \) denote the discriminatory power of sequence \( s \) with respect to the two collections of sequences \( S_1 \) and \( S_2 \), where a larger \( d_s \geq s \) is a more powerful discriminator.
Given the two collections of sequences $S_1$ and $S_2$, learn as a collection of sequences $S(\|S\| < |S_1|, |S_2|)$ such that $\forall s \in S, d_s$ with respect to $S_1$ and $S_2$ is greater than a given threshold ($th$). We note that pruneByDominance is a function to eliminate those patterns $q$ that are obtained by augmenting an existing pattern $p$, where $p$ is shorter or more general than $q$, and has a higher confidence of predicting a class than $q^{16}$. Algorithm 1 shows the pseudo-code for discriminatory sequence mining (DSM).

**Experimental Analysis and Results**

In this section, we present a set of experiments conducted to answer the two research questions outlined in the Introduction, by analysing contraceptive use and discontinuation from different angles to provide a holistic view of the problem landscape to domain experts. First, motivated by (Q1), the discriminatory sequence mining algorithm is used to mine frequent temporal patterns of contraceptive use across all countries. Second, regarding (Q2), contraceptive transitions is studied to answer the following questions: how long an individual continues to use a contraceptive option? And what they transition to when a method is discontinued?

**Experimental setup for Q1: Discriminatory subsequence mining for fine-grained pattern extraction**

**Data Preprocessing**

For sequence mining experiments, more than 95,855 contraceptive calendars corresponding to women population from five Sub-Saharan countries were analysed, i.e., DHS Kenya (2014), DHS Nigeria (2013), DHS Ghana (2014), DHS Ethiopia (2016), and DHS Burkina Faso (2010). Retrospective reporting of contraceptive use and discontinuation rely heavily on the ability of respondents to accurately recall events. To reduce recall bias, the 12 months prior to a discontinuation event are used in this analysis, and the three months immediately before the survey is removed to account for under-reporting of first trimester pregnancies at the time of the survey. For all the experiments presented in this section, calendar data from individuals who wanted to become pregnant are excluded (DHS Code 2).

As described in the Methods section, two parameters are needed to train the Discriminatory Sequence Model, namely the time window to be analyzed ($w_{\text{max}}$) and the minimal support required ($\sigma_{\text{min}}$). These parameters were tuned in consultation with domain experts, understanding that smaller minimal support within a time window provides more sequences needing to be examined for interpretation, and a shorter window provides patterns including short-term contraceptive methods. A time window of $w_{\text{max}} = 12$ months is constructed to use the full calendar year extracted and capture both long- and short-term contraceptive methods. We selected 0.3 as a minimum fraction of the population required for the patterns to be significant for minimal support. In order to work with DSM, two groups for evaluation were determined. For example, Table 2 shows the discrimination patterns of calendar data that contain discontinuations due to health concerns as opposed to the rest of the population. The reason for discontinuation is extracted from the
Table 2: Discriminatory subsequences mined in the subpopulation of women who discontinue due to health concerns (DHS Discontinuation Code 4), as opposed to the rest of the population that discontinue for any other reason. Injectables (DHS Code 3), non-use (DHS Code 0)

Results

All subsequences found under health concern discontinuations contained episodes of injectables (DHS Code 3) as the contraceptive method (Table 2). Additionally, patterns for DHS Kenya (2014), DHS Ghana (2014) and DHS Burkina Faso (2010) are discriminant (See Support Left, Support Right and Lift metrics) while for DHS Ethiopia (2016) the pattern containing injectables was not discriminant for the health concern discontinuations. Additional discriminatory subsequence experiments with other reasons for discontinuation can be seen in Table 3. We can observe that in both DHS Kenya (2014) and DHS Ghana (2014) discriminative patterns were found with consecutive use of Rhythm (DHS Code 8) as a contraceptive method in the group of calendars that reported to discontinue due to becoming pregnant while using a contraceptive method (DHS Discontinuation Code 1). For sequence mining visualization, a combination of directed graphs and bar plots (for support metrics) are used, with an example provided in Figure 3.
Table 3: Examples of discriminatory subsequences with particular discontinuation reasons. DHS Code Discontinuation Reasons (DR): Became pregnant while using a contraceptive method (DHS Discontinuation Code 1), wanted to become pregnant (DHS Discontinuation Code 2). Episodes: Rhythm (DHS Code 8), Pregnancy (DHS Code P).

Figure 3: Discriminatory subsequences with support for Side effects/Health concerns (4) versus other discontinuation reasons (X) for DHS Ghana (2014). (A, B): The support value of the pattern for the left dataset and the right dataset respectively, are aggregated for all individual subsequences. i.e., the mean and standard deviation are computed. (C, D): Each episode e.g. Injectable, is repeated n number of times where n is indicated using the corresponding color intensity on the color bar (E). A subsequence may consist of a single repeated episode as in (D) or multiple episodes linked with an arrow as in (C).

Experimental setup for Q2: Contraceptive Transitions

Probability distributions of contraceptive transitions

To provide an overview of contraceptive use across each country based on the calendar data, the probability distributions per contraceptive type is estimated. The domain expert can define the time interval to use for the estimations, which can be a specific year of the calendar data or the totality of years available. To determine how long an individual used a particular contraceptive before switching to other methods or discontinuing to non-use, the frequencies of consecutive months of use for each specific contraceptive per country was calculated. Given the itemset of type of episodes, $D_i$ the set of sequences of calendar data for the country $i$, we extracted subsequences with one type of episode $j \in I - \{B, P, T, 0\}$. The length for each subsequence was then calculated, excluding episodes that do not correspond to a contraceptive method. As a result, a set of vectors is constructed $V_{j|i} = ([T_j], \cdots, [T_n])$, where $j \in I$ and $i \in D$ $|T_i|$ is the length of each subsequence found for that contraceptive over all calendar data in $D_i$. The Kernel Density Estimation (KDE) algorithm is used to estimate the probability density function applied to $\{V_{j|i} | j \in I - \{B, P, T, 0\}\}$. An example of interactive violin plots for consecutive months of contraceptive use distributions for DHS Kenya (2014) with six different contraceptive methods (five modern methods and one traditional method) is shown in Figure 2. This type of visualisation provides the domain expert with the tools to compare distributions across countries and methods. The probability of an individual using a particular method of contraception for a number of months is also estimated. Domain experts may find such analyses helpful for visualizing the switching patterns between different contraceptive;
not simply who discontinued or why, but also some insight on what the type of transition was (i.e., what type of contraception the person used next, if any). Furthermore, the probability distribution of consecutive episodes may allow experts to see and compare length of use in ways that show patterns not apparent from the usual “average months of use” that is commonly used.

After studying the trends for consecutive months of use for each country, a simple one-to-one pattern transition is provided. Using the subsequence already extracted in the previous section, ordered pairs such as a set of tuples $P_k = ((T_1, T_2), \ldots, (T_{n-1}, T_n))$ are formulated, where $T_i$ is a subsequence of one type of contraceptive $j$ with $j \in I$, $k \in D$ and $(T_1, T_2)$ is a transition pair from each subsequence found to other contraceptive methods in $D_k$. Examples of these transitions can be seen in Figure 4. In each Sankey plot, transitions from one type of episode, in this case an Injectable and Rhythm episode, to all the other types of episodes, may be observed. For women that transit, domain experts would find it useful to know what they transition to, in order to better understand contraceptive uptake. These one-step transitions are visualized using a Sankey plot, wherein the contraceptive of interest is selected as the ‘source’ of the flow and plot the amount of transition (indicated by the flow size) to all other ‘destinations’ i.e., contraceptive methods. The Sankey plots in Figure 4 illustrate the transitions from injectables in DHS Burkina Faso (2010). This analysis was repeated for all five countries and the results are summarized here for brevity.

**Results**

The percentages of transitions to non-use (no contraceptive used) constitute the largest proportion among all the countries studied: 85.36% in DHS Burkina Faso (2010), 57.39% in DHS Kenya (2014), 76.7% in DHS Ethiopia (2016), 70.42% in DHS Nigeria (2013) and 75.72% in DHS Ghana (2014). Importantly, injectables as a method of contraception had high rates of transition to episodes of non-use in all countries. In contrast, episodes of Rhythm use showed high rates of transition to both pregnancy and non-use in all countries. Figure 4 shows the transitions from injectables in DHS Burkina Faso (2010). The percentages to pregnancy episodes were: 57.38% for DHS Burkina Faso (2010), 59.67% for DHS Kenya (2014), 34.38% for DHS Ethiopia (2016), 55.36% for DHS Nigeria (2013) and 67.18% for DHS Ghana (2014). And the percentages to non-use were 34.43% for DHS Burkina Faso (2010), 16.57% for DHS Kenya (2014), 53.12% for DHS Ethiopia (2016), 30.36% for DHS Nigeria (2013) and 24.43% for DHS Ghana (2014). An interesting result that emerged was the bimodal distribution of Rhythm users compared to other methods, a finding that was not evident to the team until the episodes were visualized in this way (Figure 2). This finding implies that while some women briefly try the Rhythm method, a significant portion of them use this method for extended periods of time. Given that Rhythm has a high transition rate to unintended pregnancy, this insight draws attention to domain experts who aim to reduce the risk of unintended pregnancy.
Discussion

Our goal with this work was to illustrate the potential of sequence mining techniques to provide a data-driven approach to understanding contraceptive dynamics using the DHS survey data. This may inform policymakers and health workers as they address unmet needs in contraceptive usage. As such, this work provides domain experts with the ability to visualize and compare frequency distributions and discontinuation flows across different methods, sub-populations, and countries. Our analysis shows that patterns of continuous injectables episodes were a precursor to contraceptive discontinuation due to health concerns in four out of five datasets studied. These results need further examination to understand why these patterns appear and how the subpopulation that exhibits these sequences of episodes can be better characterized. Nonetheless, from the research literature, we know that side effects of modern family planning methods, either experienced or anticipated, have been identified as a common reason women choose not to start or discontinue contraceptives. Fear of side effects may occur when a woman or someone she knows has experienced side effects with a method when rumors are considered as facts, or rare complications are exaggerated\textsuperscript{20–23}. The temporal patterns found in this work complement existing research while providing a time-window that potential interventions can be made. For example, targeted education plans for subpopulations characterized by a pattern of contraceptive use identified result in discontinuation.

In another experimental setup, the domain experts aimed to create a “super dataset” by combining calendar data from multiple countries so as to perform a stratified DSM analysis such that there is sufficient sample size in rare classes. However, discriminatory patterns were hardly extracted from the combined datasets from different countries, which reflects the need to avoid blind merging of different datasets, with different years, countries and/or cultures. An approach of this kind will benefit from taking into account sub-populations that show some similarity in terms of their FP uptake or other factors. This has opened up a new research question: can we identify sub-populations that are “similar” enough to be able to combine their data, thus enabling sufficient data sizes for stratified analysis?

Conclusions

Our proposed approach provides subject-matter experts with insights based on data-driven automatic sequence mining and interactive visualization tools. This work analyzes a series of episodes in a contraceptive uptake pattern and identifying which sequences lead to discontinuation, to what extent these sequences are discriminatory, and whether these sequences are common across sub-populations. The proposed approach was tested across large datasets such as DHS Survey and Contraceptive Calendar Data. As more reliable calendar information becomes available in the future, such as PMA2020\textsuperscript{24}, this work demonstrates the potential to provide information to policymakers regarding contraceptive use and discontinuation for a given subpopulation. After finding contraceptive patterns on reliable data, subpopulations with the same patterns may be identified to perform targeted interventions. These interventions can range from educational material regarding a particular method to guarantee access to contraceptive methods after a given time-window.

Abstract

The central task of causal inference is to remove (via statistical adjustment) confounding bias that would be present in naive unadjusted comparisons of outcomes in different treatment groups. Statistical adjustment can roughly be broken down into two steps. In the first step, the researcher selects some set of variables to adjust for. In the second step, the researcher implements a causal inference algorithm to adjust for the selected variables and estimate the average treatment effect. In this paper, we use a simulation study to explore the operating characteristics and robustness of state-of-the-art methods for step two (statistical adjustment for selected variables) when step one (variable selection) is performed in a realistically sub-optimal manner. More specifically, we study the robustness of a cross-fit machine learning based causal effect estimator to the presence of extraneous variables in the adjustment set. The take-away for practitioners is that there is value to, if possible, identifying a small sufficient adjustment set using subject matter knowledge even when using machine learning methods for adjustment.

Introduction

In the absence of randomized trials, it is common for researchers to attempt to estimate treatment effects using observational healthcare data (e.g. from an insurance claims or electronic health record – EHR – database). Under strong assumptions, statistically adjusted comparisons of outcomes in patients receiving the treatment alternatives of interest provide unbiased estimates of the results that would be observed in the hypothetical randomized trial researchers wish they could run.

The central aim of statistical adjustment is to remove confounding bias that would be present in naive unadjusted comparisons. Statistical adjustment can be broken down into two steps. In the first step, the researcher selects some set of variables to adjust for. In the second step, the researcher implements a causal inference algorithm to adjust for the selected variables and estimate the average treatment effect (ATE). In this paper, we use a simulation study to explore the operating characteristics and robustness of state-of-the-art methods for step two (statistical adjustment for selected variables) when step one (variable selection) is performed in a realistically suboptimal manner. (Simulation studies to address questions like this are common and crucial in causal inference\textsuperscript{1–5} in particular, since counterfactual ground truth under alternative treatment strategies is rarely available in real data.)

If the selected set of variables to adjust for in an observational study is appropriate for removing bias, then the exchangeability assumption is said to hold\textsuperscript{[2]}. Exchangeability is partially an assumption about the richness of the database in that the assumption cannot hold if the database does not contain sufficient confounding variables. Exchangeability is also partially an assumption about the researcher’s ability to select the right variables to adjust for out of those available. Even if a database contains a sufficient adjustment set, a researcher may fail to adjust for a variable in the set or adjust for an extraneous variable that actually induces bias (so-called ‘M-bias’\textsuperscript{4,7}, which we will discuss in more detail later). Because it is not empirically verifiable from data whether exchangeability holds for a given set of variables, and because it is possible to run afoul of exchangeability by choosing either too many or too few variables to adjust for, variable selection is a very challenging problem\textsuperscript{3}. In practice, researchers typically err on the side of adjusting for too many variables and risking M-bias, rather than adjusting for too few and risking bias due to unobserved confounding. This approach has the effect that even if a selected adjustment set satisfies exchangeability and does not induce M-bias, it will often contain extraneous variables not strictly necessary to adjust for to estimate the treatment effect. Such extraneous variables are theoretically inconsequential from a bias perspective. But in practice, with finite data, extraneous variables of any kind may influence performance.

334
Once an adjustment set is selected, most statistical adjustment procedures require fitting so-called ‘nuisance’ models, i.e. regression models predicting treatment conditional on the covariates and regression models predicting outcome conditional on treatment and the covariates. These nuisance models are not directly of interest (hence the name), but rather they serve as inputs to treatment effect estimators. ‘Standardization’ or ‘g-computation’ estimators depend only on a nuisance model for the outcome, which must be correctly specified. Inverse probability of treatment weighted estimators depend only on a nuisance model for the treatment, which must be correctly specified. Doubly robust estimators take as inputs nuisance models for both the outcome and the treatment, but the estimators are consistent if at least one of the two nuisance models is correctly specified. Realistically, when data generating processes are nonlinear or complex, parametric nuisance models (such as generalized linear models) are bound to be misspecified. Flexible nonparametric data adaptive machine learning nuisance regression models have the desirable property that they will not be misspecified and will lead to unbiased treatment effect estimates asymptotically. But machine learning models converge slowly to the truth, leading to poor confidence interval coverage and significant bias when they are used to estimate nuisance models in traditional effect estimators with datasets of realistic size. Recently, though, it was shown that doubly robust estimators computed via cross-fitting and using machine learning outcome and treatment nuisance models behave as well (i.e. converge to the truth at the same rate) as estimators using correctly specified parametric models. (Cross-fitting means splitting the data into two portions, generating two estimates by plugging nuisance model estimates from one half of the data into effect estimators trained on the other half, and then averaging the estimates.) This approach constitutes the state-of-the-art, as it greatly ameliorates misspecification bias without sacrificing fast convergence rates.

A recent simulation study nicely illustrated the utility of cross-fitting with machine learning in a realistic setting. The authors generated data for a (simulated) observational study assessing the effects of statins on atherosclerotic cardiovascular disease (ASCVD). Their data generating process included four confounding variables based on treatment guidelines for the management of blood cholesterol. These confounders were generated to be interpreted as age, cardiovascular risk score, diabetes, and blood cholesterol levels. Probability of statin use was generated as a complex nonlinear function of the confounders, and probability of ASCVD incidence was generated as a complex nonlinear function of the confounders and statin use. Treatment effect estimators based on simple parametric nuisance models that were (inevitably) misspecified were biased for the true effect. Effect estimators based on flexible nonparametric machine learning nuisance models (but not doubly robust and estimated via cross-fitting) were also biased. Only doubly robust cross fit machine learning estimators were found to be unbiased in this realistic but relatively simple setting. While this simulation demonstrated the necessity of machine learning with cross-fitting, it did not explore the approach’s robustness to settings where the small set of truly important confounders is not known a priori.

In this paper, we build on the above study by evaluating performance of cross-fitting with machine learning in the (common in practice) presence of extraneous covariates. We find that performance can degrade as extraneous variables are added, with the degree of degradation depending on properties of the extraneous variables. We considered extraneous variables that are pure noise, weakly or strongly associated with the outcome but not the exposure, weakly or strongly associated with the exposure but not the outcome (except possibly through the exposure), or weakly or strongly associated with both outcome and exposure so as to induce M-bias. Generally, this simulation study highlights potential drawbacks of the tempting adjustment strategy: “throw everything in and let the machine learning models sort it out”. There is real value to, if possible, identifying a small sufficient adjustment set using subject matter knowledge, even when using state-of-the-art machine learning methods for adjustment.

Methods

The data generating process developed in Zivich and Breskin provides the core of all of our simulations. In each simulation, we first generate the variables $Z$, $X$, and $Y$ as in their study. $Y$ denotes the observed binary outcome variable, to be interpreted as incidence of atherosclerotic disease. $X$ denotes the treatment, to be interpreted as statin use. $Z$ is a vector of four confounding variables meant to be interpreted as age, cardiovascular risk, diabetes, and cholesterol levels. We denote the individual confounders as $Z_{age}$, $Z_{risk}$, $Z_{diab}$, and $Z_{chol}$. We first generate $Z$ as
described in the appendix of Zivich and Breskin. We next generate $X$ given $Z$ according to the treatment model:

$$
\Pr(X = 1|Z) = \text{Bernoulli}(\exp( -3.471 + 1.390 Z_{\text{diab}} + 0.112 Z_{\text{chol}} + 0.973 I(Z_{\text{chol}} > \log(60))
- 0.046(Z_{\text{age}} - 30) + 0.003(Z_{\text{age}} - 30)^2 + 0.273 I(0.05 \leq Z_{\text{risk}} < 0.075)
+ 1.592 I(0.075 \leq Z_{\text{risk}} < 0.2) + 2.46 I(Z_{\text{risk}} \geq 0.2)))
$$

This treatment model was designed based on the primary prevention guidelines for management of blood cholesterol such that statin prevalence matched empirical results in US adults. Let $Y(x)$ denote the counterfactual outcome under treatment assignment $X = x$. We generate $Y(x)$ given $Z$ from the outcome model:

$$
\Pr(Y(x) = 1|Z) = \text{Bernoulli}(\exp(-6.250 - 0.75x + 0.35x(5 - Z_{\text{chol}})I(Z_{\text{chol}} < \log(130)) + 0.45(Z_{\text{age}} - 39)^{0.5}
+ 1.75Z_{\text{diab}} + 0.29 \exp(Z_{\text{risk}} + 1) + 0.14 Z_{\text{chol}}^2 I(Z_{\text{chol}} > \log(120)))
$$

and then set the observed outcome $Y$ to be the counterfactual outcome corresponding to the received treatment, i.e. $Y = XY(1) + (1 - X)Y(0)$.

We are interested in estimating the average treatment effect $E[Y(1)] - E[Y(0)]$ from the observed data $Z, X, Y$. The data generating process satisfies the three causal assumptions necessary to do so:

1. Consistency: $Y = Y(X)$
2. Exchangeability: $Y(x) \perp X|Z$ for all $x$
3. Positivity: $\Pr(X = x|Z = z) > 0$ for all $x, z$ such that $\Pr(Z = z) > 0$

However, in addition to these causal assumptions holding, for treatment effect estimators to be unbiased it is also necessary to accurately specify the nuisance treatment and/or outcome models (1) and (2). Because these models are (realistically) complex, standard parametric model specifications would inevitably be incorrect. Therefore, it is necessary to use nonparametric machine learning methods to estimate the treatment and outcome models. (Zivich and Breskin showed that parametric specifications of the nuisance models using just the main effect terms for the four confounders led to biased estimates.) And when plugging in machine learning estimates of nuisance models to a treatment effect estimator with cross-fitting to attain unbiased estimates and nominal coverage under minimal assumptions. Indeed, in this particular data generating process, machine learning with cross-fitting was the only approach that yielded unbiased estimate.

The focus of our simulation study is on the robustness of cross-fit machine learning estimators to the presence of a vector of extraneous covariates $L$. We roughly follow Brookhart et al. and Liu et al. in considering extraneous variables of varying types – pure noise independent of both treatment and outcome, associated with treatment but not outcome (except possibly through the treatment), associated with the outcome but not the treatment, and associated with both outcome and treatment so as to induce M-bias. Graphical models describing the dependence structure for each extraneous variable type are shown in Figure 1.

We also consider varying strength of association and number and mix of extraneous variables, as illustrated in the schematic in Figure 2. Table containing our results, enumerates the simulation settings we evaluated. Below, we describe in detail how we generated the extraneous variables for each simulation setting.

1) Noise variables ($n = 10, 20$): Continuous variables were generated as independent identically distributed $\mathcal{N}(0, 1)$ and binary variables were generated as independent identically distributed Bernoulli(.5). As illustrated in panel (A) of Figure 1, these variables are completely independent of treatment ($X$), confounders ($Z$), and outcome ($Y$). Assumptions 1-3 required for causal inference would still hold in this dataset with $\{Z, L\}$ as the adjustment set.
2) Variables associated with exposure $X$ but not the outcome $Y$, except through exposure $(n = 10, 20; \text{association} = \text{‘strong’, ‘weak’})$: First, we generate a binary intermediary variable $U$ associated with exposure as $U \sim \text{Bernoulli}(\expit(\beta X))$. Using the same $U$, we generate each binary component of $L$ as $\text{Bernoulli}(\expit(\beta U))$. Using the same $U$, we also generate each continuous component of $L$ as $\mathcal{N}(U, \sigma^2)$. The parameters used are

$$
\beta = \begin{cases} 
0.65 & \text{if weak association} \\
1.55 & \text{if strong association} 
\end{cases} \quad \text{and} \quad \sigma = \begin{cases} 
2 & \text{if weak association} \\
0.5 & \text{if strong association} 
\end{cases}
$$

See Figure 1 panel (B) for a graph depicting the dependencies in this data generating process. We chose $\beta$ such that the coefficient of a logistic regression of $X$ on $L$ would be equal to 0.5 in the strong case and 0.1 in the weak case. These coefficients approximately matched the 80th and 20th percentiles, respectively, of the distribution of log odds ratios of baseline variables (indicators of all pre-treatment diagnoses and medications) and exposures in several trial emulation cohorts we constructed from a claims database for another study. Assumptions 1-3 required for causal inference would still hold in this dataset with $\{Z, L\}$ as the adjustment set in place of $Z$.

Note that generating $L$ as a function of $U$ has several consequences. First, it induces dependence among the various components of $L$. Second, it caps the strength of the joint association between all elements of $L$ and $X$ by the strength of association between $U$ and $X$. Observing 20 independent variables with strong associations with exposure would allow us to almost perfectly predict exposure. But observing 20 dependent variables (linked by $U$), each with a strong marginal association with exposure, only allows us to predict exposure at best as well as we could by directly observing $U$. This is a desirable property in our simulation as it is not usually possible to perfectly predict exposure in healthcare datasets.

3) Variables associated with outcome $Y$ but not exposure $(n = 10, 20; \text{association} = \text{‘strong’, ‘weak’})$: First, we generate a binary intermediary variable $U$ associated with the counterfactual untreated outcome as $U \sim \text{Bernoulli}(\expit(\beta Y(0)))$. Using the same $U$, generate each binary component of $L$ as $\text{Bernoulli}(\expit(\beta U))$. Using the same $U$, we additionally generate each continuous component of $L$ as $\mathcal{N}(U, \sigma^2)$. The parameters used are

$$
\beta = \begin{cases} 
0.65 & \text{if weak association} \\
1.55 & \text{if strong association} 
\end{cases} \quad \text{and} \quad \sigma = \begin{cases} 
2 & \text{if weak association} \\
0.5 & \text{if strong association} 
\end{cases}
$$

Assumptions 1-3 required for causal inference would still hold in this dataset with $\{Z, L\}$ as the adjustment set in place of $Z$. See Figure 1 panel (C) for a graph depicting the dependencies in this data generating process. As for the exposure associated variables, we chose $\beta$ such that the coefficient of a logistic regression of $Y$ on $L$ would be equal to 0.5 in the strong case and 0.1 in the weak case.

As in the exposure associated variable data generating process, including the intermediate variable $U$ induces dependence among components of $L$ and prevents perfect prediction of the (counterfactual) outcome even in the presence of many variables that are each marginally strongly associated with the outcome.

4) Variables associated with treatment $X$ and outcome $Y$ so as to induce M-bias $(n = 10, 20; \text{associations} = \text{‘strong’, ‘weak’})$: We generate hidden exposure-associated variable $U_1$ as $\text{Bernoulli}(\expit(\beta X))$ and hidden outcome-associated variable $U_2$ as $\text{Bernoulli}(\expit(\beta Y(0)))$. Then, we generate each continuous component of $L$ as $\mathcal{N}(U_1 + U_2, \sigma^2)$ and each binary component of $L$ as $\text{Bernoulli}(\expit(\beta (U_1 + U_2)))$, where

$$
\beta = \begin{cases} 
0.7 & \text{if weak association} \\
1.65 & \text{if strong association} 
\end{cases} \quad \text{and} \quad \sigma = \begin{cases} 
1.75 & \text{if weak association} \\
0.8 & \text{if strong association} 
\end{cases}
$$

See Figure 1 panel (D) for a graph depicting the dependencies in this data generating process. As for exposure and outcome associated variables, we chose $\beta$ such that the coefficients of logistic regressions of $X$ and $Y$ on each component of $L$ would be equal to 0.5 in the strong case and 0.1 in the weak case.

Under the M-bias data generating process, the exchangeability assumption is not satisfied with $\{Z, L\}$ as the adjustment set in place of $Z$. Adjusting for $L$ induces so-called \’collider bias\’ generating a spurious association between $X$ and $Y$. Thus, bias observed under this setting is not just due to degradation of the estimator’s

We produced 2,000 datasets with 3,000 observations containing extraneous variables of each type listed above. Table 1 illustrates the characteristics of a single simulation sample under the mixed setting with \( n = 20 \) extra covariates, with an example of each extraneous variable type. In each dataset, we estimated the average treatment effect using the doubly robust augmented inverse probability weighted estimator via cross fitting. We used ensembles of regression models (multi-layer perceptron with a hidden layer containing 4 nodes, a random forest with 500 trees, logistic regression without regularization, empirical mean, generalized additive model with 4 splines, and a generalized additive model with 6 splines) to estimate the nuisance treatment and outcome models. Results for each simulation setting are summaries of performance of the estimator over the 2,000 datasets generated under that setting. All simulation code for our analyses can be found at https://github.mit.edu/rcobzaru/simulation-study.

Results

Results are summarized in Table 2. As in Zivich and Breskin, the cross-fit machine learning estimator produces unbiased estimates of the treatment effect when only true confounding variables were adjusted for. Adding extraneous noise variables led to moderate degradation in performance. Adding variables weakly associated with the treatment but not the outcome did not add more bias than noise variables. Adding variables strongly associated with the treatment but not the outcome did significantly increase bias compared to adding noise variables. Adding variables weakly associated with the outcome but not the treatment led to approximately the same bias increase as noise variables. Adding variables strongly associated with the outcome but not the treatment led to substantially less additional bias than noise variables, with 20 strongly outcome-associated variables leading to no additional bias at all. Adding variables with only weak M-bias inducing associations did not cause more bias than just adding noise variables. Predictably, adding variables with strong M-bias inducing associations led to the largest increase in bias of the estimator. A mix of extraneous variables of all types also induced bias in line with what might be expected from the individual mixture components. Standard errors and corresponding confidence interval widths were increased in the presence of strong variables.
Figure 1: Directed Acyclic Graphs describing the relationships of the four types of extraneous covariates ($L$) to treatment ($X$), outcome ($Y$), and confounders ($Z$).

Figure 2: Schematic of the space of simulation studies we explore
Table 2: Each row corresponds to one simulation setting described in the Methods section. The first three columns jointly define the simulation setting. Bias is the difference between the mean effect estimate over 2,000 datasets and the true effect (as computed via a simulation of a dataset with 1,000,000 observations). Absolute bias as percentage of true effect is just $100 \times \text{bias}/(\text{true effect size})$. RMSE is the root mean squared error of the 2,000 effect estimates. ESE is the empirical standard error of the 2,000 estimates. CLD is the average ‘confidence limit difference’ of the confidence intervals over 2,000 datasets. Coverage is the proportion of the 2,000 confidence intervals that contained the true effect size.

exposure-associated variables, but otherwise similar across settings. Thus, degradation of confidence interval coverage below the nominal 95% rate stemmed mainly from bias.

Conclusion

While optimal variable selection for causal inference is theoretically possible with detailed knowledge of the causal graph underlying the data generating process\cite{16} in practice it is an intractable problem\cite{8}. It is not empirically verifiable from data whether a given adjustment set satisfies the exchangeability assumption, and a variable that would induce M-bias is statistically indistinguishable from a confounder that is important to adjust for. Thus, without excellent subject matter knowledge, adjustment sets are bound to be imperfect. If a researcher is able to identify a set of variables they are confident contains a sufficient adjustment set, it probably contains extraneous variables as well. Past simulation studies have produced insights and heuristics about the consequences of extraneous variables for causal inference. However, it is not known to what degree these general heuristics extend to settings in which recently introduced cross-fit doubly robust estimators with machine learning nuisance models are required. How well can cross-fit machine learning effect estimators discard (or utilize) extraneous adjustment variables?

Our results were largely consistent with past simulation studies. In particular, Brookhart et al\cite{2} found that adjusting for variables associated with exposure but not the outcome could increase variance and inflate unmeasured confounding bias. This result was confirmed and generalized theoretically by Ding et al\cite{17}. In our extraneous exposure-associated variable simulation setting, there was no structural bias due to unmeasured confounding to inflate, i.e. the exchangeability assumption held. Presumably, if we had generated very large data sets under this setting the bias would have shrunk to zero. However, in our realistically sized data sets, there was some residual confounding bias due to failure to properly statistically adjust for the observed confounding variables, especially in the presence of extra adjustment variables. This residual confounding bias was inflated by adjustment for extraneous strongly exposure-associated...
variables.

Past simulation studies have further shown that adding variables associated with the outcome is generally beneficial, reducing variance without inducing bias. Our results were somewhat consistent with this finding, with extraneous strongly outcome-associated variables inducing little to no bias. However, weakly outcome-associated variables did induce some bias, possibly reflecting that when it is difficult to properly adjust for the actual confounders due to complex nuisance models, ‘distractions’ in the form of extraneous variables of any kind can be detrimental.

Of course, it is not surprising that M-bias inducing variables lived up to their name. There was no expectation that machine learning could magically compensate for violation of the exchangeability assumption required for causal inference. It might be reassuring that, at least in this setting (designed to be fairly realistic), M-bias from 10 variables with weak associations with exposure and outcome was hardly stronger than the bias induced by extraneous noise variables.

We might have hoped that pure noise variables would have been discarded by the machine learning algorithms and thus caused undetectably little bias. Unfortunately, it seems that even adding a relatively small number of noise variables ‘distracts’ the nuisance models enough to induce moderate residual confounding bias with a sample size of 3,000.

We believe our ‘Mixed’ simulation setting offers a roughly realistic picture of the impact of extraneous variables one might see in practice. Bias is non-negligible, enough to highlight the potential importance of strong subject matter knowledge to winnow down the adjustment set but without causing too much pessimism at the prospect of reliable causal inference from observational data.

Of course, in all of our simulation settings the true set of confounders was contained in the adjustment set, which would seldom be the case in a real study. But these results still suggest some guidance for variable selection (and, from an informatics perspective, collection) with state-of-the-art machine learning causal effect estimators if nuisance models are thought to be complex. In particular, the simulations illustrate that when nuisance models are complex the (common) strategy of ‘throwing everything in’ for the machine learning models to sort out comes with a price. Extraneous variables provide little to no upside in this setting (unlike the simple nuisance model case, where outcome-associated variables are net beneficial) and potentially significant downside (exposure-associated variables induce bias even in the absence of unmeasured confounding, M-bias lurks). The simulation does not offer guidance on how to trade off the risks of extraneous variables against the risks of omitted variable bias in a given application, but makes clear that the tradeoff does still exist even when using machine learning for adjustment. This is contrary to the attitude (that we have often heard expressed and even held ourselves) that, apart from M-bias, including extraneous variables is inconsequential when using machine learning to fit nuisance models. The primary contribution of machine learning to causal inference should probably be viewed as fitting flexible nuisance models to adjust for carefully selected covariates, not variable selection. That said, apart from rather extreme cases of M-bias, effect estimates were pretty reasonable across settings, and this study is not cause for despair for researchers who lack strong subject matter knowledge to guide variable selection and nonetheless find themselves in the fortunate situation of believing that available covariates contain a sufficient adjustment set.

Abstract

Use of Electronic Nicotine Delivery Systems (ENDS, colloquially known as “electronic cigarettes”) has increased substantially in the United States in the decade since 2010. However, currently relatively little is known regarding the documentation of ENDS use in clinical notes. With this study, we describe the development of an annotation scheme (and associated annotated corpus) consisting of 4,351 ENDS mentions derived from Department of Veterans Affairs clinical notes during the period 2010-2020. Analysis of our corpus provides important insights into ENDS documentation practices at the VA, in addition to providing a resource for the future development and validation of Natural Language Processing algorithms capable of reliably identifying ENDS-use status.

Introduction & Motivation

Electronic cigarettes — e-cigarettes, e-cigs, vapes, or Electronic Nicotine Delivery Systems (ENDS) — have exploded in popularity over the last ten years in the United States. It is estimated that by 2012, 75% of American adults had heard of ENDS, and 8.1% had tried them.1 By 2014, 94% of Americans had some awareness of ENDS, and 12.6% had tried them.2,3 Despite the growth in popularity of the product, little consensus currently exists regarding the safety of ENDS devices, with regulatory authorities, professional associations, and individual clinicians divided as to whether ENDS constitute a valuable smoking cessation tool,4,5 or rather are a potentially harmful technology that risks eroding hard-won achievements in denormalizing smoking.6,7 This uncertainty regarding the potential safety risk of ENDS use was further amplified by the 2019 outbreak of E-cigarette or Vaping Product Use-Associated Lung Injury (EVALI) in the United States,8 a development that sparked calls for enhanced regulation and surveillance of the products.9

Clinical practices regarding the documentation of ENDS use in the Electronic Health Record (EHR) are currently poorly understood, and what evidence that does exist regarding documentation patterns suggests that ENDS use is massively under-documented.10,11 This under-documentation is perhaps partially due to the absence of a standardized means of recording ENDS use in EHR systems,12 a situation that — at least for some health systems — has recently seen changes with the introduction of specific fields for capturing ENDS use.13 However, it holds true that, in the majority of cases, ENDS documentation, if it exists at all, is dispersed across clinical notes, thus necessitating the application of Natural Language Processing (NLP) methods or manual abstraction to extract relevant information. Further, the type of documentation commonly found in clinical notes (e.g. type of ENDS device, duration of ENDS use, frequency of ENDS use, ENDS start date, ENDS end date) is currently not well understood.

With this study, we describe the development of an annotation scheme (and associated annotated corpus) consisting of 4,351 ENDS-related mentions derived from Department of Veterans Affairs (VA) clinical notes during the period 2010 to 2020, in order to better understand how clinicians document ENDS use, and to develop a validated resource for the future training and evaluation of NLP algorithms to execute the task of automatically determining ENDS use status.

Background

The VA EHR provides a unique national dataset with which to investigate ENDS documentation and usage patterns, given that it is the largest healthcare system in the United States with 1,255 healthcare facilities nationwide and is used by over nine million veterans per year.12 The VA patient demographic is particularly interesting from a tobacco
The VA collects data regarding patient smoking history and current smoking status using several different approaches at the time of patient encounter. Chief among these is the utilization of Health Factors. However, health factors cannot easily be used to reliably identify the type of tobacco product used, and — most salient to our research question — whether a patient is an ENDS user. In the VA context, this ENDS-use information is typically found embedded in clinical text.

Automatically identifying smoking status using the EHR is a well-developed research area that has utilized a number of different methods, including the use of structured data, semi-structured data, and NLP approaches. However, there has been relatively little work focused on how ENDS use — as opposed to combustible tobacco use — is currently documented in the EHR. Notable exceptions include ENDS annotation scheme and corpus development work at Fairview Health System in Minneapolis and analyses of ENDS documentation using keyword matching methods conducted at the VA and on a larger scale, at Kaiser Permanente. All these health systems exhibited an increase in ENDS use documentation (i.e. the prevalence of ENDS-related keywords) over time, but notable, this increase is below what would be expected given the prevalence of ENDS use in the general population, indicating that ENDS use is systematically under-documented in these systems.

Our overarching aim with this study is to analyze ENDS documentation patterns in VA clinical notes, including how ENDS documentation practices have changed over time. More specifically, we report on the development of an annotation scheme (and a manually annotated corpus based on that annotation scheme) suitable for the annotation of ENDS mentions in VA clinical notes. Our resulting corpus consisted of 4,351 annotations across sixteen annotation categories related to ENDS usage (e.g. potential-user, passive-exposure, attempting-to-quit-ENDS) that can be utilized as a resource for the future development and validation of NLP algorithms. The contribution of this work consists in (a) the development of validated annotation guidelines for annotating ENDS mentions in VA clinical notes and (b) based on this annotation scheme, the development of a high-quality manually annotated corpus that provides important insights into the range of current and historical ENDS use documentation practices, in addition to providing a resource for the future development and validation of NLP algorithms. The development of an annotated corpus is a necessary condition for the creation and validation of an NLP algorithm capable of reliably determining ENDS use status, which in turn is required to interrogate EHR systems regarding key open epidemiological questions concerning ENDS use (e.g. what proportion of ENDS users quit tobacco? are clinicians recommending ENDS use as a cessation method?)

Materials & Methods

Our initial cohort consisted of VA patients with a history of smoking (as determined by VA Health Factors) who had utilized clinical services between 2010 and 2020. To better understand how ENDS terminology has changed over time, we used a set of ENDS-related keywords derived from various sources, including previous work, additional iterative corpus data analysis, and a word-embedding model trained on the totality of VA notes. This process resulted in 77 keywords that were categorized into five broad groups (electronic cigarette, e-cigarette, e-cig, vape) or other keywords (other variants). Using these keywords, we performed a search across our corpus of 4,604,856 million patients in order to allow us to identify the prevalence of ENDS keywords and observe changes in ENDS terminology over time. This process resulted in the identification of 1,638,884 ENDS mentions for 418,170 patients across 1,191,133 clinical notes. From our cohort of VA patients, we randomly sampled notes containing ENDS mentions. We then iteratively developed an annotation scheme for VA ENDS use documentation, using prior work reported in Winden et al. as our starting point. Four individuals participated in the annotation scheme construction process (authors MC & PA, in addition to two annotators with a background in nursing). The resulting annotation scheme consisted of five top level annotation categories (Active-User, Usage-Unknown, Irrelevant, Former-User, and Non-User) and sixteen lower level categories (see Figure for a graphical representation of the annotation scheme workflow, with additional examples provided in Table). In addition to annotation type, each ENDS mention is associated with demographic characteristics derived from structured data in the VA EHR (including gender, urban/rural location, outpatient/inpatient status, and age range). Further, each annotation is associated with its source note type (e.g. primary care, mental health,
Figure 1: Annotation scheme flowchart
As can be seen from Figure 2, there have been striking changes in ENDS-related terminology since 2010, with “vape”-related keywords superseding previously dominant ENDS keywords like “e-cigarette”.‡ Given this observation — i.e. that keywords used to refer to ENDS in clinical documentation shifted substantially over time — we elected to construct a stratified sample of ENDS mentions for the development of our annotated corpus. The initial stratified set of documents was created by selecting 200 random ENDS mentions every year from 2010-2020 (n = 2,200). In order to account for the increased variation and changes in usage in recent years, a second set of instances was selected using 250 randomly selected mentions every year from 2016-2020 (n = 1,250). The third and final set of annotations was selected to be held out for final testing of any NLP algorithms. This third set was selected using a random set of ENDS mentions proportionate to the total number of mentions identified each year (n = 901). In total, our annotated corpus consists of 4,351 ENDS mentions. Annotations were completed at the mention-level using Chex,27,28 a web-based, VA-developed application. Chex provides a simple user interface that allows annotators to view a small snippet of text surrounding an anchored keyword with the ability to expand to a complete document for further context when needed.

In order to ensure annotation quality, we double annotated sections of the corpus (10% of the training set and 100% of the test set), achieving comparable agreement scores to those gained during the annotation scheme development process. We computed agreement using Cohen’s kappa.29 Our annotation effort resulted in 4,351 ENDS mentions, derived from 4,345 clinical notes and 4,213 individual patients between 2010 and 2020.§

Results

Using our cohort of 4,604,856 patients we identified 1,638,884 ENDS mentions for 418,170 patients across 1,191,133 clinical notes in the VA EHR and observed rapid growth in both the volume and variety of ENDS-related terms over time (see Figure 2). The total volume of clinical notes containing ENDS-related keywords exhibited an average annual growth rate of 52.8% over the 10 year period, with 8,234 clinical notes identified in 2010 and 202,842 in 2019; this is

‡Note that a simple string matching approach was used to determine prevalence of a predetermined list of ENDS-related keywords that occurred in notes over the period 2010-2020. See previous footnote for a link to the complete set of keywords used.

§In line with our approved University of Utah Institutional Review Board protocol, and VA policy, the annotated corpus reported on in this paper cannot be publicly shared as it contains sensitive medical data.
compared to a 2.3% annual growth rate across all clinical notes, with or without ENDS documentation.

Our annotated corpus of ENDS mentions consisted of 4,351 annotations from the period 2010-2020. Table 1 shows a breakdown of the annotation types, with five top-level annotation categories and sixteen lower-level annotation categories. It can be seen that Active-User is the most frequent annotation type (43%) with Former-User the least frequent annotation type (3%). Of the Active-User group, the majority of mentions were related to tobacco cessation (either tobacco-cessation-related, cessation-counseling-pro or counseling-non-descriptive), with only a small proportion relating to attempts to quit ENDS. Four percent of mentions were found to be Irrelevant by annotators, with the majority of these Irrelevant posts referring to vaping cannabis. The initial annotation scheme development process yielded an agreement (kappa) of 0.7. The subsequent annotation effort yielded an overall agreement of 0.65 (0.85 for the top-level annotation categories Irrelevant, Usage-Unknown, Active-User, Non-User, and Former-User) on those portions of the corpus that were double annotated.

As discussed above, each ENDS mention is associated with patient demographic information derived from structured data in the VA EHR. Table 1 shows that — consistent with the wider VA patient population — 91% of annotated ENDS mentions are derived from the notes of male patients, and 9% of annotated ENDS mentions are derived from the notes of female patients. The difference between urban and rural locations was less marked than that between male and female, with 65% of annotated ENDS mentions derived from the notes of urban patients — or rather, patients who attended a VA facility in an urban area — and 35% derived from the notes of rural patients. Regarding age range, the majority of ENDS mentions were derived from individuals between the ages of 50 and 69, with the lowest number of mentions derived from the youngest age group (≤ 29). Documentation occurred in a range of clinical note types, with Other (a “catch-all” category that covers several internal medicine specialties) the most frequent note type (32%). Additionally, primary care notes and mental health notes were both well represented (31% and 12%, respectively).

**Discussion & Conclusion**

Our research has shown a considerable increase in ENDS documentation in the VA EHR over the period 2010-2020 (see Figure 2), with an average year-on-year growth rate of 53%, broadly reflecting ENDS use prevalence in the general population over the same period. In addition to the increase in the volume of ENDS mentions during the study period, our results show that the language of ENDS documentation has evolved over time, with terms like “vaping”
and “juul” (an ENDS brand name) supplanting previously popular terms like “electronic cigarette” and “e-cigarette” towards the end of the decade. This finding suggests that NLP systems designed to automatically identify ENDS use status must be flexible and adapt to change in language use over time. Unlike smoking status (i.e. combustible tobacco smoking status), where terminology is, if not standardized, then at least relatively stable over time (e.g. “2ppd”, “15 pack years”), ENDS documentation patterns are likely to continue to change quickly as technology and usage trends develop. As such, NLP systems designed to identify ENDS use must also evolve over time.

Winden et al.’s work on ENDS-related annotation scheme construction and corpus development provided a starting point for our VA-specific annotation scheme development process. However, there were some key differences in both the motivation of our work and in the specific characteristics of VA clinical note data that led us to substantially modify Winden et al.’s model for our specific needs. The work reported in this paper was primarily motivated by the goal of developing an annotation scheme and annotated corpus as a means of training and validating an NLP algorithm for identifying ENDS use status in the VA EHR. Given this motivation, it was necessary to include an Irrelevant annotation category for examples that include “false positive” ENDS-related keywords. Most of the examples of irrelevant mentions relate to cannabis use, particularly cannabis vaporization (e.g. “pt vapes marijuana”). A further distinctive feature of our annotation scheme is that it explicitly accounts for numerous types of semi-structured templates embedded in VA notes (e.g. “e-cigarette: Yes/No”) and use of facility-specific boilerplate language characteristic of VA notes (e.g. “the VA campus is a smoke free environment, including the use of e-cigarettes”). Excluding cannabis-related mentions, unfilled templates, and boilerplate language that does not directly refer to a patient’s specific ENDS use circumstances is a core requirement for an NLP algorithm capable of identifying ENDS use status at the VA.

Table 2: Corpus characteristics
Research presented in this paper is not without limitations. First, our data collection spanned the period from January 1st 2010 to March 1st 2020 (i.e. immediately before the first major impacts of the COVID-19 pandemic in the United States were felt). Given systematic and drastic changes in ENDS documentation patterns at the VA since the onset of the pandemic and the increased scrutiny of potential ENDS-related COVID-19 transmission at the VA, it will likely be necessary to annotate additional contemporary ENDS mentions in order to ensure that a resulting NLP algorithm can be successfully applied to both contemporary and post-pandemic clinical notes. Second, our annotation scheme was designed primarily for the annotation of VA clinical notes, and may not be suitable without modification for other EHR environments. Third, given the relatively small size of the corpus compared to the universe of VA clinical notes and the stratified sampling method adopted in the corpus construction process, the corpus cannot in itself form a basis for forming epidemiological conclusions regarding, for example, ENDS use prevalence in VA patients.

In conclusion, the research described in this paper provides useful insights into changes in VA ENDS-related documentation practices during the period 2010-2020, as well as providing a resource for the future development and validation of NLP algorithms designed to identify ENDS use status.

Acknowledgments

We would like to take this opportunity to thank Mr Gregory Stoddard, MPH for the provision of valuable statistical advice that served to guide our sampling and stratification strategy.

Funding Statement

Research reported in this publication was partially supported by the National Institute on Drug Abuse of the National Institutes of Health under award number R03DA047577 and received further support in terms of resources and facilities from the Department of Veterans Affairs (VA) Informatics and Computing Infrastructure under award number VA HSR RES 13-457. The views expressed in this article are those of the authors and do not necessarily reflect the position or policy of the National Institutes of Health, the Department of Veterans Affairs, or the United States government.

Abstract: Supported by the Centers for Medicare & Medicaid Services (CMS), Brigham and Women’s Hospital (BWH) has retooled the existing claims-based measures NQF1550 and NQF3493 into an electronic clinical quality measure (eCQM) to assess the risk-standardized complication rate (RSCR) following elective primary total hip (THA) and knee arthroplasty (TKA) at the clinician group level. This novel eCQM includes risk-adjustment for social determinants of health, includes all adult patients from all payers, leverages electronic health records (EHRs) rather than claims-based data, and includes both inpatient and outpatient procedures and complications which offers benefits compared to existing metrics. Following testing in two geographically different healthcare systems, the overall risk-standardized complication rate within 90 days following THA and TKA at the two sites was 3.60% (Site 1) and 3.70% (Site 2). This measure is designed for use in the Merit-Based Incentive Payment System (MIPS).

Introduction

Total hip arthroplasty (THA) and total knee arthroplasty (TKA) are common elective surgical procedures with 650,674 primary TKAs and 374,873 primary THAs performed in the United States in 2018 alone.1 Although rates of complications (including pneumonia, pulmonary embolism, periprosthetic joint infection, and wound infection) following these procedures are relatively low (ranging from 1.8%-9.0%)2 they can be life threatening.1 The danger of these complications and the variation in rates suggests a need for routine measurement and quality improvement.3 The demographics of patients receiving TKA and THAs are rapidly changing, and the fastest growing age group undergoing the procedures are individuals under the age of 65.4,5 Considering the projected rise in THA and TKA in the coming years,6 there is a need for robust, inclusive, and accessible evaluation measures for these procedures.7

Electronic clinical quality measures (eCQMs) are quality tools which are available to eligible hospitals, clinicians, or clinician groups that measure and track the quality of health care services.8 Starting in 2013, eCQMs across medical specialties have been developed to work within EHR systems to capture, export, calculate, and report information to provide outcome data without imposing documentation burden on clinicians.9 This proposed risk-standardized complication rate (RSCR) eCQM is designed for use within the Centers for Medicare & Medicaid (CMS) Merit-Based Incentive Payment System (MIPS) which provides an opportunity for clinicians and clinician groups to receive performance-based payment based on the quality of care provided to their patients and efforts taken to improve the quality of care.10

There are currently two related measures approved for use by the National Quality Forum (NQF), NQF155011 and NQF3493.12 Both measures are Clinical Quality Measures (CQMs) rather than eCQMs, meaning that they use claims-based data rather than electronic health record (EHR) data. These measures include only Medicare beneficiaries, and are limited to inpatient hospitalization complications.11,12,13 The objective of this research was to retool the NQF1550 and NQF3493 measures into an eCQM with an expanded inclusion population to provide a more meaningful way to analyze complication rates following joint replacement procedures.10 The
Testing of a Risk-Standardized Complication Rate eCQM for THA and TKA

retooled measure would include all adult patients and assess clinician group level complication rates in patients post-THA and TKA for use in the MIPS pathway.

This manuscript details the testing of the proposed RSCR eCQM in two geographically distant U.S. healthcare systems to assess post-THA/TKA complication rates at the clinician group level. If endorsed, this RCSR eCQM has the potential to improve patient outcomes as there are currently no NQF approved measures which track complications following elective primary THA and TKA that include all payers and all patients aged 18 years and older.

Materials and Methods

Study design

The development of this measure was comprised of alpha and beta testing of longitudinal data from all clinician groups within two large U.S. healthcare systems. This project was approved by the Human Subjects Committee, the Institutional Review Board (IRB) of Mass General Brigham. Alpha testing was used to assess the feasibility of implementing the measure into EHR systems, and beta testing quantitatively assessed the measure’s reliability and validity, providing RSCRs across sites, and additional information about feasibility.

The measure is comprised of a numerator and denominator, where the denominator is the total sample of THA patients and TKA patients who fit the inclusion criteria, and the numerator is the subset of patients who experienced the defined complications within 90 days of their procedure. This ratio is expressed as a percentage, where a lower RSCR is indicative of higher quality care. Complications are dichotomous as a yes/no event, where the occurrence of one or more complications results in inclusion of a patient in the numerator. Risk adjustment variables were harmonized with the NQF1550 to include: one or two procedures, comorbid conditions, and age. The model was then expanded to include race, sex, household income (using zip code as a proxy), language (English, non-English), smoking status, and body mass index (BMI). These risk adjustment variables were included in the retooled measure as they are all associated with worsened outcomes following THA and TKA; as this eCQM measures clinician level outcomes, the goal of the risk adjustment model was to reflect surgical performance without the influence of patient risk factors.

Post-procedural THA/TKA complications (harmonized with NQF1550) are defined as the following: acute myocardial infarction (AMI), pneumonia, sepsis/septicemia/shock, surgical site bleeding, pulmonary embolism, mechanical complications, periprosthetic joint infection/wound infection, and death. Table 1 below describes the number of days following the procedure date that a complication can be attributed to the procedure for inclusion in the numerator. A complication is counted in the numerator if it occurs at any point during the index admission, even if the index admission lasts longer than 7, 30, or 90 days. These time frames were harmonized with the NQF1550.

Setting and Participants

eCQM testing used data from two large, geographically different, healthcare systems (described as ‘Site 1’ and ‘Site 2’) in the United States. Site 1 was comprised of six clinician groups with data from 2016-2019 and used the EHR vendor ‘Epic.’ Site 2 was comprised of eleven clinician groups with data from 2017-2019 and used the EHR vendor ‘Cerner.’ The following types of data were analyzed from EHR systems: administrative and billing data, patient demographics, procedures performed, and diagnoses.

All patients aged 18 years and older who received a primary elective THA and/or TKA from the two geographically different healthcare sites from 2016-2019 (Site 1) and 2017-2019 (Site 2) were included in the cohort. Harmonized with NQF1550, patients were excluded if they did not fit the inclusion criteria, if they left the hospital against medical advice (AMA), or if they had more than two THA/TKA procedure codes documented during the index admission. Unlike NQF1550 and NQF3493, both inpatient and outpatient procedures were analyzed. Clinician groups within each site who performed <50 THA and TKA procedures were excluded due to low sample size.

Alpha Testing

Alpha testing was performed to determine the feasibility of implementing the RSCR eCQM into EHR systems in two sites. Factors of interest in this testing included how eCQM data elements are captured, where they originate, how they are recorded and defined, their availability in different EHR systems, and if the eCQM data
element’s format and structure are consistent with the intent of the proposed measure. Alpha testing was performed using data from all patients aged 18 years and older that received a primary elective THA or TKA irrespective of inclusion/exclusion criteria.

The frequency of data elements in the samples from both sites was tested to confirm the data elements needed for risk-adjustment were routinely available. Reliability was tested using the NQF Feasibility Scorecard. Under CMS criteria, the feasibility of data elements is scored in the categories of data availability, data accuracy, data standards, and workflow. Chart reviews were conducted to assess measure agreement between the eCQM and manual review to confirm that the eCQM was correctly categorizing patients into the numerator, denominator, or excluded group. Separate chart reviews were performed on both random samples of patients who met the inclusion and exclusion criteria. Cases of disagreement between EHR abstraction and the eCQM were documented and discussed between team members. Disagreements were analyzed to implement changes that increased the accuracy of the eCQM. Kappa scores and 95% confidence intervals were assessed for each round of review.

**Beta Testing and Risk-Adjustment**

Beta testing was conducted using data from both sites to determine a complication rate by site, and by clinician groups within sites. Data from the included samples from both sites were randomly split into test and validation samples (50% in each sample) and fit the same generalized linear mixed model (with same covariates) in both samples. The demographics of the test and validation samples were compared (using P values) to explore similarities between the groups. Predicted over expected ratios (P/E) and 95% confidence intervals were calculated for the test and validation samples for all clinician groups who performed ≥50 procedures (for risk-adjustment, a minimum of 25 procedures were needed for both the test and the validation samples).

The RSCR is calculated as the ratio of the number of “predicted” to the number of “expected” cases with a complication within a given clinician group, multiplied by the unadjusted rate of the total sample. The measure estimates clinician group-level RSCRs using hierarchical logistic regression models. This approach models the log-odds of a patient experiencing a complication occurring within 90 days of the index admission using the risk adjustment variables and clinician group-specific intercepts. At the clinician group level, it models the group-specific intercepts as arising from a normal distribution. In this model, the clinician group intercept represents the underlying risk of complications for procedures performed by said group, after accounting for the patient risk factors in the risk adjustment model. If there were no differences among clinician groups, then after adjusting for patient risk, the group level intercepts should be identical across all groups.

The agreement between the estimates of the complication rates from each provider group in the test and validation samples was compared using a Spearman correlation coefficient. The risk-adjustment of this measure at the clinician group level was performed by multiplying the predicted/expected ratio in the test and validation samples by the total sample complication rate. 95% confidence intervals were calculated for each clinician group RSCR. Several statistical tests were performed to test the adequacy of the model. A C-statistic in the test and validation samples was calculated to see if discrimination was similar between both groups. A ROC curve was performed to compare the performance between test and validation samples. A Hosmer-Lemeshow test was used to assess the goodness of fit for the logistic regression model used for risk adjustment. An intraclass correlation coefficient (ICC) was performed to assess the variability in clinician groups.

**Results**

**Alpha Testing**

The total sample was comprised of 29,069 patients, 17,548 from Site 1, and 11,521 from Site 2. Across the total sample, data elements needed for risk adjustment were commonly populated (>98% complete) across both sites for insurance type, BMI, primary language, zip code, sex, admit age, and condition (Table 2). Data were missing for racial identity in Site 1 (95.67% complete) and smoking status in Site 2 (86.81% complete). Missing data comprised less than 3% for all other variables and therefore was viewed as unlikely to impact measure results.

Using the NQF feasibility scorecard, the eCQM development team confirmed that all data elements were available, accurate, coded using nationally accepted terminology standards, and captured by clinicians during the course of care without additional documentation burden in both sites. Manual chart reviewers and the eCQM had excellent agreement, the included sample (n=217) had a final Kappa=0.95 (Table 3), and the excluded sample (n=217) had a final Kappa=1.0 (Table 4). These indicate near perfect inter-rater reliability in the included sample chart reviews, and perfect inter-rater reliability in the excluded sample chart reviews (Table 6).

**Beta Testing and Risk Adjustment**

At Site 1 from 2016-2019, 88.93% (n=15,607) of patients met the inclusion criteria with an unadjusted complication rate of 3.24%. At Site 2 from 2017-2019, 88.94% (n=10,247) of patients met the inclusion criteria with a crude complication rate of 4.28%. Descriptive statistics of the included sample can be found in Table 5.

| COPD | 4.49% | 3.55% | Trauma | 0.04% | 4.85% |

*Low rate of osteoarthristis in Site 2 is validated; Site 2 comorbid condition information was pulled from ICD10 codes upon discharge following THA and/or TKA, while Site 1 comorbid condition information was pulled from ICD10 codes upon admission prior to the THA and/or TKA.

Site 1 (n=15,607) had an overall unadjusted complication rate of 3.24% with rates ranging from 1.36%-4.51% across clinician groups. Site 2 (n=10,247) showed an overall unadjusted complication rate of 4.28%, with rates ranging from 3.02%-26.79% across groups. The total sample complication rate was 3.66%.

Table 6 displays the unadjusted complication rates with the associated test and validation samples of the predicted/expected ratios by clinician group, where 50% of patients per clinician group are in the test sample, and 50% of the patients per clinician group are in the validation sample. With these ratios, 1.0 represents the overall complication rate in the total sample, and the higher or lower the P/E score is, the higher or lower the complication rate within that specific group. Site 1 Group G and Site 2 Group A were excluded due to low sample size. A full list of the logistic regression coefficient estimates used to calculate the P/E can be found in Table 10.

We compared sociodemographic characteristics of patients included in our test and validation samples (Table 7) and found there were no differences at the patient level (p=0.434-0.840), by patient SES variables (p=0.085-0.820) or between clinician groups (p=0.999). The test and validation samples give similar rankings of the six clinician groups with respect to the predicted/expected ratios and gives a Spearman rank correlation of 0.978. The model has similar performance in both the test and validation samples (ROC=0.670 in both the test and validation sample).

Unadjusted complication rates demonstrated a large amount of variation between the two healthcare systems, as well as between individual clinician groups. In the unadjusted results, the crude rate at Site 2 (4.28%) was 1.32 times greater than the unadjusted complication rate at Site 1 (3.24%). When accounting for the risk factors, rates across sites became more similar. The overall Site 1 adjusted rate was 3.60% (ranging from 3.27%-3.90%). The overall Site 2 adjusted rate was 3.70% (ranging from 3.46%-4.25%) (Table 8).

Table 8: Risk-Adjusted Complication Rates with 95% Confidence Intervals

Unadjusted complication rates demonstrated a large amount of variation between the two healthcare systems, as well as between individual clinician groups. In the unadjusted results, the crude rate at Site 2 (4.28%) was 1.32 times greater than the unadjusted complication rate at Site 1 (3.24%). When accounting for the risk factors, rates across sites became more similar. The overall Site 1 adjusted rate was 3.60% (ranging from 3.27%-3.90%). The overall Site 2 adjusted rate was 3.70% (ranging from 3.46%-4.25%) (Table 8).
Testing of a Risk-Standardized Complication Rate eCQM for THA and TKA

Differences in patient characteristics were controlled well across both sites, with an intraclass correlation coefficient (ICC) of 0.0055 (95% CI = -0.017 - 0.027), meaning that only 0.55% of variation in complications was explained by provider-group after risk-adjustment. Patient level characteristics (within effects) were predictive of the outcome with a c-statistic of 0.672 (test: 0.674, validation: 0.670). A Hosmer-Lemeshow calibration approach was used to test the goodness of fit of the logistic regression model. The Hosmer-Lemeshow calibration approach resulted in a P value of 0.8202, where a P value >0.10 demonstrates good fit between the predicted and expected values.24

Fig. 1: Total Sample and Results

Discussion

The overall risk-adjusted complication rates following THA and TKA ranged from 2.84%-3.43% in Site 1, and from 3.0%-3.75% in Site 2. The increase in overall rate (3.604% in Site 1, 3.694% in Site 2) compared to the NQF1550 overall rate (2.4%)2 demonstrates the strength of the proposed measure in capturing a more accurate complication rate by expanding the inclusionary population of the measure to include both inpatient and outpatient procedures and complications.

Several limitations were acknowledged during the measure testing process. Data were used from two different sites, however additional testing at other health systems is needed to fully assess eCQM performance. Measure testing across sites is both time consuming and financially straining, and it is challenging to test an eCQM across multiple sites. Provider groups from both sites used in the analysis were affiliated with large academic medical centers, meaning that these rates do not reflect complication rates in smaller community health systems or independent clinician groups.

At the health system policy level, differences were seen in data element availability and diagnostic practices. Although smoking status information was only available for 86.81% in Site 2, less than 3% of data was missing across all other variables and was not likely to impact measure results. In the Site 1 sample, 99.26% of patients had a diagnosis of osteoarthritis, these high rates were to be expected as joint arthroplasties are recommended for patients who suffer from osteoarthritis.25 In comparison, only 28.50% of patients in the Site 2 sample had a diagnosis of osteoarthritis, reflecting differences in how these conditions are defined in EHRs. An explanation for these differences could be that Site 1 documented comorbid conditions upon index admission prior to the TJA procedure, and that Site 2 documented comorbid conditions following the TJA procedure. Rates of post-traumatic osteoarthritis were low in both sites (Site 1: 0.0%, Site 2: 0.37%). As this measure quantifies the complication rate among patients undergoing primary elective THA and TKAs, patients with a diagnosis of post traumatic osteoarthritis (which indicates a joint injury)26 are likely to be excluded as these procedures would no longer classify a procedure as ‘primary’ or ‘elective.’ This measure focuses on primary elective THA and TKA procedures because procedures associated with injury face higher risks of complications and mortality and are not equally reflective of clinician group performance.27

Several statistical tests were performed to assess the risk adjustment model, including a C-statistic of 0.672. A C-statistic of 0.5 indicates that the predictive model is no better than random chance, and a C-statistic of 0.7 or
Testing of a Risk-Standardized Complication Rate eCQM for THA and TKA

above indicates a good model, indicating that our model was better at predicting complications than random chance, but has room for improvement in future site testing. In comparison, the C-statistic for the NQF3493, which is already implemented into the MIPS pathway, was 0.65 across datasets.

The risk adjustment model for the RSCR eCQM was developed using published literature and stakeholder advisement from patients, healthcare plan payers, and providers. More information on the development of the risk-adjustment model can be found in Dykes et al., 2021. There are concerns within the field of quality measurement that payment programs, like MIPS, subject hospitals with higher proportions of socioeconomically disadvantaged populations to disproportionate financial penalties where providers are penalized for patient population risk factors, rather than clinical performance. During the measure development process, patient demographics including race, income level, and primary language were found to be associated with worsened outcomes following THA and/or TKA, and were included in the risk-adjustment model to quantify rates reflective of clinician group performance. While this risk-adjustment strategy aims to reflect surgical performance, measure developers must also acknowledge that adjusting for race and income may imply that worsened outcomes by race and income are justified or are not to be further explored. While the RSCR eCQM adjusts for socioeconomic variables, future research is needed to understand the significant differences in TJA outcomes by race and income, and to amend these disparities with equity-based interventions.

In comparison to the NQF1550 and NQF3493 measures, the RSCR eCQM provides several unique benefits. Firstly, this eCQM uses widely available and routinely collected EHR data, making it possible to use the eCQM in a timely manner without imposing documentation burden on clinicians. Using EHR data coded with established standards also means that this measure is interoperable between different EHR systems (e.g., Epic, Cerner) that use national coding standards. Secondly, including both inpatient and outpatient complications in the measure gives more insight into the true THA/TKA complication rate. Next, as this eCQM involves elective primary THA and TKA procedures from all payers, rather than solely from Medicare beneficiaries, the inclusion age is lowered from 65 to 18 years, which is especially relevant as the fastest growing segment of the population receiving these procedures are under 65 years of age. Finally, this proposed eCQM risk-adjusts for a more diverse set of health determinants than the existing NQF1550. As MIPS provides financial incentives to physicians to achieve lower complication rates, risk-adjusting for patient variables which are known to be associated with higher complication rates means physicians would not face MIPS penalties by treating complex patients. Table 9 describes the similarities and differences between the two existing measures and the proposed RSCR eCQM.

| Table 9: Comparison Between Existing RSCR Measures and the Proposed RSCR eCQM |
|---------------------------------|--|------------------|-----------------------|
| **Care Setting:**               | Hospital Level | Individual Clinician, Clinician Group Level | Clinician Group Level |
| **Measure Type**                | CQM (claims based) | eCQM (EHR based) |
| **Sample Population:**          | Medicare Fee for Service Beneficiaries | All Payers |
| **Insurance Type:**             | Patients age 65+ | Patients age 18+ |
| **Age:**                        | Inpatient Procedures | Inpatient and outpatient procedures and complications |
| **Location:**                   | Inpatient Procedures | Inpatient and outpatient procedures and complications |
| **Risk Adjustment Variables:**  | Age | Sex | Number of Procedures (1,2) | Procedure Type (THA, TKA) | Comorbid Conditions |
|                                | Age | Sex | Number of Procedures (1,2) | Procedure Type (THA, TKA) | Comorbid Conditions |
|                                | +Race | +Income (Zip Code) | +Smoking status | +Primary Language | +Body Mass Index (BMI) |

The RSCR eCQM has been submitted for NQF approval and CMS Measures Under Consideration (MUC) list consideration. If endorsed, this will be the only NQF approved eCQM which measures the risk-standardized complication rate following THA and TKA for all adult patients from all payers. If this measure is endorsed, the RSCR eCQM has the potential to enhance the MIPS program by informing healthcare provider groups about opportunities to improve care, strengthen incentives for quality improvement, and ultimately improve the quality of care received by patients.

Abstract

**Objective:** To establish and validate mappings between primary care clinical terminologies (Read Version 2, Clinical Terms Version 3) and Phecodes. **Methods:** We processed 123,662,421 primary care events from 230,096 UK Biobank (UKB) participants. We assessed the validity of the primary care-derived Phecodes by conducting PheWAS analyses for seven pre-selected SNPs in the UKB and compared with estimates from BioVU. **Results:** We mapped 92% of Read2 (n=10,834) and 91% of CTV3 (n=21,988) to 1,449 and 1,490 Phecodes. UKB PheWAS using Phecodes from primary care EHR and hospitalizations replicated all (n=22) previously-reported genotype-phenotype associations. When limiting Phecodes to primary care EHR, replication was 81% (n=18). **Conclusion:** We introduced a first version of mappings from Read2/CTV3 to Phecodes. The reference list of diseases provided by Phecodes can be extended, enabling researchers to leverage primary care EHR for high-throughput discovery research.

Introduction

Phenotype codes (Phecodes), are a hierarchical phenotype classification system offering a reference list of diseases for genetic and clinical research\textsuperscript{(1,2)}. Phecodes were originally created by mapping to coded electronic health records (EHR) using International Classification of Diseases (ICD) 9-Clinical Modification (CM), and more recently ICD-10 and ICD-10-CM\textsuperscript{(3)}. Phecodes may overcome some of the shortcomings of these and other clinical classification systems with each leaf node representing a clinically recognisable diagnosis. In the UK Biobank\textsuperscript{(4)}, a large scale resource of genomic sequencing and longitudinal phenotypic information, linkage has been obtained to longitudinal primary care information as well as information on hospital admissions. Although hospital episodes are coded using the ICD system, primary care data are coded using the Read version 2 (Read2) and Read version 3 (Clinical Terms 3 or CTV3) controlled clinical terminologies. Both terminologies provide a common standard vocabulary for clinicians and have been widely used for research\textsuperscript{(5,6)}.

Phecodes validated for the primary care setting, might offer several advantages. First, acute and chronic disease is often diagnosed within primary care settings in the UK. Patients with a disease treated in primary care may represent less severe forms of the disease than those who are treated in hospital. Phecodes can potentially act as data scaffolding providing a reference list of diseases between primary and secondary care settings. At a practical level, there is a need to reduce dimensionality of primary care EHR (with ~ 400K unique ontology concepts utilized) in a reproducible fashion to enable high-throughput phenotypic and genetic analyses\textsuperscript{(2)}. Controlled clinical terminologies that are used in primary care data however have not been mapped to Phecodes. As a result, the extent to which using primary care derived Phecodes offer a valid approach or whether they can provide additional statistical power or markers of disease severity is yet to be explored.

In this paper, we sought to develop and validate a mapping of clinical terminologies used in UK primary care EHR to Phecodes. Specifically, this was achieved through three objectives:

1. Create mappings between the Read controlled clinical terminology (Read2 and CTV3) and Phecodes.
2. Translate primary care EHR data in the UK Biobank to Phecodes.
3. Evaluate the mapping quality by conducting PheWAS analyses in the UK Biobank and BioVU and seeking to replicate previously-reported genotype–phenotype associations.
**Methods**

**Population and data sources**
We used data from the UK Biobank (UKB), a prospective study of 500,000 deeply phenotyped individuals recruited from England, Scotland and Wales. Longitudinal follow up for UKB participants is achieved through linkages to national data sources covering primary care, hospitalizations, cancer registrations and mortality. Specifically, information on hospital admissions for the entire cohort is available for all admitted patient episodes and is coded using ICD-9 and ICD-10 for (primary and secondary) diagnoses and OPCS-4 for surgical procedures. Approx 50% of participants have their primary care record linked which provides information on diagnoses, symptoms, laboratory results, referrals, examination findings and prescriptions.

Primary care EHR were extracted from four data sources based on three EHR vendors (two in England from Vision and TPP SystmOne, and two in Scotland and Wales combining data from EMIS and Vision). The basic unit of interaction in primary care is a consultation (similar to an admission in secondary care) during which the clinician records information directly into the EHR. In the UK, primary care healthcare concepts (except prescriptions) are recorded using Read codes, a hierarchical controlled clinical terminology. Read codes are used in two versions: Read Version 2 (Read2), also known as the 5-byte Read consists of ~100,000 concepts and Clinical Terms Version 3 (CTV3), consists of ~390,000 concepts and contains all Read 2 concepts. Both versions of Read are organized in 30 top level chapters in a fashion similar to ICD-10; e.g. chapter “G” is for Circulatory System Diseases Relationships in Read2 are derived directly through the code structure meaning only single parent-child term relationships are supported. In CTV3, relationships are defined through a separate relationship table and supports polyhierarchical relationships (e.g. ‘Infective pneumonia’ has two parents: ‘Pneumonia’ and ‘Acute lower respiratory tract infection’). SNOMED-CT, which is now becoming an international standard for recording information across healthcare settings and has >400K concepts encapsulates by definition all CTV3 terms since CTV3 was one of its core components.

**Mapping Read2 and CTV3 to Phecodes**
We implemented a systematic data-driven approach leveraging terminology reference sets, cross-map files, and expert input to map primary care EHR to Phecodes (Figure 1). The approach, which was similar for both Read2 and CTV3 is described below:

1. Retrieve all unique Read2/CTV3 codes from the UKB `gp_clinical` file.
2. Establish eligible codes Read2/CTV3 terms for mapping
   a. Remove Read2/CTV3 codes related to drug prescription events (defined in the Read Codes Drug and Appliance Dictionary (DAAD) dictionary and identified by having a lower-case first character).
   b. Remove invalid Read2/CTV3 codes (e.g. ‘XXXX’, ‘@@A2’) or local General Practitioner (GP) codes which could not be identified in the NHS terminology reference and are often used as placeholders (e.g. ‘UTEST’ or ‘UAB00’).
   c. Remove Read2/CTV3 codes related to occupations, examinations, symptoms, diagnostic and laboratory procedures (all codes in Read chapters 0 to 9 inclusive).
3. Map Read2/CTV3 codes to ICD-10 using the NHS Digital Technology Reference data Update Distribution (TRUD) (7) cross-map file and remove codes which were not not found in the map file.
   a. Remove Read2/CTV3 codes where the mapped ICD-10 chapter is X (Other external causes of accidental injury, self-harm), Y (Assault, legal interventional, complications) or Z (Factors influencing health status and contact with health services) as they were excluded in the original Phecode definitions.
   b. Exclude Read2/CTV3 codes mapping to an entire ICD-10 chapter (e.g. “H…. Respiratory diseases” maps to ICD-10 Chapter X “Diseases of Respiratory System”) since they are rarely used and are too broad.
4. Apply manual refinements e.g. recode specific ICD-10 leaf nodes to parent nodes (described in next paragraph)
5. Map ICD-10 codes to Phecodes using the existing translation file (3) (version 1.2beta).

Mappings between Read codes and ICD-10 defined in the “cross map” file used in the algorithm are defined in a different approach as outlined in Table 1. Where multiple target ICD-10 concepts existed (e.g. “one-to-block” mappings in Read2 or “type A” mappings in CTV3) we chose the broadest ICD-10 concept available (often, but not always, identified by the fourth digit being equal to ‘9’ e.g. L21.9 – Seborrheic dermatitis, unspecified). This was
done in order to avoid assigning a specific diagnosis when the source Read concept was broader than the candidate target ICD-10 concept. Where asterisk, dagger or asterisk and dagger terms were specified in the map file, we retained the most specific of ICD-10 (e.g. “H36.0 Diabetic Retinopathy” was preferred over “E14 Unspecified diabetes mellitus”). In instances where one Read2/CTV3 to many target ICD-10 concepts were defined in the map file, we added all individual ICD-10 codes as new records (e.g. Read2 code “F4K0.0 Scleritis and episcleritis” was mapped to two ICD-10 codes “H15.0 Scleritis” and “H15.1 Episcleritis”). In all other cases where a one-to-one map type was supplied, we used the target ICD-10 code specified. Finally, in order to align the target ICD-10 codes with the ICD-10-Phecode map, in some cases we upcoded (specific to broad) or downcoded (broad to specific) terms. Specifically, in some cases four character ICD-10 codes were remapped to children terms (e.g. “J34X Other disorders of nose and nasal sinuses” was remapped to “J34.8 Other specified disorders of nose and nasal sinuses”). In other cases, specific children terms were remapped to broader parent terms (e.g. “I48.9 Atrial fibrillation and flutter, unspecified” was remapped to “I48 Atrial fibrillation and flutter”).

Table 1. Map types specified by the NHS TRUD terminology cross-map files between source terms in Read2 and CTV3 to target ICD-10 codes. The Type column denotes the cardinality of the map; for example, one-to-one denotes one source term with exactly one target term while one-to-many denotes one source term with multiple potential target terms.

Assigning Phecodes, separately in primary care and hospitalisation data

All unique codes from primary care (Read2, CTV3) and hospitalisations (ICD-10) from each UKB participant were extracted and translated into Phecodes. For hospitalization data, we included all ICD-10 codes (recorded as either a primary or secondary diagnosis) and used an existing ICD-10-Phecode translation file (3). In order to enhance the specificity and positive predictive value, individuals were considered a “case” if they had at least two occurrences (irrespective of when) of an ICD-10 code that mapped to a Phecode. Individuals were marked as “controls” if they did not have any ICD-10 codes belonging to the exclusion codes defined in the Phecode definition files. Individuals with ICD-10 codes in the Phecode exclusion range were excluded from the respective analyses. We excluded Phecodes that occurred in less than 100 participants (0.05 prevalence) in order to reduce data sparsity.

Comparative PheWAS analysis

To evaluate the quality of the Phecode data derived from primary care EHR, we performed a PheWAS analysis in the UK Biobank seeking to replicate existing known GWAS associations identified through previous analyses (8,9) in seven Single Nucleotide Polymorphisms (SNPs): rs3135388, rs17234657, rs2200733, rs1333049, rs6457620, rs8050136, and rs7903146. We obtained up-to-date estimates between the seven SNPs and 25 phenotypes which we used as comparators by conducting a PheWAS analysis in BioVU(10), the Vanderbilt University Medical Center biobank.

The main analysis used phenotypes derived from both primary care and hospitalization billing data in the UK Biobank. We performed a subsequent sensitivity analysis by analyzing phenotype data derived only from primary care EHR. SNP-phenotype associations were assessed using a logistic regression model assuming an additive genetic model. UK Biobank models were adjusted for sex, genotyping array and the first 11 principal components. BioVU models were adjusted for age at most recent medical encounter, sex, 10 principal components and length of EHR (defined as the time between each patient’s first and most recent medical encounter). We calculated and reported the expected effect sizes as odds ratios (OR) and assumed a SNP-phenotype association was significant if it’s P-value surpassed Bonferroni significance.

UK Biobank and Bio VU Genotyping and Quality Control (QC)

487,409 UKB participants were genotyped using one of two custom genome-wide arrays and data were imputed to a combination of the UK10K, 1000 Genomes Phase 3 and the Haplotype Reference Consortium (HRC) reference panels resulting in 93,095,623 variants. We applied additional variant level QC and excluded variants with: a) Fisher’s exact test <0.3, b) minor allele frequency (MAF) <1% and, c) a missing call rate of ≥5%. We applied individual-level QC and excluded participants with: a) excessive or minimal heterozygosity, b) more than 10 putative third-degree relatives as per the kinship matrix, c) no consent to extract DNA, d) sex mismatches between self-reported and genetic sex, and d) non-European ancestry (more details on QC provided elsewhere (11)). BioVU samples were genotyped on the Infinium Multi-Ethnic Genotyping Array (MEGA). To curate the genotyping data, a quality control step was conducted. Briefly, the quality control has been performed with following steps: a) the samples with per-indvividual call rate less than 95% were removed, b) the samples with wrongly assigned sex were deleted, c) the samples from related individuals (PI_HAT ≥ 0.25) were removed, d) other unexpected duplications were eliminated. A genome imputation process was applied to increase coverage of the GWAS, using the Michigan Imputation Server(12) and referring to the HRC.

Implementation

Phenotypic data extraction and translation was performed in Python 3.7.7, genetic data extraction and QC was performed using bgenix, PLINK 1.9 and qctool v2. PheWAS analyses were conducted in R v. 4.0.0 using the PheWAS library (https://github.com/PheWAS/PheWAS(. The Read-Phecode map file, programming scripts, and

Results
In the UKB, we processed 123,662,421 primary care clinical events: 3,6175,235 using Read2 and 87,487,186 using CTV3. We extracted 38,228 unique Read2 terms and 80,994 unique CTV3 terms which were recorded among 230,096 participants. After applying the mapping algorithm (described previously), we identified 11,775 and 23,881 unique Read2 and CTV3 terms respectively which were eligible for mapping. We mapped 10,834 (92%) of Read2 terms to 1,449 Phecodes, and 21,988 (91%) of CTV3 terms to 1,490 unique Phecodes (Table 2). We additionally processed 3,541,618 admitted patient hospitalization events from 435,632 patients and translated 6,758 unique ICD-10 primary and secondary diagnoses from 9,493,039 hospitalizations to Phecodes.

In Read2, the top five unmapped terms were: a) G84. Hemorrhoids (n=9,601), b) Eu32z Depressive episode (n=7,702), unspecified, c) Eu32. Depressive episode (n=3,684), d) G843. External haemorrhoids, simple (n=1701), and e) N224. Ganglion and cyst of synovium, tendons, bursa (n=1,553). In CTV3, the most common unmapped terms were: a) XE2q5 Serum creatinine level (n=1,194,627), b) XE2q0 Serum sodium level (n=1,142,496), c) XE2pz Serum potassium level (n=1,140,859), d) XM0lt Serum urea level (n=1,041,244) and e) XE2eA Serum albumin level (n=1,014,201). In Read2, laboratory test results are in chapter 4 while in CTV3 concepts on laboratory measurements exist across multiple chapter chapters (e.g. “44M4. Serum albumin” and “XE2eA Serum albumin”).

The five most commonly recorded leaf Phecodes in hospital administrative data were: a) 401.10 Essential hypertension (n=100,940), b) 272.11 Hypercholesterolemia (n=35,033), c) 716.90 Arthropathy NOS (n=32,345), d) 550.20 Diaphragmatic hernia (n=21,203) and e) 562.10 Diverticularis (n=20,763). In primary care EHR data, the most frequently-recorded leaf Phecodes were: a) 745.0 Pain in joint (n=46,343), b) 401.1 Essential hypertension (n=40,645), c) 716.9 Arthropathy Not Elsewhere Specified (NOS) (n=30,516), d) 519.8 Other diseases of respiratory system, Not Elsewhere Classified (NEC) (n=29,146) and e) 760.0 Back pain (n=25,562).

In the primary analyses (Figure 2., Table 3) using Phecodes from hospitalization and primary care events, we performed a PheWAS in 408,415 UKB participants (54.4% female, mean age 59 SD 7.96) and 65,561 BioVU participants (55.6% female, mean age 57.87 SD 22.78) using 1,851 Phecodes respectively. We replicated 22 (100%) of 22 previously-reported genotype-phenotype associations with adequate statistical power across both of the datasets. In the secondary analyses, we performed a PheWAS in 185,648 UKB participants (~50% of the cohort is linked to primary care EHR, 54.5% female, mean age 58 SD 7.96) and 1,851 Phecodes and replicated 18 (81%) of 22 previously-reported PheWAS associations.
Figure 1. Exemplar flowchart of the process of mapping Read 2 and CTV3 terms, to ICD-10 and to Phecodes. CTV3 contains all Read2 terms but these were not duplicated in the display. CTV3=Clinical Terms Version 3.

Figure 2. Manhattan plot of phenome-wide association analyses in 185,648 participants (UKB, left) and 65,561 participants (BioVU, right) and 1,851 Phecodes derived from electronic health records. The red line shows the Bonferroni level of significance. Only phenotypes that cross the Bonferroni level of significance are annotated.
Table 3: PheWAS comparison of Phecodes derived from UK Biobank electronic health records (primary care EHR exclusively and from primary care and hospitalization data combined) to BioVU PheWAS analyses for seven variants with known associations. For each variant, the mapped genes and Genome Aggregation Database (gnomAD) identifiers are provided. P-Value columns with gray shading indicate results did not survive Bonferroni correction. Phenotypes with no identifier (in first column) are reported to illustrate differences in coding between data sources.

OR = Odds Ratio, PheWAS = Phenome-Wide Association Study. “n/a” denotes analyses which were not run due to a very low number of cases or no of cases due to a Phecode not being present in the data.

Discussion

In this study, we described the process of mapping primary care EHR data recorded using the Read2 and CTV3 controlled clinical terminologies to Phecodes. We performed a PheWAS in two contemporary international biobanks, the UK Biobank (UK) and BioVU (US) and provided evidence towards the validity of Phecodes derived from longitudinal primary care EHR by showing concordant findings. Similar to the US, UK hospital data are collected for billing purposes which may influence the coding process however billing codes in BioVU additionally include ambulatory care. UK primary care has a true EHR generated and captured during clinical care by healthcare professionals; billing and funding may also have a modest effect (e.g. through the Quality and Outcomes Framework (15)). Reassuringly, the distribution of most frequently mapped Phecodes between sources reflected these differences with Phecodes on symptoms (e.g. back pain, joint pain) being more prevalent in primary care EHR.

Our study is the first, to our knowledge, to develop and evaluate Phecodes sourced from primary care EHR data and show the validity of the translation file through a PheWAS analyses in two international resources. Comparison between UKB and BioVU uncovered challenges with regards to the resolution of diagnosis codes used in the UK and the US. ICD-10-CM used in the US has a higher fidelity than ICD-10 used in the UK which directly influenced the level at which Phecodes were assigned. For example, in BioVU, the availability of ICD-10-CM codes meant that sleep apnea was recorded using a lower-level Phecode “Obstructive sleep apnea (327.32)” whereas in the UK, a higher level one “Sleep apnea (327.3)”. As a result, while the PheWAS analyses failed to show concordant results between the resources, each individual analyses on the Phecodes that were actually available in the data sources was significant. The same effect was observed in atrial fibrillation and flutter which are recorded using a single ICD-10 code in UK data but are split across two different codes in ICD-10-CM (and as a result two different Phecodes).

The main limitation of our study is the fact that only approximately 50% of the population in the UK Biobank has primary care data available. As a result, our PheWAS analyses using Phecodes derived from primary care EHR failed to replicate previous associations due to low statistical power (e.g. 740 cases of sleep apnoea recorded in primary care EHR). Some diagnoses in primary care were not mapped to Phecodes. This could be due to the fact that the target ICD-10 code was not in the ICD-10-Phecode map; for example, in the case of haemorrhoids we observed a mismatch between the ICD-10 code available in the cross-map file “K64 Hemorrhoids and perianal venous thrombosis” and the ICD-10 code available in the ICD-10-Phecode map “I84 Haemorrhoids”. Another reason for missed mappings was that source Read2/CTV3 concepts were too generic (e.g. S3zFracture of unspecified bones) and could not be mapped. In some cases, such as Read code Eu32z "[X]Depressive episode, unspecified", the target term was ICD-10 F32 "Major depressive disorder, single episode" which is a non-billable code with no associated Phecode. Finally, some Read codes (e.g. E2273 Impotence) were not defined in the Read-ICD-10 cross-map files and as a result were not mapped to a relevant Phecode during data extraction.

Despite the relatively small number of events not mapped to Phecodes, in subsequent studies, it will be important to further refine these mappings and ensure higher fidelity by establishing new Phecodes where needed. Primary care EHR contains a wealth of information which is not captured in administrative hospital records. For example, Read contains terms on examination findings, laboratory tests, risk factors and symptoms. A potential future expansion of Phecodes could include a custom set of codes to capture these events despite not having a valid ICD-9-CM or ICD-10 target code. This would be relevant not only for UKB participants but also to other deeply phenotyped/genotyped resources e.g. Genomics England (16) or the NHS Digital (17).

Conclusion

In this paper, we introduced our work of mapping the Read2 and CTV3 clinical terminologies used in primary care EHR to Phecodes. We validated our results by replicating previously-reported PheWAS genotype-phenotype associations by performing analyses in the UK Biobank and BioVU. We provide an initial version of the mapping file that can be used by researchers to leverage primary care data for high-throughput translational research.

Golden opportunities for clinical decision support in an era of team-based healthcare

Paul R. Dexter, MD,1,2 Titus Schleyer, DMD PhD,1,2

1Regenstrief Institute, Inc., Indianapolis, IN; 2Indiana University School of Medicine, Indianapolis, IN

Abstract

Computerized clinical decision support (CDS) will be essential to ensuring the safety and efficiency of new care delivery models, such as the patient-centered medical home. CDS will help empower non-physician team members, coordinate overall team efforts, and facilitate physician oversight. In this article, we discuss common clinical scenarios that could benefit from CDS optimized for team-based healthcare, including (1) low-acuity episodic illness, (2) diagnostic workup of new onset symptoms, (3) chronic care, (4) preventive care, and (5) care coordination. CDS that maximally supports teams may be one of biomedical informatics’ best opportunities to decrease health care costs, improve quality, and increase clinical capacity.

Introduction

Intractable challenges confront healthcare in the United States,1 including unsustainable rising costs,2,4 primary care physician shortages,5 physician burnout,6 and increasing demand for healthcare services.7 Primary care has been described as in crisis.8 Healthcare is too often inadequately standardized, of poor quality, and unsafe.9,10

Some have suggested that health information technology (IT) holds the promise of driving improvements in healthcare.2,11-13 Others have suggested that solutions to healthcare’s challenges reside in the form of multi-disciplinary coordinated primary care, delivered through team-based approaches such as those found in patient-centered medical homes (PCMHs).14,15 The most effective solutions to healthcare’s critical challenges seem likely to arise from the synergistic combination of CDS and team-based approaches.16 Health IT’s (and CDS’) primary contribution may be in making new care delivery models possible.17

Clinical decision support for multi-disciplinary teams

Excellent opportunities exist for transforming primary care practice by fully leveraging the expertise of clinical teams. Both physicians and non-physician clinicians frequently practice below their level of licensure, with resultant underutilization of nurses and medical assistants.18 Pelak and colleagues estimate that over half of overall care performed by primary care physicians could be safely performed by nurses and other non-physicians.19 Similarly, Altschuler and colleagues estimate that 77% of time spent on preventive care and 47% of time spent on chronic care could be delegated to non-physicians, such as registered nurses, pharmacists, health educators, and medical assistants.20

In the sections below, we describe common clinical scenarios and forms of computerized clinical decision support that could coordinate the parallel efforts of multi-disciplinary primary care clinical teams. We have categorized these primary care tasks into the following clinical domains: low acuity episodic illness, diagnostic work-up of new onset symptoms, chronic care, preventive care, care coordination and other tasks.

Primary care tasks performed by teams utilizing CDS

Clinical domains that could benefit from CDS optimized to support teams include:

Low-acuity episodic illness. As demonstrated by care delivered at an increasing number of retail clinics, nurse practitioners or physician assistants employing guideline-based protocols can effectively manage common low-acuity episodic illness, such as sinusitis and pharyngitis.21,22 Compared with primary care clinics, there is evidence that retail clinics can deliver this healthcare at lower cost with equivalent quality.21,22 In one study, ten conditions commonly treated at retail clinics accounted for an estimated 18 percent of all primary care physician visits.23
Primary care clinics could readily adopt similar guideline-based methods to manage low-acuity episodic illness using computer-based standing orders protocols administered by nurses. An advantage that primary care clinics would have over retail clinics is improved capacity to evaluate persistent symptoms, which in some cases represent serious underlying disease. Computer logic could route these persistent cases to the physician if a scripted telephone follow-up administered by a medical assistant indicated that the symptoms did not resolve or respond as expected.

**Diagnostic workup of new onset symptoms.** For patients who present with symptoms suggestive of more serious underlying disease (e.g., hemoptysis), computer-based scripted methods might provide valuable first-pass diagnostic workup immediately prior to physician evaluation. Through computer-based standing order protocols, preliminary diagnostic tests could be performed prior to the physician's interview of the patient - e.g., a chest x-ray for hemoptysis in an older smoker who has not previously had chest imaging.

Using structured questionnaire data acquired by non-physicians (including from the patient directly) that relate to the patient's symptoms, computer logic could generate a draft differential diagnosis and draft treatment plan for physician review available as the physician goes into the exam room. Such a draft differential diagnosis could list relevant physical exam findings or diagnostic testing that could further narrow the range of diagnostic possibilities.

The availability of first-pass diagnostic approaches acquired through non-physician personnel has the potential to improve upon the estimated 10 to 15% diagnostic error rate. Such efforts might also finally provide the means to insert differential diagnosis generators, such as DXplain, into routine clinical workflow. In turn, draft treatment plans generated by questionnaire data could incorporate recommendations that reflect the best and latest medical evidence, potentially reducing the long delays between definitive research findings and widespread practice. In all cases, it would be the physician or other treating provider who would determine based on their exam if the draft differential diagnosis or treatment plan were appropriate for that particular patient.

**Chronic care.** Guided by electronic questionnaires, non-physicians could capture a much larger portion of history-taking and documentation related to chronic care than currently performed. For example, non-physicians could collect longitudinal patient data necessary for physician decision-making related to asthma therapy, such as the frequency of inhaler use, coughing, or episodes of shortness of breath. They could also capture structured data needed for chronic care quality measures.

To the significant extent that questions are predictable on the basis of a patient's presenting symptoms, the goal would be to use computer logic to collect the answers to those questions directly from the patient (e.g., using tablet technologies) or through a medical assistant. For example, if a patient reports chest discomfort, questions regarding its location, severity, radiation, and association with shortness of breath could follow. Such capture of patient history could relieve the physician of significant portions of visit documentation, allowing the physician to instead focus on verifying the "pertinent positives" from the captured history, supplementing with any needed clarifying questions, and establishing a therapeutic plan with the patient.

For patients with problems identified by a physician, computer logic might also help guide the selection or titration of various medications related to chronic care conditions. An early example of CDS for medication selection in diabetes has been developed by Tarumi et al. Such computer logic has been demonstrated as beneficial for anticoagulants and insulin compared with routine care. There is also demonstrated utility for computer-based hypertension management. Logic could generate medication recommendations to be approved by the physician, or eventually with the proper safeguards, computer-based standing order protocols could directly guide medication titration.

With safeguards in place, a physician might identify a patient in the future with a new diagnosis of hypertension or in need of improved glucose control. That physician could then choose to turn over the choice of medication and/or the subsequent medication titration to non-physicians using computer-based standing order protocols. For purposes of choosing the “right” anti-hypertensive agent, the computer logic itself could search for evidence that the patient has a history of systolic heart failure, diabetic nephropathy, or recent myocardial infarction.

**Preventive care.** Through computer-based standing order protocols, non-physicians could directly coordinate much more preventive care than commonly occurs. In the case of vaccinations, we have previously demonstrated that automated standing order protocols are more effective than physician-directed computer reminders.
Using these approaches, the default for a particular clinic might be that age-specific preventive care is offered to all patients, unless and until such time that the patient in coordination with their physician chooses to stop (e.g., choosing not to proceed with screening colonoscopy due to terminal illness). In cases where the patient refuses recommended preventive care, the reason could be captured electronically and routed automatically to the physician, on the possibility that additional patient education would be useful.

Rather than spending as much time directly ordering preventive care for individual patients, physicians could instead focus on practice-level oversight. There is much potential for saving physician time through such methods given estimates that 7.4 clinician hours per working day are needed to fully follow national recommendations for an average-size panel of 2,500 patients.32

Care coordination and other tasks. Compared to the case where a single clinician is responsible for all orders and documentation, team-based primary care does complicate issues of care coordination. Consequently, the potential value of CDS software is arguably much greater in a team-based environment than in the simpler single physician case. The goal would be that regardless of how work is dynamically allocated or delegated within a practice, or regardless of the sequence by which tasks are completed, there would be software verification that all aspects of healthcare are addressed by the end of the visit.33

Apart from the clinical scenarios described above, many other activities occur frequently in primary care clinics34 that could benefit from team-based CDS software:

- Establishing the patient’s agenda and priorities for the imminent physician visit
- Medication reconciliation
- Reviewing potential side effects of newly prescribed medications with the patient
- Follow-up of hospitalizations and emergency department visits employing standardized questionnaires with forwarding of summaries to the physician.
- Renewals of non-narcotic medications using electronic standing order protocols
- Triage of returning test results, incoming emails and phone calls, insurance clarifications.
- Tracking of referrals from the original order to returning recommendations from the specialist
- Follow-up of missed clinic appointments or diagnostic testing

Team-based approaches hold the key to allowing physicians to spend more of their time overseeing the delivery of healthcare within their practice, rather than personally delivering the vast majority of healthcare. To fully take advantage of the opportunity for physician supervision of practice-level information, much would need to be learned regarding how to optimally summarize the results of team efforts. Valuable reports might include both summary and patient-level data on (1) preventive care administered or refused, (2) blood pressures before and after changes in treatment, (3) medication titrations, and (4) the frequency and nature of various concerning patient symptoms.

Discussion

In team-based care models, CDS software has the potential to be invaluable, transforming potentially fragmented team efforts into highly effective integrated healthcare delivery. Despite risks of fragmented care, the clinical advantages of multi-disciplinary medical care will likely drive wide adoption of team-based practice. CDS that maximally supports teams may be one of biomedical informatics’ best opportunities to decrease healthcare costs, improve quality, and increase clinical capacity.

In this paper, we have outlined clinical tasks that a diverse group of clinicians might effectively address using CDS. Collectively, low-acuity episodic illness, diagnostic workup, chronic care, preventive care, and care coordination account for a large portion of medical practice. Many issues would need to be worked out. For example, full adoption of team-based care approaches might require changes to reimbursement methods, rewarding practices for overall care delivered rather than who delivered what care.

Practices also differ in their precise assortment of team members, so CDS software would need to be highly configurable in terms of which team members are assigned particular tasks. Depending on the practice, available non-physician team members might include nurses, physician assistants, pharmacists, medical technicians,
rehabilitation specialists, social workers, check-in personnel, or patient navigators. In a number of cases, more research would be required prior to wide deployment, such as ensuring that adjustment of anti-hypertensive or diabetic medications employing computer-based standing orders is safe and effective.

Our suggested approaches take advantage of the fact that a significant portion of healthcare is algorithmic in nature, even for the preponderance of cases where “the art of medicine” must subsequently be applied. In a handful of cases, some interventions and clinical scenarios are sufficiently straightforward that they can be safely administered by non-physician clinicians with only high-level provider oversight (e.g., flu shots). For most clinical scenarios, however, the goal would be to simply provide the clinician succinct diagnostic and therapeutic considerations that they can review at the point of care. Ready availability of such considerations at the point of care would best be complemented by trivial methods to directly order those same diagnostic tests or therapies.

The shortcomings of EHR support for team-based care have been previously recognized. The American Medical Association has called for EHR software that (1) facilitates clinical staff to perform work to the extent their licensure and privileges permit, and (2) allows physicians to dynamically allocate and delegate work to appropriate members of the care team. Bates et al. recommends the development of EHR functionality to enable real-time communication and coordination among team members. O'Malley et al. suggests that EHRs could facilitate primary care teamwork by enhancing communication within the practice team, supporting task delegation, and integrating standing orders and protocols. In this paper, we identify specific primary care tasks that could be performed by non-physicians supported by software. We believe these specific examples strengthen the already-compelling case for improving team support in CDS software.

Team-based approaches have been associated with increased physician satisfaction and decreased burnout. Too many PCPs practice within a “frantic bubble,” experiencing workdays as a non-stop stream of patients. Almost all aspects of a primary care physician's busy day could benefit from team-based assistance. CDS software can make that possible.

Abstract To date, there have been 180 million confirmed cases of COVID-19, with more than 3.8 million deaths, reported to WHO worldwide. In this paper we address the problem of understanding the host genome’s influence, in concert with clinical variables, on the severity of COVID-19 manifestation in the patient. Leveraging positive-unlabeled machine learning algorithms coupled with RubricOE, a state-of-the-art genomic analysis framework, on UK BioBank data we extract novel insights on the complex interplay. The algorithm is also sensitive enough to detect the changing influence of the emergent B.1.1.7 SARS-CoV-2 (alpha) variant on disease severity, and, changing treatment protocols. The genomic component also implicates biological pathways that can help in understanding the disease etiology. Our work demonstrates that it is possible to build a robust and sensitive model despite significant bias, noise and incompleteness in both clinical and genomic data by a careful interleaving of clinical and genomic methodologies.

Introduction

COVID-19 (Corona Virus Disease of 2019), caused by the SARS-CoV-2 virus, is one of the worst pandemics in human history. As of July 6 2021, it has infected 183,700,343 people while claiming 3,981,75 deaths worldwide. The disease exhibits a wide range of symptoms ranging from asymptomatic to mild to rapid progression to critical stage. In general, patients with mild symptoms recover easily whereas severe COVID-19 patients require further treatments such as ventilation in ICU. Such heterogeneity in terms of symptoms poses great challenges for understanding the disease etiology and designing treatment protocols. Characterizing the factors that impact the severity of this illness has been an open research question that we tackle in this work. Typically, severe effects of infectious diseases like COVID-19 are hypothesized to be associated with the variations of host genome. GWAS (Genome wide association studies) have been reported in literature to understand the impact of host genomics on the disease. In addition to viral load environmental factors such as demographics, socio-economic status, lifestyle may also have an impact on the spread, exposure, and severity. The availability of rich Electronic Health Records (EHR) provides an opportunity for picking apart clinical factors associated with COVID-19.

Most of the existing studies that aimed at finding the common risk factors for severe COVID-19 patients focused on either the clinical or the genomics factors, but not on both. In this study, we aim to study both these factors in concert using large-scale datasets that have both EHR and patient genomic data.

Pursuing such joint analysis to find clinical and genomic factors associated with COVID-19 that can be used as biomarkers comes with a few challenges. First, defining COVID-19 severity from EHR is often challenging, as it is not directly collected in these datasets. Hence, the severity has to be inferred using appropriate clinical knowledge as a surrogate phenotype which in turn may introduce label noise and data collection bias. Thus, building machine learning models on clinico-genomic dataset needs special adjustments to handle such noise and bias associated with COVID-19 severity. Second, assessing the impact of genomic factors on COVID-19 severity may be confounded by several other clinical factors such as the prior comorbidities of patients and treatment protocols. The effect of such confounding factors has to be addressed carefully when conducting the combined clinico-genomic studies. Third, the impact of clinico-genomic factors may also vary depending on the variations of diverse COVID-19 strains that have been observed due to genetic mutations.

§ Author contributed while he was at IBM Research, Yorktown Heights, NY.
We propose in this work a combined framework for finding the clinical and genomic factors associated with COVID-19 severity using a large COVID-19 dataset from the UK Biobank (UKBB). To address the above mentioned challenges, we first use the COVID-19 related hospitalization as a surrogate outcome for defining severe COVID-19 cases. Second, we use a machine learning technique called positive-unlabeled (PU) learning to address the noise and reporting bias present in COVID-19 severity labels. Moreover, we use a recently proposed genomic analysis framework entitled RubricOE to select the set of genomic factors after adjusting for the common prior comorbid conditions which may act as potential confounders. Finally, we aim to assess how the importance of the extracted biomarkers evolve over the pandemic marked by events such as the introduction of using Dexamethazone as treatment for COVID-19 severity and the emergence of the reportedly more contagious B.1.1.7 SARS-CoV-2 (alpha) strain.

Related Works

To combat the global pandemic caused by COVID-19, scientists across different disciplines have been studying the disease to understand various facets such as its spread, epidemiological and patho-physiological characteristics, and societal impact.

To help consolidate and streamline the efforts around studying the host genetics for susceptibility, the COVID-19 Host Genetics Initiative was launched in mid 2020 with a primary focus on disease severity. As part of this initiative, Hou et al. found that ACE2 or TMPRSS2 DNA polymorphisms were likely associated with genetic susceptibility of COVID-19, while Li et al. found that genetic variants under a polygenic model shows promising improvements in prediction accuracies. Wang et al. presented further genetic insights into phenotypic difference among the COVID-19 patient groups, highlighting genes and variants of interest. More specifically, they conducted both single-variant and gene-based association with respect to five severity groups finding insights such as variants involved in IL-1 signaling pathways. While studies identified a gene cluster on chromosome 3 as a risk locus for respiratory failure after infection with COVID-19, Zeberg et al. found that the risk is conferred by a genomic segment that is carried by around 50% of people in South Asia and 16% of people in Europe.

Simultaneously, there have been concerted efforts to characterize the clinical characteristics of COVID-19 including the patho-physiology and the risk factors for COVID-19. Several large-scale meta-analysis studies were conducted either on previous studies or by summarizing published articles to identify common clinical symptoms and lab abnormalities among severe COVID-19 patients. Some common risk factors observed among critical/mortal COVID-19 patients are socio-demographic information such as male, older than 65, smoking, and prior history of hypertension, diabetes, cardiovascular disease, respiratory diseases, kidney diseases, obesity, immunosuppresion, and cancer. In addition to these prior conditions, depression as well as other cognitive and neurological disorders were also found as risk factors by a nationwide cohort study in Israel, although this study found that smoking and presence of respiratory diseases do not significantly increase the risk of complications. These factors were also found in a separate study performed on 40% of all patients in England. In addition, socio-economic deprivation, diabetes, severe asthma, Black and South Asian ethnicity were observed as high risk factors. Research has also been conducted to characterize risk among sub-populations such as obesity, heart failure, and Parkinson’s Disease concurrently. Mathew et al. found three immunotypes revealing different patterns of lymphocyte responses among hospitalized COVID-19 patients.

Besides finding either clinical or genomic risk factors of severe COVID-19, several machine learning (ML) and artificial intelligence (AI) have also been applied successfully to solve a wide range of needs, ranging from fast ML based COVID-19 infection prediction to routine blood-test as fast alternatives to costly and time-consuming PCR tests to predicting disease state of individual cells given their transcriptome. However, to the best of our knowledge, we did not find any machine learning model built on combined clinico-genomic dataset to assess the COVID-19 severity.

Method

Dataset. We analyzed the large prospective cohort of patients from the UK collected in the UKBB repository. The dataset contains diverse information including demographics, diagnosis, medications, lab tests, and genomic information of approximately half a million patients. In addition, the national SARS-CoV-2 laboratory test data were made available in UKBB through the Public Health England (PHE). This COVID-19 dataset contains a flag indicating specimen origin of COVID-19 tests: hospital inpatient origin vs other settings. It also notes the specimen collection.

date and the *specimen result* in addition to a few other information about how the specimen was collected. Data were available from Mar 16, 2020 and the repository has been updated once or twice every month. In our current study, we used data from Mar 16, 2020 to Jan 21, 2021.

**Preparing the outcome and feature sets.** Although the COVID-19 dataset in UKBB is a prospective study, it did not collect the disease severity explicitly. The nature of this dataset is very diverse depending on national testing strategy which evolved over time as the pandemic progressed. For example, in UK, testing was initially restricted to those with symptoms in hospital and thus under this assumption, using the positive tests of these subjects in hospital can be a reasonable proxy for severity. However, when the testings were expanded covering even asymptomatic patients from diverse facilities, defining the severity required analyzing information regarding the specimen sources of test.

Among several different fields available in the COVID-19 table of our the UKBB, we settled on *specimen origin* and *specimen results* to track severity. We have used a combination of these two flags for assessing disease severity under the assumption that patients with a positive COVID-19 test obtained in hospital (i.e., *specimen origin=1*) are likely to be severe cases than those COVID-19 patients who were tested in outpatient services (i.e., *specimen origin=0*). Table 1 contains the number of unique patients who had at least one positive test result and at least one ‘inpatient’ indicator retrieved from the origin field. We used inpatient COVID-19 samples (*specimen origin=1 and result =1*) as the severe COVID-19 patients while other COVID-19 patients (*specimen origin=0 and result = 1*) as the non-severe cases.

While this approach estimates severity, it may be prone to a selection bias problem by defining all inpatient COVID-19 patients as severe cases. For instance, some patients may have been hospitalized due to other conditions or may have been experiencing other problems before they were COVID-19 positive. To cope with aspects of this problem, a separate field covering hospitalization-acquired infections was collected in the database to filter out such patients from actual severe COVID-19 infection related hospitalization. However, this field was enabled in the dataset very recently and the protocol for marking that field is not yet uniformly applied to all samples.

Another potential issue with the dataset pertains to defining the non-severe COVID-19 patient cohort. While hospitalization data for acute COVID-19 patients were collected carefully, the non-severe patients are harder to define. For example, patients who tested positively for COVID-19 in outpatients or non-urgent care service centers (*specimen origin=0*) may have experienced severe symptoms. The lone presence of the Origin flag set to 0 does not always mean that patients did not have severe reaction at a later stage, in fact, they may not have been traced prospectively in the dataset. Such tracing would most likely require conducting another test while being in an inpatient service. To cope with this issue, we used a special class of machine learning to handle this kind of noise associated in the outcome labels.

To build our severity prediction models, we used several clinical and genomic features that may have an impact on COVID-19 severity. For the clinical features, we manually curated some of the most relevant features which may have association with COVID-19 for further analysis. Our clinical features include demographics, lifestyles, comorbidities based on patient’s prior history, self-reports, and their chronic disease histories curated from prior inpatient records.

**RubricOE: the Omic Framework.** The pipeline of RubricOE (learning rubric for multi-omics Genetic Epidemiology) is outlined in Figure 1. We describe data treatment in two stages as follows.

1. **Pruning Genomic Features:** Starting with 12,965 overlapping samples with genomic information in the UKBB COVID-19 dataset, we only retained high quality imputed genomic markers in the form of Single Nucleotide Polymorphism (SNPs) with imputation quality INFO score > 0.3, resulting in approximately 4.4 million SNPs. We further
did a standard quality control (QC) for filtering informative variants, removing SNPs as well as individuals with more than 2% of missing data. We further filtered for Minor Allele Count (MAC) > 0.05, sex discrepancy in individuals, variants deviating by more than $p < 1e^{-6}$ in the Hardy-Weinberg equilibrium (HWE) for cases and $p < 1e^{-10}$ in controls. We also filtered for individuals with ±3 standard deviation in heterozygosity rates and very closely related individuals (second degree). All of the QC analysis was done using PLINK v1.9. We ended up with 12,389 individuals and 4,539,795 SNPs which passed all the QC thresholds. Of these 12,389 individuals, 4,000 were cases with severe COVID-19 infection and 8,389 were non-severe individuals who tested positive. We further pruned for linkage disequilibrium (LD), removing correlated SNPs with $r^2 > 0.2$ with a variance inflation factor of 10 on a window size of 50 kb. We performed a Genome-wide Association Study (GWAS) on this pruned dataset for a sanity check of the QC protocol and observe significant loci associated with the severity of COVID-19 infection. GWAS was performed by the package SAIGE, while correcting for population structure, sex and age. We computed the top 20 principal components (PCs) with TeraPCA as a proxy for population structure and used them as covariates along with the biomarkers.

2. **Stable Feature Extraction:** The learning rubric employs a nested test-training set configuration on the genomic data after QC and pruning for LD. The outer test-training set split reserves the test set (“validation”) for final SNP evaluation and denotes the training set as “working” data. Within the latter, further train-test splits are performed to rank the features by their Youden index (also known as J statistic). RubricOE is applied on the genomic data, accounting for top 20 PCs, sex, year of birth and Diabetes Mellitus (DM) as covariates. It iteratively finds a “stable” set of SNPs which persistently remains highly ranked with their respective Youden index. Annotation, Gene Ontology (GO) and enriched pathway analysis of the “stable” set of SNPs produced by RubricOE has been evaluated using the R package clusterProfiler.

**Clinico-Genomic Framework.** We used a predictive learning framework called Positive-unlabeled (PU) learning for extracting the most significant clinical and genomic features associated with COVID-19 outcome. Note that our dataset is more robust in terms of defining the severe COVID-19 patients than the non-severe cases. Hence, using a classical binary classification algorithm will not be appropriate and able to cope with such noisy class labels. PU learning algorithms have alternatively been reported to be especially suitable for learning from a noisy negative class by treating instances in this class as unlabeled while predicting the positive class (severe COVID-19 cases).

PU learning is a variant of the classical binary classification problem, where it is assumed that the unlabeled examples could belong to either positive or negative class. We refer to [30] for a comprehensive review of such PU learning.
techniques. Among several state-of-the-art PU learning techniques, we use PU Adapter, uPU, and nnPU for learning the COVID-19 severity. All of these PU learning techniques have the basic assumption that the observed samples are drawn uniformly from the positive distribution, which enables PU learning techniques to leverage standard binary classification methods with minor modification of data or algorithm.

The PU-Adapter technique pre-processes the available PU data so that any standard binary classification method can be used for learning on the PU dataset. In particular, this method reweights the samples of PU data so that learning a traditional binary classifier on the weighted samples yield to similar target probability threshold on the PU dataset. Moreover, it has been shown that the classifier trained on positive and unlabeled examples predicts probabilities that differ by a constant factor from the true probabilities of positive class. Unbiased PU learning (uPU) uses two separate loss functions for the positive and unlabeled samples using convex optimization framework.

Model Evaluation. We evaluate the effectiveness of PU-learning algorithms with a comparison with baseline traditional classification algorithms using logistic regression with a $L_1$ loss. Computing traditional metrics such as precision, recall, $F_1$ score, and accuracy is challenging in the positive unlabeled scenario since the only information available relates to the positive label while no sample from the negative class is clearly provided. One straightforward solution to this problem is to assume that the unlabeled data are negative. However, this is not fully accurate. A modified $F_1$ score (we call it as $F_1^{pu}$ score) has been proposed to address this issue. This score is computed as $r^2 / (y + 1)$, where $r$ is the recall and $p(y = 1)$ is the prevalence of the predicted positive label. As shown in, the $F_1^{pu}$ score can take values greater than one but shares the same property as $F_1$ score; it is high when both precision and recall are high and small when either one is small. We also report metrics used to evaluate traditional classification methods for completeness although these are not recommended for our setting. They include accuracy, precision, recall, and $F_1$ score. We used a 5-fold cross-validation (CV) approach for evaluating the performances of the predictive models, where in each CV fold, the hyper-parameter for $L_1$ loss was tuned internally using a grid-search over the range of $[10^{-3}, 10^{-2}, 10^{-1}, 1, 10]$. In particular, for clinico-genomic feature importance, 100 bootstrapping runs were used to estimate their confidence intervals. We used DPM360 workbench to conduct the analysis in a repeatable and reusable manner.

Results

The results of the baseline $L_1$ regularized logistic regression are shown in Table 2. We report the metrics for three different models: clinical, genomic, and the combined clinico-genomic model. Overall, we can observe that clinical model has worse predictive power than the genomic model. However, the clinico-genomic model shows significant improvement in terms of predictive power.

Table 3 and Table 4 show the same metrics from the three different models using two different PU learning techniques: nnPU and PU-Adapted logistic regression, respectively. The nnPU model does not perform well for categorical genomic features, moreover it is harder to interpret such model. In contrast, the PU-adapted method uses logistic regression as the baseline model. Hence it is easier to interpret the resulting coefficients as log-odds ratios of clinico-genomic features. The combined clinico-genomic model of the PU adapted logistic regression model yields significant improvement from the models built on clinical and genomic model individually. Although the $F_1$ score of the PU learning model is similar to the score of the baseline logistic regression model, the adjusted $F_1$ score is higher for the PU model, which justifies the use of the PU model for our noisy class level.

We interpret the log-odds of the PU-Adapted logistic regression model to denote the importance of a particular feature toward COVID-19 severity. Figure 2 shows the feature importance of top 30 statistically significant features associated with COVID-19 severity computed by the final combined clinico-genomic model using the PU learning framework. The statistical significance of a feature is computed using bootstrapping with 100 runs and the confidence interval is represented as error bars in the figure which are beyond zero (the vertical line).

Discussion

Our final combined clinico-genomic model finds the significant features associated with COVID-19 severity (Figure 2), which may act as potential biomarkers. Some of the top significant clinical features have already been found in previous studies. For example, age and black ethnicity have been reported in studies on COVID-19 and prior conditions like diabetes mellitus, hypertension have been reported in previous studies. Note that our study finds smoking status (past smoker, current smoker, pack years of smoking) is related to severe COVID-19 patients, which has ambiguous evidence in literature. A few studies have reported it with increased risk factors, while others did not find it to be a significant risk factors for COVID-19 severity.

In addition, our study found a few more features such as number of medication taken per day to be significant. Such features are related to the overall health status of the patient and correlate indirectly to high severity risk factors. Interestingly, distance from home to workplace has also been reported with lower risk of severity, which may be confounded by people commuting by car for longer distance instead of public transport or cycling for shorter commutes.

Is the clinico-genomic model sensitive to treatment protocols? UKBB does not have direct information on COVID-19 drugs and detailed treatment protocols that a COVID-19 patient went through, so we assess the impact of a COVID-19 drug indirectly using its date of approval. In particular, we study the change in coefficients of the top features (Figure 3) before and after the drug approval date. Dexamethazone was approved for use in UK on Jun 15, 2020. We observe (see Figure 3) that most of the significant factors from the whole dataset still had similar impact after the drug being used, but only 5 features—age, current smokers, DM, gene MACROD2 and SNP rs10733122—had significant impact before the approval date. MACROD2 is known to be associated with ischemic stroke and large-artery atherosclerosis, both of which are correlated with COVID-19 severity. Similarly, age, DM and smoking status are also shown to be affected by corticosteroids including Dexamethazone. While we observe that the model is sensitive to treatment protocols in general, it should be noted that this analysis may be confounded due to small sample size or other environmental factors linked with the use of corticosteroids. Also,
medication data were not directly available in the cohort we used - as such this analysis has a strong assumption that the treatment strategy was majorly adopted for severe COVID-19 patients after it was approved. We aim to explore the effect of medication and treatment procedure more systematically in future.

**Is the clinico-genomic model sensitive to the evolving virus?** UKBB did not collect the virus genome prospectively. So we use the date of diagnosis as a proxy for the dominant strain. In the UK, a reportedly more contagious strain named B.1.1.7 started surfacing from early September 2020 and it is estimated that by December 2020, over 60% of new COVID-19 patients had the newer strain. We divided the whole cohort into three: those diagnosed before Aug 31, 2020 (older strain), between Sep 1st, 2020 and Dec 15, 2020 (both strains), and, after Dec 15, 2020 (newer strain). Figure 4 shows how the effect of the top clinico-genomic features change over these three cohorts. We observe that some factors like age, prior DM condition and number of medication are consistent across both strains, while the smoking history (current and present) had larger impact on older strain than the newer strain. Such analysis of temporal trend of a factor’s impact on severity can help elucidate important clinical insights.

**Biological implications of the clinico-genomic model.** The genomic features obtained from the model are enriched in a host of biological pathways related to transmembrane transporters and receptor activities (Figure 5(a)). The most significant is transmembrane receptor protein tyrosine phosphatase which on increasing activity might affect T cells and contribute to their depletion and immunoparalysis in severe COVID-19 patients. Other important pathways such as ion channel, metal ion and inorganic cation transmembrane transporter activities reaffirm the notion that SARS-CoV-2 E protein is a potential ion channel like other coronaviridae. Focusing on the significant biomarkers from the combined model, we observed two new GO enriched terms, passive transmembrane transporter activity and PDZ domain binding (Figure 5(b)). It has been shown that PDZ-containing proteins among binders of the SARS-CoV-2 proteins E, 3a or N affect viral replication under knock-down gene expression in infected cells, significantly particularly in the E protein. The model highlights genes such as CDC42BPA and LARS2 which are previously shown to be associated with COVID-19 antibodies and respiratory failure caused by COVID-19 respectively. It also highlighted regions in Chromosome 19 which is associated with critical illness caused by COVID-19 and possible candidate chromosomal regions in Chromosomes 15, 8 and 4 which can be linked with COVID-19 severity when taking clinico-genomic factors into account.
Figure 4: Mean coefficients with 95% CI of features from Fig 2 indicating severity of COVID-19 with dominance of (a) older strain, (b) both strains, and (c) newer strain (B.1.1.7) in UK. Features that are still significant (not significant) are shown via deep grey (light grey) bars with diamond (circular) markers.

(b) Pathways of significant SNPs from combined model.

Conclusion

In this study, we extracted significant clinical and genomic factors associated with severe COVID-19 from a large-scale EHR and genomic dataset available from UK. In particular, we used a special class of machine learning methods called positive-unlabeled learning to address the challenge of noisy class label of COVID-19 severity outcome, and paired it with a state-of-art omic analysis tool, RubricOE, to enable efficient use of the limited amount of genomic data available. We demonstrated significant improvement in disease severity prediction using this novel clinico-genomic modeling. We also showed that the model is sensitive to patient treatment, sensitive to the evolving virus and implicates biological pathways that can even potentially inform drug-targeting. Thus collectively the results can be used in discovering potential biomarkers for better clinical decision making. The novel clinico-genomic modeling combination presented in this paper represents a step forward in combining clinical and genomic data towards clinical insights, and has implications beyond COVID-19, as many of the limitations in clinico-genomic data we sought to overcome are common across many disease areas.

Specifically with COVID-19, in the future we plan to further investigate the effect of treatment protocols as even more data at higher resolutions become available including effects of vaccination, COVID-19 induced deaths and long-COVID effects.

Abstract

The learning health systems aim to support the needs of patients with chronic diseases, which require methods that account for electronic health recorded (EHR) data limitations. EHR data is often used to calculate cardiovascular risk scores. However, it is unclear whether EHR data presents high enough quality to provide accurate estimates. Still, there is currently no open standard available to assess data quality for such applications. We applied the DataGauge process to develop a data quality standard based on expert clinical, analytical and informatics knowledge by conducting four interviews and one focus group that produced 61 individual data quality requirements. These requirements covered all standard data quality dimensions and uncovered 705 quality issues in EHR data for 456 patients. These requirements will be expanded and further validated in future work. Our work initiates the development of open and explicit data quality standards for specific secondary uses of clinical data.

Introduction

The development of learning health systems depends on reliable secondary use of Electronic Health Record (EHR) data.1,2 Research endeavors including comparative effectiveness research,3,4 precision medicine5–7 as well as the delivery of precision care8,9 relies on EHR secondary use. Populations at risk for chronic diseases are among those that would benefit most from such approaches via clinical data reprocessing to provide further support to clinicians9,10 For example, patients with diabetes (12–14% of U.S. adults)11 are at increased cardiovascular disease (CVD) risk12,13 and likely to benefit from routine personalized CVD risk prediction to guide clinical care due to the changing nature of their risk factors over time.14 In the context of learning health systems, this can be explored efficiently by leveraging existing EHR databases.1,2

EHR-based risk assessment approaches hold great promise to improve care and outcomes via patient-centric learning health care practices including data-driven personalized medicine,5–7 real-time clinical decision support15 and real-world evidence-based comparative effectiveness-base practices.4 However, EHR data quality remains a core barrier to this goal.1,3,16 Data quality issues such as the pervasiveness of incomplete data is a direct threat to risk prediction reliability.4,17–19 Also, discordant data sources within and across EHRs can generate uncertainty on patient information,20,21 which reduces confidence in EHR-extracted conclusions. It has been shown that there are significant differences between independent research cohort data and EHR data quality,22 which raises further questions for secondary uses. At present, it is known that data quality has the potential to impact risk prediction accuracy23,24 but the extent is yet to be quantified and accounted for to ensure accurate risk assessment.16 A major barrier to achieving this is the lack of an explicit, validated data quality standard to assess EHR data destined for CVD risk assessment.

In this paper, we present our initial evaluation results and data quality assessment standard prototype for the assessment of EHR data destined for CVD risk assessment. We built this standard using the DataGauge process25 to design and implement data quality assessments for EHR data. This method defines an explicit data quality standard including a data model paired to discrete data quality requirements based on qualitative research methods and expert knowledge that enable open and transparent reporting of data quality evaluation parameters and data quality assessment results.26 We developed our standard for the Framingham 10-year hard coronary heart disease risk prediction model27 based on expert interviews and a focus group session. Our standard was validated for coverage of existing data quality framework features including data quality dimensions, levels of data granularity and knowledge domains necessary for data quality assessment.26,28–30 This standard represents the first step toward open, standardized data quality assessment of EHR data destined to estimate CVD risk in the context of learning health systems. Our aim is to pave the way toward open development and evaluation of data quality assessments for secondary analyses of clinical data in learning health systems.
Methods

To develop our data quality gold standard, we followed the DataGauge process.\textsuperscript{25} We selected this approach because it provides a systematic methodology to generate an explicit data quality standard, ensuring transparency\textsuperscript{26,31} in reporting. This approach also ensures coverage of a broad set of aspects required for exhaustive and complete data quality assessment.\textsuperscript{25,29,30,32} Applying the DataGauge process entails iteratively developing a model to explicitly frame the evaluation scope and clearly define the data needs for a specific secondary use. In our case, our intended use was leveraging EHR data to calculate patients’ CVD risk using the Framingham 10-year hard coronary heart disease event risk model.\textsuperscript{27} This risk assessment model was selected for its coverage of many factors used for other risk scores such as the Atherosclerosis and Cardiovascular Disease Pooled Cohort Equations\textsuperscript{33} and the Multi-Ethnic Study of Atherosclerosis (MESA) risk score.\textsuperscript{34} The model was also selected for its relative simplicity compared to other models, which fit the purpose of this initial pilot study.

The DataGauge process entails developing an explicit list of data quality requirements using qualitative research methods based on the initial data needs model. We developed these requirements using a two-stage approach involving interviews and focus group sessions.\textsuperscript{35} Specifically, we developed an initial interview guide based on the third version of the data needs model and the guidance provided with the DataGauge methodology along with three rounds of feedback from informaticians and qualitative researchers. This aimed to ensure the coverage of data quality dimensions and levels of data granularity.\textsuperscript{25,30,36} To ensure coverage of all areas of expertise needed for this secondary analysis of EHR data, we recruited one informatician, one epidemiologist, one clinician and an interdisciplinary expert covering all three areas. Following these four initial interviews, we developed a focus group guide with three rounds of review. We then conducted a focus group session including all four experts. The goal of this session was to ensure agreement across data quality requirements and discuss issues across areas of expertise. Our qualitative research approach was based on grounded theory.\textsuperscript{35} We employed a purposive sampling approach where experts were selected based on their areas of expertise but also were familiar with secondary analyses of clinical data, in accordance with the DataGauge process guidance. Saturation was ensured by providing relatively ample time for interview sessions (one hour each), multiple passes on the interview guide and allowing for additional expert review of the data quality requirements to ensure that no additional requirements could be generated.

We evaluated the resulting data quality standard in two ways. First, we evaluated the coverage of our data quality requirements based on existing EHR data quality assessment frameworks. Specifically, we assessed our requirements’ coverage of data quality dimensions,\textsuperscript{25,29,32} levels of data granularity\textsuperscript{25,36,37} and knowledge domains required for secondary analyses of clinical data (i.e., clinical, analytical and informatics), in agreement with the DataGauge methodology’s framework.\textsuperscript{25,30,38} As an external validation, we also assessed the coverage of dimensions reported by Weiskopf’s 3x3 DQa framework\textsuperscript{28} which includes completeness, correctness and currency as data quality dimensions and patient, variable and time as data constructs to be covered for any data quality assessment. Coverage was represented by the number of areas touched on by the requirements. The requirements were classified along each dimension by two raters and then we calculated inter-rater agreement\textsuperscript{39} and two-rater Cohen’s Kappa\textsuperscript{40} to verify inter-rater reliability across methods using the irr R package.\textsuperscript{41} Discrepancies were discussed and reconciled for the final report. Then, we conducted an initial effectiveness evaluation by implementing the data quality assessment as defined by our data needs model and quality requirements. The goal was to test whether our data quality standard was capable of catching data quality issues in real-world EHR data. Specifically, we extracted all EHR data elements needed for CVD risk scoring for 456 patients. We included all data for all patients between 45 and 54 years of age, with ten or more hypertension diagnoses, from the Wake Forest Baptist Health system (Winston-Salem, NC) for this pilot evaluation. The age range was selected to fall well within the target age range of the CVD risk assessment model. Hypertension was selected due to its known indirect interaction with CVD\textsuperscript{26} as well as the need for long-term follow-up; the ten-diagnosis cutoff was selected to ensure that the patient was followed in the EHR for a minimum of 10 visits and would contain enough data to assess data quality but also to limit the number of patients in the evaluation dataset. The data was reshaped to conform to the data needs model and evaluated according to the data quality requirements using custom-built code including queries developed.

Multiple software tools were used to carry out this analysis. Data extraction was done using Wake Forest Baptist Health’s 12h\textsuperscript{41} clinical data warehouse. The data needs model visualizations were created using MySQL Workbench (version 8.0.23, Oracle, Corp., Austin, TX). The same tool was used to shape data extraction to fit our analytical data model. Rater analyses were done in R version 3.6.2\textsuperscript{40} and RStudio (version 1.2.5033, RStudio, Inc., Boston, MA). Visual exploration and analyses were performed using Tableau (version 2020.4.2, Tableau Software, Inc., Seattle,
Results

Our final data needs model was established after three rounds of feedback (Figure 1). The final model was a single- table design representing a patient data “snapshot” containing the latest data available for the calculation of a CVD risk score at the time of a visit. This design was chosen to align with the data’s intended purpose and also as a means to facilitate the assessment of the data’s fitness for purpose.\(^\text{31,45}\) Multiple values can be available over time or on the same visit despite needing a single value for CVD risk assessment and our data model addresses this data management concern to simplify analysis and quality assessment. The variables included are a direct reflection of those for CVD risk calculation as defined by the Framingham 10-year hard coronary heart disease event risk model.\(^\text{27}\) This data needs model was subsequently used to develop data quality requirements.

Developing our data quality requirements in accordance with the DataGauge process entailed conducting four interviews and one focus group session. The interview lengths ranged between 49 and 87 minutes and were conducted between 01/19/21 and 02/10/21. Our focus group lasted 59 minutes and was conducted on 02/18/21. The interviews produced 47 individual data quality requirements. The focus group generated 14 new requirements and allowed the adjustment and fine-tuning of 12 requirements. Table 1 presents the list of all expert feedback leading to primary quality requirements along with the exhaustive list of data quality requirements for EHR data destined to calculate patients’ CVD risk over time using the Framingham 10-year hard coronary heart disease event risk model.\(^\text{27}\) The final list of requirements contained value-level requirements such as type checks, value checks, range checks and NULL value checks (e.g., requirement ID 1, 2, 6, 10 and 49) as well as more complex requirements such as normality checks at the variable level (e.g., requirement ID 4), cross-variable checks such as (e.g., requirement ID 38) and patient-level checks for alignment with clinical knowledge (e.g., requirement ID 41).

Our evaluation results confirmed that the requirements generated using the DataGauge process were capable of covering all targeted aspects of data quality. The classification of our requirements by two reviewers yielded inter-rater agreement and reliability of 95.1% (Kappa=0.977, p<.0001), 90.2% (Kappa=0.879, p<.0001) and 100% (Kappa=1, p<.0001) for data quality dimensions, knowledge domains and levels of data granularity, respectively. Classification of the 3x3 DQA constructs was slightly more challenging but feasible with reasonable levels of inter-rater agreement, returning agreement values of 88.5% (Kappa=0.801, p<.0001) and 90.2% (Kappa=0.924, p<.0001) for data quality dimension and construct, respectively. Figure 2 presents the coverage of data quality dimensions, knowledge domains necessary for secondary analyses of clinical data and levels of data granularity from the DataGauge Framework but also the coverage of all construct combinations from the 3x3 DQA framework, as an external validation. Coverage ranged from 2 to 26 requirements across data quality dimensions, from 2 to 18 for knowledge domains and from 5 to 36 for variable granularity level. These variations are expected and due to the particular aspects of the data quality assessment design. Still, all aspects were covered by at least 2 requirements. Our requirements also covered most combinations of the 3x3 DQA framework. Coverage ranged from 22 requirements for variable-level requirements checking for correctness to 1 patient-level requirement checking for currency. The process did not generate any variable-level requirement checking for data currency, likely due to the data needs model design that split variables and their corresponding temporal variables, allowing for variable-level definitions of accuracy to cover this.

On implementing our data quality requirements to assess real EHR data, we found that our requirements were able to identify data quality issues that would impact or prevent the calculation of CVD risk assessment. Our dataset contained data for 456 patients followed for at least one year with a mean (± standard deviation) age of 57 (±16) years. The unprocessed dataset contained 506,268 diagnosis entries (4560, relevant to our quality assessment), 732,925 vital value entries (213,294, relevant), 3,194,129 medication entries (18,765, relevant) and 1,178,552 lab value entries (6786 relevant). The data quality assessment revealed that our requirements were capable of uncovering 705 data quality issues in the data representing this patient set. These issues included 4 data type violations (e.g., requirement ID 1), 350 NULL value violations (e.g., requirement ID 53), 5 value range violations (e.g., requirement ID 24), 12 patient ages outside of usable range (e.g., requirement ID 33), 332 timing of values harvested (e.g., requirement ID 36) and distribution issues for 2 variables (e.g., requirement ID 46).
Figure 1 – Data Needs Model Versions. Figure (c) presents the final data needs model as used to develop the data quality requirements list.

Figure 2 – Coverage of Data Quality Dimensions, Data Reuse Knowledge Domains, Data Granularity Levels and Construct combinations from the 3x3 DQa framework.

Discussion

To pave the way toward more reliable CVD risk prediction through transparent and standardized EHR data quality assessments, we developed an explicit data quality assessment standard using the DataGauge process. This standard was composed of a data needs model that explicitly described the data and structure needed for CVD risk assessment using the Framingham 10-year hard coronary heart disease risk prediction model and a list of 61 data quality requirements to test EHR data’s fitness for CVD risk assessment. We also evaluated the standard’s coverage of data quality dimensions, knowledge domains needed for secondary use and levels of data granularity targeted by the DataGauge process, finding that all aspects were covered by our requirements. Assessing the coverage of dimension combinations from the 3x3 DQa framework, we found that all but one combination was covered by our requirements. Finally, we implemented our data quality standard to assess real-world EHR data for 456 patients, which identified 705 data quality issues in this limited test dataset. The core contribution of this work is to provide an initial, open data quality standard for CVD risk assessment using repurposed EHR data, previously unavailable, to our knowledge. This standard aims to serve as a starting point for the development of open, standardized and uniform data quality standards for the secondary use of EHR data. This is fundamental to the reliable secondary analysis of clinical data in the context of learning health systems.

The impact of EHR data on CVD risk assessment has been explored in the past, providing an initial understanding of the impact of EHR data’s imperfections on CVD risk scores. Specifically, the literature provides evidence that EHR risk assessment presents a great opportunity for the improvement of care, that there are still major challenges to ensuring that EHR-based CVD risk assessment is reliable, that EHR data quality and biases affect risk modeling, that the clinical context that impacts these data will impact the performance of these models and that EHR-specific bias seems to impact in risk assessment, but can be controlled for. Our paper extends this existing body of work in three ways. First, it provides an explicit data quality standard developed from expert knowledge for review, reuse and further development in future work. This opens up new avenues for research including collaborative standard development that will support both thorough “fitness for purpose-oriented” data quality assessments of EHR data, the transparent reporting of EHR data quality for secondary analyses and the support the reliable reuse of clinical data in the clinical setting. Second, our work also introduces the idea of integrating and cross-referencing health informatics data quality frameworks for the validation of data quality assessment designs. Though this has been explored as a means to harmonize data quality terminologies, using such integrations for data quality assessment work purposes has not been published in the past, to our knowledge. Finally, our findings show that it is possible to develop effective, purpose-specific data quality assessments based on expert knowledge following an explicitly-defined process, likely to improve the repeatability and reproducibility of data quality assessments, a standing problem in the field of EHR data quality assessment.

One of learning health systems’ aims is to identify and improve the care of patients at increased risk. Patients suffering from chronic disease such as those with diabetes (12-14% of U.S. adults, depending on criteria) have increased risk of CVD. The time-varying and risk-increasing nature of diabetes make this population particularly likely to benefit from EHR-derived, personalized CVD risk assessment over time. Still, personalized risk prediction models have not fully penetrated clinical practice. EHRs offer an opportunity to implement such models seamlessly in clinical practice leveraging large, longitudinal datasets for patients matched to specific populations. However, EHR databases present data quality issues that impact the reliability of these risk scores. Moreover, current data quality assessment methods are complex, challenging to implement, human-intensive and burdensome to implement. This reduces the likelihood and feasibility of conducting thorough data quality assessments for every secondary analysis of clinical data.

The routine reuse of clinical data for CVD risk assessment in the context of learning healthcare and clinical decision support may warrant the development of standardized data quality standards to increase the reliability of such analyses. For example, if EHR data were to be leveraged routinely to generate CVD risk assessment estimates at every visit, the repeated use would justify the overhead work of developing a data quality standard ahead of time. Approaches similar to the requirement testing used by the DataGauge approach appear to be scalable, providing further assets for implementation. Another way of increasing the efficiency of data quality standard development would be enabling quality standards (i.e., data needs models and corresponding requirements) sharing across research groups. This would save time and enable collaborative improvement of such standards. This is similar to the Automated Characterization of Health Information at Large-scale Longitudinal Evidence Systems (ACHILLES) module developed by researchers at the Observational Health Data Science and Informatics (OHDSI). However, this module only checks for general
(i.e., not purpose-specific) data quality and only focuses on the Observational Medical Outcomes Partnership (OMOP) data model. Further development along this approach for purpose-specific data quality standard development is likely to lead to fully-shareable quality standards for semi-automated quality assessments along with open, purpose-specific quality standards that could be developed, improved and refined via crowdsourcing the requirements development task within the informatics community. This is akin to the open-source development model. Despite the inherent potential of this approach, further development is needed to the fundamental infrastructure to enable and test its merits.

Our development and evaluation work presents four limitations mostly related to its preliminary nature. First, our data quality standard covers a single CVD risk assessment model (i.e., the Framingham 10-year hard coronary heart disease risk prediction model), despite a large number of alternative options. This risk model fits the needs of an initial pilot quality standard as it covers many factors included in other models but is also relatively simple compared to other models. Other models will be included in future work to expand the scope to CVD risk assessment at large. Second, we had access to a limited number of experts for the development of our data quality requirement standard. However, our development process covered all areas of expertise required for secondary analysis of clinical data according to the DataGauge guidelines. We also included an interdisciplinary expert to ensure that requirements affecting multiple areas of expertise would be covered. Still, we anticipate including a larger pool of single and multi-domain experts in future iterations of our CVD risk data quality assessment standard and hope to crowdsource the development of these requirements to the informatics community making routine secondary use of clinical data. Third, we evaluated our requirements’ validity according to two frameworks, despite many more being available in the literature. These frameworks were selected, on one hand, to align with our quality standard development method and test the internal validity using the data quality dimensions provided by the DataGauge methods and, on the other hand, to integrate our requirements with at least one existing published framework while testing their external validity. We selected the 3x3 DQa framework because its design dovetails with the DataGauge process, which frames the development of data quality requirements via a series of questions that integrate dimensions of data quality with levels of data granularity, whereas the 3x3 DQa framework integrates data quality dimensions with data constructs. Still, we will expand our integration of other data quality frameworks in future work. Finally, our initial data quality standard effectiveness evaluation was conducted using a limited set of patients from a single EHR system. The nature of this pilot work required a limited and focused dataset to test our standard’s capacity to identify data quality issues in real-world EHR data under restrictive conditions. Future work will address these limitations by expanding our focus to a larger set of patients representing the general population qualifying for CVD risk assessment and, subsequently, expanding to other EHR data sources.

Conclusion

We developed an explicit data quality assessment standard to support reliable CVD risk prediction via transparent and standardized EHR data quality assessments. The standard contained 61 data quality requirements that covered all data quality dimensions, knowledge domains needed for secondary use and levels of data granularity targeted by the DataGauge process and all but one of the 3x3 DQa framework quality dimension-data construct combinations. Our standard uncovered 705 data quality issues in a limited set of real EHR data for 456 patients. This explicit data quality standard for CVD risk assessment using repurposed EHR data can serve as a starting point for the development of open, standardized and uniform data quality standards for the secondary use of EHR data, which is fundamental to the reliable secondary analysis of clinical data in the context of learning health systems. Future work will include expansion of this standard to other risk prediction models as well as validation using other data quality frameworks and EHR databases.

Technology to Support Collaborative Dissemination of Research with Alaska Native Communities
Lisa G. Dirks, MS, MLIS & Wanda Pratt, PhD
University of Washington Information School, Seattle, WA, USA

Abstract
Marginalized communities often mistrust research due to a history of unethical practice and limited community engagement. Research community engagement is expected with Indigenous communities, but few empirical studies have explored engagement in results dissemination, let alone using technology. Studies on using technology to disseminate results focus on health and research professional audiences. This paper discusses Alaska Native stakeholder values on technology to facilitate collaborative results dissemination. In this formative study, six participants engaged in participatory design activities on collaborative results dissemination. Sketches and interviews were analyzed deductively using a value-based codebook. Study findings highlight the importance of community context and transparency. Contextual awareness includes understanding local culture and power dynamics, acknowledging the diversity of cultural practices within Alaska Native groups. Transparency is tied to clear communication: encouraging active dialogue and providing alternatives to communicate research. Technology that supports such collaborative dissemination could increase trust and improve adoption of research-recommended actions.

Introduction
Health research has impact when the people affected by health conditions can access and understand the research results, yet all too often, sharing coherent health research results with research participants and non-academic audiences is often neglected or done ineffectively. For many researchers, the primary method of disseminating research results is to submit manuscripts to peer-reviewed journals or conference presentations which limits their audience to academic scholars. Limiting dialogue between non-academic community participants and researchers, many of whom may be unacquainted with community perceptions of health or community systems of sharing information, decreases the likelihood that study results will be implemented at a community level. Collaboration between researchers and the communities that studies are conducted in can increase the likelihood that information is shared in more relevant community-centric ways. Studies suggest that research participants want to receive research results and propose that participants have a right to receive them for contributing to the research. Other than using traditional academic dissemination methods (i.e. journal articles, conference presentations), limited progress has been made to ensure health research results are returned to participants or otherwise shared with non-academic community audiences.

These dissemination limitations can lead to the spread of misinformation and mistrust, which is especially problematic for communities facing extensive social determinants of health. American Indian & Alaska Native (AIAN) people have encountered innumerable research injustices, such as being exposed to procedures without informed consent and having research results disseminated without community input or approval. For example, in the 1950’s Alaska Native people were unethically recruited into a study that involved ingesting radioactive iodine (I-131) at excessive doses without adequate consent and without appropriate documentation for follow-up which further motivates research mistrust. Oversights like these increase the need for transparency and accountability in research at all stages from project conceptualization to results dissemination. Moreover, AIAN people have been under-represented in national research initiatives—such as NIH’s All of Us research program—or have not been consulted about how best to implement research or disseminate actionable findings relevant to community context. Trust in health research influences trust in health services. Marginalized communities, such as AIAN people, are less likely to trust the scientific community as a result of unethical research practices. Egregious research violations have led to crucial research sovereignty in AIAN communities which has helped begin to mend their relationships with health research.

In the past several decades, research in AIAN communities has become much more collaborative or community driven. Despite this progress, only limited research has explored AIAN collaboration specific to results dissemination. Preliminary studies suggest that AIAN communities are interested in being engaged in the dissemination process. Previous research indicates that AIAN people want results that consider local context, appropriate language, information that is both practical to researchers and community members, and information that...

398
considers AIAN values, knowledge, and expertise. A collaborative approach to dissemination has potential to strengthen AIAN trust in research and enhance researchers’ awareness of community concerns and perceptions of research. Recently, AIAN-led organizations have seen success in informing AIAN communities about the risks and benefits of the COVID-19 vaccine. For example, the Urban Indian Health Institute conducted a US national survey with 1,435 AIAN respondents on community perspectives of the Covid-19 vaccine. Data from this survey have been used by the Urban Indian Health Institute and other AIAN serving organizations to develop social media campaigns and educational material about COVID-19 and vaccinations. A key finding from this survey reinforced the importance placed on community with 74% of respondents sharing a responsibility to their communities for getting vaccinated. This information has helped tailor COVID-19 prevention and education materials to community vs. individual benefit. Despite advances, limited empirical evidence is available about values AIAN stakeholders place on technology-facilitated collaborative dissemination let alone what they would want these technology tools to include. Further dialogue could encourage multi-directional learning and enhance partnerships leading to improved communication and trust in research promoting more participation in research where AIAN representation is now limited. New methods and technologies for respectful and culturally responsive research results dissemination are urgently needed both to help researchers engage diverse participants and to serve these communities better.

Internet-based technologies (i.e. social media, podcasts, websites, and mobile applications) have become more interactive and consumer-centered allowing for engagement and control over content that users interact with. These technologies increase the potential for conveying health-related research results to a broader audience. Moreover, these technologies have democratized access to research information, giving users the flexibility to manipulate how they see and share information including health research results. Bernhardt, Mays & Kreuter have coined the term “Dissemination 2.0” to represent the use of cooperative internet-based technologies to disseminate research products (e.g. results, educational content) claiming that it “represents an interactive approach of exchanging scientific evidence among collaborative members of a research-to-practice network that leverages their user-generated knowledge and harnesses their collective intelligence for increased effort and continuous improvement...” and takes advantage of the core foundations of Web 2.0 applications—collaboration, participation, multidirectional information exchange—to improve current dissemination activities and advance the translation of research to practice. This approach leverages relationships with healthcare practitioners, rather than average community members, but the core foundations of collaboration, participation, and multidirectional information exchange are potentially valuable for a wide range of communities. Preliminary studies on the use of internet-based and mobile technologies indicate a need to further explore these modes of research dissemination, particularly to community audiences.

Social media is recommended as a possible tool to broadly disseminate research results. Most studies investigating using internet-technologies to disseminate research results have focused on sharing results with academic and healthcare provider communities. Many have only reported web analytic data on website and social media reach, indicating increased access to their research content but did not provide much context about the user or their experiences. One study conducted with Australian, Indonesian, and Malaysian researchers asked about their social media research dissemination practices. Only 15% of the survey respondents reported using social media to share research results. In one web analytic study, Twitter was the most active platform for disseminating research articles; however, it is unclear whether these research articles were shared outside of academic networks or how tweeting them might impact science practice. Still, another survey conducted with clinical trial research participants suggested letters or fliers distributed via email and study website postings as most desirable, while Twitter, text messages, and conference calls were least desirable. It may be that using Twitter to share research results is more accessible to academic communities than it is for research participants.

Internet-based technologies have also been used to engage research-related dialogue between a research center and other researchers and community stakeholders. Soto et al. used Twitter to promote online community-engaged research training curriculum to both researchers and community members. Only 10% of the trainees were community members. While the researchers suggest social media-based community engagement is promising, there were important study limitations. Particularly, their inability to study demographic characteristics, including a user’s status as a community member vs. a researcher, means more research is needed to understand who the users of these strategies include. Feasibility studies on linking podcasts via social media (e.g. Twitter, Facebook) have also been explored as a novel form of communicating health research and facilitating engagement and dialogue. In one case, dialogue occurred through user comments and researcher replies on social media posts that linked research podcast recordings. As the study only examined web analytics and comments made on social media posts, the results of the study were limited to the comments made to the posts, and web analytics such as internet shares, and number
and duration of podcast plays. The authors suggest future studies are needed to explore how effective the podcasts were for reaching audiences, acquiring knowledge, and successfully communicating health topics content.  

This formative study explores health researcher and Alaska Native community stakeholder perspectives on technology-facilitated collaboration in the dissemination of health research results. Participants were engaged in a design process to develop low fidelity prototypes for community-researcher collaborative dissemination. This paper discusses participant preferences and values with respect to using technology to facilitate collaborative results dissemination.

Researcher Stance
Ms. Dirks positions herself as a mixed-heritage Alaska Native/White community-engaged researcher with community roots in an Alaska Native village in the Aleutian Islands. As an Alaska Native researcher, she has had experience being both a health and social sciences researcher as well as a community participant in health and social research studies. A significant amount of her research experience has been with Tribal communities in Alaska and elsewhere on topics relevant to community mental health and wellbeing. This dual role as a health services researcher and an Alaska Native person motivates her work and gives her unique perspective on both sides of the relationship between community and research.

Methods
This formative study was approved by the University of Washington Institutional Review Board. This study was conducted to develop a better understanding of: (1) stakeholder-defined risks and benefits in using technology to collaborate on health research results dissemination; and (2) stakeholder values related to collaborative research results dissemination. This exploration was framed using components of a value sensitive design (VSD) theoretical approach. VSD is an adaptable approach that engages moral and ethical considerations for technology design while also leaving room to explore other value considerations important to system stakeholders. It holds an “interactional position” which places attention on how people’s values determine how they interact with a technology even if it wasn’t designed for the explicit ways it is being used. It is an iterative process holistically integrating conceptual, empirical and technical aspects. This study involves the formative stages of a conceptual and empirical investigation of values relevant to community-researcher collaborative dissemination. Interest at this initial stage is to examine how well the conceptual value components compiled from the existing Indigenous community-engaged dissemination research literature align with the data contained in the participatory design activity artifacts created in this study. It is our intention to use data from this formative study to improve upon and iterate a value-based conceptual framework for collaborative dissemination considering an Alaska Native context.

Conceptual Investigation Methods
Reflecting on the flexibility of VSD, prior to empirical data collection, a literature review on researcher-community collaborative dissemination in Indigenous communities was conducted to create a list of value-based themes related to the design artifact data that were collected for this study (Table 1). These values were examined in relation to the design artifacts created during participatory design activities (See Figures 1 & 2 for example sketches).

Empirical Investigation Methods
A participatory design approach was used consisting of: (1) a list making activity in which participants were asked to write out a list of risks and benefits for using technology for Alaska Native community and researcher dissemination collaboration, (2) creation of a prototype sketch of the technology-based tool considering their ideas from the list-making activity; and, (3) scenario development which involved drawing or orating a story in which their prototype might be used. Using a deductive value-oriented coding manual, data obtained from sketches and accompanying scenarios created by participants were analyzed. The coding manual was created using conceptual definitions informed by existing literature. The literature that was used to inform definitions was isolated to community-engaged and collaborative dissemination-related health research specific to Indigenous communities. Table 1 provides a working list of these value-based conceptual definitions for collaborative dissemination.

Data collection process

A purposive sampling strategy consisting of email and word of mouth was used to recruit participants with strong connections to an urban Alaskan community. Participants were selected based on our prior knowledge of them having experience either being a health research participant or a health researcher. Inclusion criteria required participants to be 18 years or older and interested in exploring health research results dissemination processes in Alaska Native communities. Recruitment and data collection took place in May 2019 and early March 2020. Participants provided verbal consent. Design sessions were audio-recorded and transcribed, and extensive notes were taken throughout the process. All data collection took place in each individual participants’ private home. Participatory design sessions ranged from 30-60 minutes.

Participants

Six participants engaged with us during one of two time periods (May 2019 & March 2020). For the four who participated in May 2019, three self-identified as women, one as a man. Three self-identified as Alaska Native and one was White. One was a health researcher and the remaining three were Alaska Native community members living in an urban Alaskan community. For the two who participated in March 2020, one self-identified as a man and one as a woman. One identified as a non-Native health researcher with experience in Alaska and other American Indian communities. The other participant identified as an Alaska Native community member living in Seattle with roots in
a rural Alaskan community. Participant ages ranged from 37-68 years old. All participants had some experience in being research participants in previous health-related studies on topics in physical and behavioral health.

Findings
The lead author (Ms. Dirks) conducted a deductive analysis of session transcripts and written text on participatory design sketches and scenarios using a deductive value-oriented codebook consisting of the conceptual values noted in Table 1. Themes are highlighted below by these literature-informed conceptual values (partnerships, context, transparency, and dialogue). To distinguish between community and researcher participants, community participants are identified with the prefix “C” and researcher participants are prefixed with “D”.

Partnerships

Power Dynamics
Partnerships could benefit from awareness of power dynamics and engaging with various stakeholder groups in the community, not just those in a power position. This engagement should occur over time as a developing process, rather than as a product. Research results dissemination is often viewed as a product (i.e. manuscript, presentation). This limits its longevity. Seeing research as a process of ongoing communication, has impacts on partnership. Participants recommended youth as a community sector to involve in collaborative partnerships. Community participant C4 suggested that young people are often left out of decisions that have potential direct effects on them; they are often placed in a subordinate position to adults. Researcher participant R1 indicated that since youth will potentially be impacted by research in the long-term, they should be present to share perspectives about what problems they want to solve and what technologies they would want to interact with.

Individual vs. collective sense of community
Technology may pose possible threats to Alaska Native community norms of collectivism. A dissemination system has potential to cause isolation and individuation. Community participant C3 highlights this concern: “How did it work in the past for everyone to work together for communities to help sustain themselves? If it becomes more individualistic there is a breakdown. When does functional become dysfunctional? Would technology encourage the [individual] me-me-me attitude that was once [traditionally the Native collective] we-we-we?”.

Figure 1. Participant Example 1 Stakeholder Scenario Sketch.

Context

Epistemological nuance
The perception of Alaska Native communities’ epistemology is an important concept related to community values. Community participant C5 suggested that “[m]aybe sometimes Native people seem to be so indecisive because they are considering other parts of the community [in their decision making]. There is [a perception from outsiders that there is] no motivation to try to make things better”. This represents a tension between collectivist worldviews such as those found in many Indigenous communities in contrast to individualistic worldviews such as those most prevalent in mainstream United States communities. For this participant, misperceptions on decision-making processes can cause conflict if community context is misunderstood. Researcher participant R2 also stressed that each community has its own unique characteristics, especially within Alaska Native communities and stated that “sometimes we
[Alaska Native people] are grouped as one culture when we have so many cultural beliefs that vary even within our people”.

**Geography**

Geographic placement also has contextual importance. Rural Alaska Native communities are often difficult to get to. Transportation to and from communities becomes an important context value to consider. Some communities rely on air travel to get to and from their home location. This limits resources and opportunities for in-person collaboration due to constraints related to weather and airfare costs. Technology can be a benefit to communicating with people at a distance where costs of travel can range in the thousands of dollars for airfare alone. However, such an approach may also pose a problem for those communities that still have limited access to technology both peripheral and via infrastructure.

**Transparency**

Participants shared views on technology as both a facilitator and barrier to collaboration. C3 stressed importance for clear ongoing communication even before research results are ready to be presented. They viewed technology (i.e. websites) as a way for community members and researchers to maintain active communication. At the same time, C3 also viewed constraints of technology for transparency. For example, community members who have limited technology skills (e.g. Tribal Elders), may feel excluded from optimal collaboration making technology training or local facilitation an important consideration. Furthermore, transparency also includes using language and defining unfamiliar terms or norms, as stated by both researchers and community members. Researchers should limit technical research jargon and community members should define local terms and contextual factors that researchers may misinterpret. Community participants (C3, C5) also illustrated potential for mistrust in using technology to collaborate. They placed value on having guidelines on who has access, what it would be used for, and when people would have access.

![Figure 2. Participant Example 2 Stakeholder Scenario Sketch.](image)

**Dialogue**

Participants discussed benefits of technology for facilitating dialogue. To some participants, this dialogue does not need to be bi-directional oral communication but may benefit from having mixed modes of communication, such as the combined use of text, video, and audio. Researcher participant R4 discussed how dialog may benefit from being
both synchronous and asynchronous. In their scenario, community participants would meet as a local group independently to review non-technical research results that researchers would have shared with them before meeting in person. They stated that, in many Alaska Native communities, people need time to reflect before having discussion. A live videoconference could occur after the community group had time to reflect and deliberate on their own. This videoconference would be an opportunity for the community to ask researchers questions and share their response to the results and for researchers to orally articulate results and ask the community questions. The idea of mutual educational opportunities was also something to consider regarding dialogue. For example, researchers may learn from Alaska Native people about local knowledge, processes and interpretations, Alaska Native community members may learn more about science and research from the researchers. This organic communication is less likely to occur if a manuscript were the primary form of dissemination. Additionally, one community participant (C3) suggested that in-person communication would be ideal yet would prefer a technological interface for dissemination to reading a peer-reviewed article.

Implications for Technology Design
Empathy and sincerity towards the values of the communities we design with help us create technology systems that are likely to be more salient to their intended needs. Values can be difficult to isolate and often overlap and form networks showing interconnectedness. Co-designing with marginalized community participants can help expose values and how they are interrelated which can help equalize power dynamics between researcher and community member as well as expose community-level power dynamics that can unintentionally impact design. By being actively involved in technology design, community participants can highlight design flaws or features that do not align well with community collective norms. Active community participation can benefit design projects by having internal members of the community who understand cultural and epistemic nuances that may otherwise be missed by researchers with less familiarity with respective community context. As was discussed by one of our community participants, Alaska Native people have diverse cultural and linguistic backgrounds which make using a one-size-fits-all approach to participatory design for all communities a major challenge. According to the Bureau of Indian Affairs, there are presently 578 federally recognized tribes in the United States and many other tribal communities do not have federal recognition. Some of these communities have similar norms and practices but there is great variation across tribal communities in cultural protocols and traditions. Additionally, urban communities include representation from many of those tribes which makes it difficult to account for representation from each tribal community in those settings. Moreover, local participation and design facilitation, particularly in rural isolated communities, can benefit design by having support "on-the-ground" should travel or access to technologies become prevalent.

As with any participatory activity, it is important to understand the contextual nuances of conducting participatory design with a marginalized community, especially if the researcher is not already affiliated with the community. Although technology can support collaboration, it can also create barriers to collaboration that may not be exposed without understanding community norms. In our study, Alaska Native Elders or other community members with limited technology skills may have an opposite reaction to collaboration and instead feel isolated rather than more involved. An essential step to reveal these contextual distinctions is to spend time developing relationships with stakeholders and getting to know the community before initiating design activity. A proactive approach involving careful contextual analysis of the community, discovering potential problems, and developing and implementing strategies to address those challenges prior to starting design activities. Awareness of context also includes understanding local culture, including how to approach participants and show respect in culturally-specific ways which can be achieved by spending time with different stakeholder groups, many of whom may not be the design’s intended end user. Furthermore, developing relationships before design activities may also help uncover hidden agendas that may conflict with participatory activities.

To support partnership, context, transparency, and dialogue, co-design methods incorporated with Indigenous epistemological approaches will be added to our future research activities to promote more community power to the design process. For example, design processes could include a digital storytelling component that integrates oral traditions with technology design and research. Digital storytelling involves a process of creating short, personal stories that are told through a recorded, first-person voiceover, still and/or moving images, and music or sound. Digital storytelling connects and supports people in natural ways and is in alignment with AIAN cultural practices that promote values through sharing stories. Using narrative methods such as digital storytelling help deconstruct power dynamics between researchers and community members and are also respectful of rich oral histories and cultural practices in AIAN and other Indigenous communities. Integrating these approaches will also contribute to the community-engaged research approach by adding to the body of knowledge on engagement in community results
dissemination. Moreover, exploring research results dissemination from an Indigenous knowledge systems framework adds advantages to developing a culturally congruent conceptual framework that will increase sanguinity in health researchers’ communication with AIAN populations. This integration has the potential to generate innovative culturally responsive user-centered design methods that may be advantageous for participatory design activities with AIAN and similar communities with robust narrative values. The digital storytelling method will provide participants control over what they choose to share and how it is represented. Engaging participants in this way may increase parity by supporting their role as educators and owners of the knowledge they choose to share.

Conclusion

Conventional health research results dissemination approaches have often constrained marginalized communities’ research engagement. Creating interactive systems that enable community-researcher collaboration may benefit Alaska Native and other marginalized communities by encouraging active communication that is germane to their respective communities. Study findings highlight the importance of community norms and context in developing interactive dissemination systems for collaboration with Alaska Native communities. Awareness of context includes understanding local culture, including how to approach participants and show respect in culturally specific ways. We need to pay attention to power dynamics and dedicate time with different stakeholder groups, many of whom may not be the design’s intended end user. We also need to emphasize transparency with clear communication that promotes more active dialogue, potentially providing a variety of ways to communicate that would not otherwise be possible (i.e., mixed digital and analog media).

The findings from this study will be used to improve upon and iterate a value-based conceptual framework for technology-facilitated collaborative dissemination considering AIAN community contexts. The results of this and our future planned research will benefit improved communication and trust in health research in AIAN communities. Such increased trust will in turn improve the impact of health research and health services by ensuring that outcomes of research are more effectively disseminated to AIAN communities. It will support communities in understanding the research and contextual community-level relevance, potentially incorporating research recommendations and support for technology adoption. Such collaborative efforts could also encourage increased participation in national research programs by increasing marginalized groups’ trust in research. Similarly, this research builds connections between informatics researchers and AIAN communities urging further user-centered design collaborations. The conceptual framework, methodologies, and technology prototypes resulting from this and our planned future research could influence other historically marginalized communities by increasing their trust in and uptake of research results.

Acknowledgements

We would like to recognize the University of Washington GO-MAP fellowship program for the graduate funding support provided to Ms. Dirks during this project. We would also like to acknowledge the Alaska Native community members and health researchers who provided insight into the participatory design activities for this project. Professors Batya Friedman and David Hendry provided advice on VSD methodological approaches to use for this study and in future related research endeavors. Finally, we would like to acknowledge the iMed research group for their thoughtful discussions which prompted ideas on a previous research presentation of this formative study.

Development of four electronic clinical quality measures (eCQMs) for use in the Merit-based Incentive Payment System (MIPS) following elective primary total hip and knee arthroplasty

Patricia C. Dykes, RN, PhD1,2, Mica Curtin-Bowen, BA1, Troy Li, BS1, Avery Pullman, BS1, Alexandra Businger, MPH1, Stuart Lipsitz, ScD1,2, Ania Syrowatka, PhD1, Michael Sainaire, MS1, Tien Thai, BS1, David W. Bates, MD, MSc1,2;

Abstract: The Centers for Medicare & Medicaid Services (CMS) supported Brigham and Women’s Hospital (BWH) Center for Patient Safety, Research, and Practice to retool one existing National Quality Forum (NQF) endorsed clinical quality measure (CQM) measure into an electronic clinical quality measure (eCQM) and develop three new eCQMs related to orthopedic care. This manuscript details the iterative process of measure development through environmental scans and stakeholder feedback prior to testing at two geographically different sites. The four measures under development are the: Risk Standardized Complication Rate (RSCR), Risk Standardized Venous Thromboembolism and Major Bleeding Rate (VTE/Bleeding), Risk Standardized Prolonged Opioid Prescribing Rate (POP), and the Risk Standardized Inpatient Respiratory Depression Rate (IRD).

Introduction:
Total hip arthroplasties (THA) and total knee arthroplasties (TKA) are common procedures that are associated with high costs and serious complications.1,2,3 Despite their frequency and cost, quality measurement tools to assess the safety of THA/TKA procedures are limited. Per the Health Services Advisory Group (HSAG) gap analysis reported in the Centers for Medicare & Medicaid Services (CMS) Quality Measure Development Plan, the orthopedics specialty has measurement gaps in areas throughout several CMS Quality Domains.4 Specifically, within the Effective Treatment/Clinical Care domain, there are no National Quality Forum (NQF) endorsed electronic clinical quality measures (eCQMs) related to orthopedic surgery outcomes.4 In addition to the lack of quality measurement tools, CMS is actively trying to reduce the regulatory burden that data collection and quality reporting in the Merit-based Incentive Payment System (MIPS) places on clinicians. MIPS provides performance-based pay to physicians based on the quality of care provided to their patients.5 To address the gaps in quality domains without adding to clinician documentation burden, CMS supported Brigham and Women’s Hospital (BWH) Center for Patient Safety, Research, and Practice to retool an existing clinical quality measure (CQM) and develop three new eCQMs for orthopedic care. eCQMs are tools used to measure surgical outcomes without adding an additional documentation burden for providers as they leverage routinely collected and readily available electronic health record (EHR) data to quantify rates at the individual clinician, clinician group, or hospital level. The measure development process focuses on the following four eCQMs at the clinician group level:
- Risk Standardized Complication Rate (RSCR) – retooled version of the existing NQF15506 and NQF34937 RSCR Clinical Quality Measures (CQMs)
- Risk Standardized Venous Thromboembolism and Major Bleeding Rate (VTE/Bleeding)
- Risk Standardized Prolonged Opioid Prescribing Rate (POP)
- Risk Standardized Inpatient Respiratory Depression Rate (IRD)
Over 139,000 TKA and 91,000 THA surgeries were performed in the United States in 2018 alone,1 and the volume of procedures being performed are projected to increase 71% for THA, and 85% for TKA by 2030.8 Considering the frequency of these procedures, these eCQMs are needed to address the current gaps in quality domains without imposing an additional documentation burden on clinicians.

Methods:
The development of the specifications for all four of the eCQMs was comprised of an environmental scan and stakeholder feedback which were used to validate the need for the measures, define inclusion/exclusion criteria, develop the risk adjustment models, and increase measure meaningfulness and feasibility.

Environmental Scan:
A structured literature review was conducted in collaboration with a Countway Librarian at Harvard Medical School. The reviews had two key objectives: 1) to identify and compile the current literature and practices published in the last five years, and 2) to determine patient-specific risk factors for each measure’s cohort. Additionally, a guideline review was conducted within Guideline Central. We searched the specialty area of “orthopedic surgery” for guidelines pertaining to THA or TKA that were published within the last five years. We then searched for general guidelines published in PubMed.

Existing measures:
A search for existing quality measures was conducted using the CMS Measure Inventory Tool (CMIT) and NQF Quality Positioning System (QPS) to locate all existing measures that are related to or competing with any of the proposed measures. A measure is defined by NQF as related if it involves either the same target population or the same concepts for measure focus, a measure is defined as competing if it involves both the same target population and the same measure focus.²

Technical Expert Panel:
Over the course of the measure development process, the BWH research team discussed the proposed measures with a Technical Expert Panel (TEP) comprised of surgeons, pharmacists, patient representatives, and measure development experts. The objective of the meetings was for the TEP to provide feedback on the specifications that would allow the proposed measures to meaningfully quantify adverse events following THA and TKA. Following the development process, the TEP also played an integral role in evaluating the field testing results for face validity and clinical meaningfulness. The BWH research team met with the TEP on five occasions throughout the development and testing process.

Structured Interviews:
The BWH eCQM development team partnered with an independent collaborator, Massachusetts Health Quality Partners (MHQP), to obtain stakeholder input on the proposed measures. MHQP used structured interviews with patients, providers, and payers to gather feedback and inform the decision-making process that led to the development of the eCQMs. To be interviewed, the following criteria had to be met:
- Patients: Adult, English-speaking patients who had undergone an elective primary THA and/or TKA at Brigham and Women’s Hospital or Brigham and Women’s Faulkner Hospital between January 1, 2017 and October 9, 2019. MHQP contacted these patients via email, and interested patients set up an interview.
- Providers: Any Mass General Brigham (MGB) orthopedic clinician was eligible to participate. This included surgeons, physician assistants, nurse practitioners, physical therapists, occupational therapists, and medical assistants. Recruitment was organized via email, and interested providers contacted MHQP to interview.
- Payers: All payers of Massachusetts health plans that provide coverage for orthopedic surgery were eligible to participate. MHQP contacted these payers via email, and interested participants set up an interview.

Public Comment:
The public comment period allows any interested parties to provide input on the measures via online surveys. Surveys were sent via email to stakeholders and relevant specialty organizations throughout the United States. The eCQM development team solicited comments via web posting for the RSCR measure and for the proposed risk adjustment model. A second round of public comments were solicited following measure development during the measure testing process.

Results:
Measure 1: Risk Standardized Complication Rate (RSCR)
Postoperative complications result in increased costs associated with THA and TKA. These complications affect the quality, and potentially quantity, of life for patients. Although complications following elective THA and TKA are rare, the impact can be devastating. Haro-Gómez et al. reports that the average cost for a hospital readmission after a THA is $17,103.² The costliest types of 90-day readmissions across the U.S. include infections (THA: $68 million, TKA: $89 million), acute cardiac events (THA: $33 million, TKA: $52 million), and acute vascular and thrombic events (THA: $13 million, TKA: $23 million), resulting in a large financial burden on the U.S. healthcare system annually.³ This proposed measure aims to quantify the complication rate at the clinician group level by harmonizing with and expanding upon the existing NQF1550 and NQF3493 measures.
Environmental Scan: 36 papers, two related quality measures\(^{6,7}\) (Table 1), and two practice guidelines\(^{10,11}\) (Table 2) met the environmental scan inclusion criteria and were used to inform inclusion/exclusion criteria, and measure specifications.

**TEP:** The TEP discussed the RSCR measure on four occasions throughout the development process. In April 2019 when the measure was conceptualized using the same criteria as the NQF1550 and NQF3493, the TEP recommended that the RSCR measure be expanded from Medicare beneficiaries aged 65+ to all payers and all adults. This expansion was incorporated into all measures. In this meeting, a minimum of 25 procedures per clinician group was also defined for all measures. In September of 2019, the TEP recommended that BWH include both inpatient and outpatient surgeries and complications rather than only inpatient. Their rationale was that many serious TKA/THA complications are treated in emergency departments or in observation units.\(^{12}\) Restricting the measure to complications in inpatient settings would miss these events. In the May of 2020 and October of 2020 meetings, the development team shared testing results with the TEP. No changes were requested in these meetings.

**Structured Interviews:** Thematic analysis showed that patients (n=18) had mixed perceptions about the value of complication rate measures. Providers (n=10) shared that eCQMs, such as RSCR, add value by motivating improvements in practice and patient care and saving time. Providers were concerned that the eCQM could potentially incentivize providers to decline care for challenging cases. These concerns have been addressed through appropriate inclusion/exclusion criteria and a risk-adjustment.

**Public comment:** During the public comment period, the RSCR received 15 responses. Respondents shared that this measure would be ‘mostly useful’ to ‘very useful’ if implemented. 93.33% (14 out of 15) of respondents agreed that this measure could be used to facilitate quality improvements in THA/TKA outcomes.

**Final Measure Specifications:** The proposed RSCR measures complications at the clinician group level, includes all patients age 18 years and older from all payers, compared to Medicare Fee for Service (FFS) beneficiaries age 65 years and older, and includes procedures and complications documented in both inpatient and outpatient settings.

**Numerator:** The subset of patients from the denominator with any of the measure specified complications occurring during a period of 90 days following the THA or TKA procedure. The complications included in the measure must occur within the specified timeframe (Table 3) in order for the outcome to be attributable to the procedure and be included in the numerator. Complications and time frames were harmonized with NQF1550/3493\(^{13}\).

</tr>
</tbody>
</table>

**Denominator:** All patients aged 18 years or older who received an elective primary THA or TKA procedure within the measurement year from all payers.

**Inclusion Criteria:**

---

410
• Aged 18 or older on the date of procedure
• Having a qualifying elective primary THA/TKA procedure (inpatient or outpatient setting)

**Denominator Exclusions:**
• Discharged against medical advice (AMA)
• Had more than two THA/TKA procedure codes during the index hospitalization
• Did not have a qualifying THA or TKA event.

These inclusion and exclusion criteria also apply to the other three measures under development.

**Measure 2: Risk-Standardized Major Bleeding and Venous Thromboembolism Rate (VTE/Bleeding) eCQM**

Major bleeding events following primary elective THA and TKA are associated with an increase in hospital length of stay, costs, and complications. \(^{14}\) Studies have estimated that about 4.7% of patients undergoing TJA would have symptomatic venous thromboembolism (VTE) without prophylaxis. \(^{15}\) There is general agreement within the orthopedic community that anticoagulant VTE prophylaxis is necessary after TJA, yet the use of anticoagulants puts patients at risk of experiencing a major bleeding event. \(^{16}\) Orthopedic surgeons face the challenge of balancing VTE prophylaxis against the associated risks of bleeding events, where insufficient anticoagulant use increases the risk for a VTE event, and a too high of a dose of anticoagulants increases the risk of a major bleeding event.

**Environmental Scan:** The BWH eCQM development team identified a total of 35 papers, five guidelines\(^{16-20}\) (Table 4), and six related measures\(^{21-26}\) (Table 5) to guide measure development. Review of existing guidelines and quality measures indicated that there are four related measures that examine major bleeding related to anticoagulants, and two that examine the incidence of VTE. No existing measures relating to VTE or major bleeding focus on THA/TKA as their target population, nor do these measures assess both VTE and bleeding.

**Technical Expert Panel:** The TEP discussed this measure on three occasions during the measure development process. This measure was originally conceptualized to quantify the rate of post-surgical major bleeding events following THA and TKA, without incorporating VTE events. As pointed out by TEP members in the January 2020 meeting, measuring both events is key in ensuring a proper balance in the prophylactic regimens. The TEP unanimously agreed that expanding this measure from only major bleeding events to include both bleeding and VTE events would limit the unintended consequence of providers under-prescribing anticoagulants in order to avoid higher bleeding rates, which could in turn cause patients to develop VTE. The development team agreed that the expansion of the measure scope would increase measure meaningfulness and modified the eCQM to track both events. In the May of 2020 and October of 2020 TEP meetings, specification changes were made to improve face validity. Some changes made at the recommendation of the TEP included removing specific ICD codes from value sets, the addition of an anticoagulant use exclusion, and lowering the number of transfusions required to be included in the numerator from ≥2 to ≥1.
Structured Interviews: 23 patients, 15 providers, and 11 payers were interviewed regarding the measure concept and development. The overall consensus was that the proposed eCQM would be effective in providing clinicians with a representation of their anticoagulant prescribing practices through the assessment of both VTE and major bleeding rates following THA/TKA. The most common concern raised across interviews was that rates of VTE events may be very low, and that many surgical risk factors are associated with bleeding events aside from solely anticoagulant use. Additionally, even following the guidelines set forth by AAOS, there is no single standard of care for anticoagulation. Lastly, was also the concern that a patient’s lack of adherence to prescription regiments, resulting in an increased risk of bleeding or VTE event, would reflect poorly on the provider. The development team aimed to account for these problems, particularly those related to individual discrepancies, by applying appropriate inclusion/exclusion criteria to the eCQM, and through statistical risk-adjustment.

Final Composite Measure Specifications:
Numerator: Patients who develop a major bleeding and/or VTE event occurring from the date of the THA/TKA procedure to 35 days postdate of procedure.
Denominator: All patients, aged 18 years or older, who received an elective primary THA or TKA procedure and do not meet any exclusion criteria.

Measure Scoring: Clinician groups will be provided with a major bleeding rate and VTE rate based on the number of numerator events. The BWH eCQM team also developed a composite scoring system that takes into account the relative harm of each event. Based on the literature, bleeding events are more common but less harmful than VTE events. Using the Harm Weight Ratio from AHRQ PSI90, a VTE event is weighted as 2.7 times as harmful as that of a bleeding event (weighted at 1). However, while this scoring approach was approved by the TEP, current limitations in the Measure Authoring Tool (MAT) preclude this scoring method. The scoring approach used in the current measure configuration is limited to an equal weighting of Bleeding and VTE events. The development team will update the measure scoring system when MAT enhancements are made to support a weighted scoring system.

Denominator Exclusions (in addition to the exclusion criteria of the RSCR measure):
- With diagnosis codes for renal insufficiency within the 365 days prior to the THA/TKA procedure
- With diagnosis codes for chronic atrial fibrillation within the 365 days prior to the THA/TKA procedure
- With diagnosis codes for cancer within the 365 days prior to the THA/TKA procedure
- Who received prescription orders for anticoagulant medications 10-90 Days Prior to Surgery and meets the following criteria:
  - Patient who received an Anticoagulant Injection/Infusion
  - Patient who received a tablet (Oral) Anticoagulant order, Quantity > 1
- With VTE diagnosis code present on admission for index admission
- With major bleeding diagnosis code present on admission for index admission
- With diagnosis code for coagulation disorder within the 365 days prior to the THA/TKA procedure
- Who had additional surgery within 35 days from the elective primary THA/TKA

Measure 3: Risk-Standardized Prolonged Opioid Prescribing (POP) eCQM
Prolonged opioid use following TJA is a concern for patients due to the risk of developing an opioid dependence, overdose, or death. The goal of this measure is to assess the rate at which orthopedic clinician groups prescribe post-operative opioids to previously non-opioid exposed patients (patients who have not been prescribed opioids within 90 days prior to surgery) for an extended period (>42 days) following an elective primary THA/TKA.

Environmental Scan: 28 articles met the literature review inclusion criteria, as well as one post-operative opioid prescribing guideline and three relevant quality measures (Table 6 and Table 7).

</table>

Table 7: Existing measures related the POP eCQM
The TEP met to discuss this measure on four occasions. In April of 2019, the TEP discussed inclusion and exclusion criteria for the measure. The TEP and development team decided that documented diagnoses of Sickle Cell Disease, Cancer, and Opioid Use Disorder, as well as receiving hospice or palliative care, would be excluded from the measure, as these conditions and care types have different pain management and therapeutic goals in comparison to patients who do not have these conditions or are not in these care settings. The measure also focuses on patients not exposed to opioids and excludes patients with an opioid prescription within 90 days of the THA or TKA procedure. In January of 2020, the development team and the TEP agreed that the Washington State Guideline (2018) would serve as an effective basis for the proposed measure. In this meeting, the team began discussions about stratifying the hip and knee rates to reflect the differences in post-surgical opioid prescribing practices based on procedure type, where the knee arthroplasty population was showing much higher rates of extended use than the hip population in early beta testing. In the May of 2020 and October 2020 meetings, the TEP agreed to the stratification of hip and knee rates.

Structured Interviews: Qualitative interview results from MHQP showed that providers and payers noted benefits to the proposed POP measure including that the measure was: helpful in creating prescribing guidelines, increased likelihood of providers adjusting prescribing behavior, and that the correlation of opioid use duration and health plan costs encouraged behavior change among individual clinicians. Interview respondents saw the following potential risks to the measure: there were concerns about the ethics of restricting access to opioids and that the measure did not address variation in patient physiology, and issues with operationalizing opioid use. There was also the concern that hospital EHRs are not accurate sources of prescription information. These concerns are acknowledged as a limitation of the measure.

Final Measure Specifications:
Numerator: The subset of patients from the denominator who were prescribed post-operative opioids for >42 days after surgical discharge within the measurement year.
Denominator: The target population is all patients aged 18 years or older who received an elective primary THA or TKA procedure within the measurement year.
Denominator Exclusions (in addition to the exclusion criteria of the RSCR measure):
- The patient was prescribed opioids within the 90 days prior to the index admission
- The patient received a diagnosis of Opioid Use Disorder (OUD) within the 365 days prior to the index admission
- The patient had a Cancer diagnosis within the 365 days prior to the index admission or 90 days following discharge
- The patient had a diagnosis of Sickle Cell Disease within the 365 days prior to the index admission or 90 days following discharge
- The patient received hospice or palliative care within the 365 days prior to the index admission or 90 days following discharge
- The patient received an additional general or major surgery within 90 days following discharge
- The patient received a separate THA- or TKA-related procedure within the 90 days prior to the index admission or 90 days after hospital discharge

Measure 4: Risk-Standardized Inpatient Respiratory Depression (IRD) Rate eCQM
Background: The estimated incidence of inpatient respiratory depression (IRD) following elective primary THA and TKA ranges from 2.4%-25% in relevant literature due to a lack of defined metrics and universal definitions. Despite the lack of standards regarding diagnosis and coding, inpatient respiratory depression is a common postoperative pulmonary complication following TJA. Respiratory depression following elective primary THA and TKA puts patients at risk for brain hypoxia, anoxia, severe brain damage, cardiac arrest, and death. Respiratory depression following surgery is associated with longer hospital stays, and mortality rates 3.4 times higher than average. Analyses of malpractice claims estimate that 97% of inpatient respiratory depression cases were preventable with more frequent monitoring and early intervention.
Environmental Scan: 22 studies, three guidelines,39-41 (Table 8) and three quality measures42-44 (Table 9) were identified to inform measure development.

TEP: This measure was originally conceptualized as a Risk Standardized Opioid Induced Respiratory Depression Rate eCQM and was intended to measure the occurrence of respiratory depression attributable to post-surgical opioid use. The measure was respecified following advisement from the TEP, described below.

In the May of 2020 meeting, the BWH team proposed that an instance of opioid induced respiratory depression would be based on any of the three respiratory depression indicators: 1) diagnosis of respiratory depression-related outcomes, 2) mechanical ventilation or intubation procedure code, or 3) naloxone administration indicated for respiratory depression, in conjunction with administration of an opioid within 24 hours prior. The TEP shared with the team that opioid induced respiratory depression is a rare event following THA and TKA,34,35 and that it would be difficult to attribute respiratory depression to opioid use. The most reliable way to attribute opioid use to respiratory depression is the presence of naloxone administration and a documented diagnosis of RD; with this approach, rates would be very low, and the proposed measure would provide little opportunity for improvement. The TEP recommended that this measure be reframed to include all postoperative respiratory depression cases, including but not limited to cases induced by opioids. Following this advisement, the OIRD measure was renamed the Risk-Standardized Inpatient Respiratory Depression (IRD) Rate following THA/TKA. In the October of 2020 meeting, the TEP and the team discussed the results of alpha and beta testing of the IRD measure, the TEP was pleased with the overall progress of the measure.

Structured Interviews: In interviews with MHQP, patients, payers, and providers noted benefits of the proposed IRD eCQM including opportunities to compare clinician groups when deciding where to receive care or for health plans in the credentialing process. Interviewees also shared that this measure is not appropriate as a measure of care quality and could be imprecise (noted as a limitation of the measure). There were mixed perceptions about the level of attribution of a measure of inpatient respiratory depression, and that that primary care providers (PCPs), anesthesiologists, nurses, and other members of the orthopedic team may have some responsibility regarding respiratory depression.

Final Measure Specifications:
Numerator: the outcome for this eCQM is IRD occurring during the index hospital admission for TKA or THA. The outcome is dichotomous (i.e., yes or no). IRD is defined here as:
- Patient has a documented diagnosis of respiratory depression-related outcomes or respiratory failure
- Patient has a documented mechanical ventilation procedure code
- Patient has a documented intubation procedure code
- Patient has 3 or more SpO2 values ≤ 88 and ≥ 30 during their index admission following the procedure
  - Patient has 2 SpO2 values ≤ 88 and ≥ 30 that occur within 24 hours of each other during the index admission
  - The 88% threshold for oxygen saturation was chosen based off the literature in addition to incorporating the margin of error to arrive at a conservative value.45

Denominator: This eCQM includes adults 18 years of age or older, covered by any payer, undergoing inpatient elective primary THA or TKA.
Denominator Exclusions (in addition to the exclusion criteria of the RSCR measure):

- Patients who received an outpatient procedure

Risk Adjustment Model

Environmental Scan: Alongside the four measures under development, the environmental scan and stakeholder feedback was also used to inform the development of the risk adjustment model used in all measures. The risk-adjustment model was originally harmonized with the NQF1550 to include the following variables: number of procedures (1,2), procedure type (THA, TKA), and age. The environmental scan highlighted the following social determinants of health (SDOH) as relevant to include in the risk-adjustment model (beyond the variables harmonized with the NQF1550/3493): race, income (using ZIP Code information), smoking status, and language.

TEP: In the May of 2020 meeting, following the literature review and phone conferences with representatives from NQF in July of 2019 where NQF advised the expansion of the risk-adjustment model, the TEP confirmed the validity of adding the following SDOH to the risk adjustment model: race, household income (using ZIP Code information), language, and smoking status. The TEP also recommended the addition of body mass index (BMI) to the model.

Public Comment: Concerns raised during public comment were that the eCQMs may result in clinicians avoiding high-risk patients. These concerns were addressed in the inclusion of more SDOH variables in the risk adjustment model which will account for patients who are at higher risk for post-operative complications.

Final Risk Adjustment Model Specifications:
The following risk adjustment variables will be used for all measures: number of procedures (1,2), procedure type (THA, TKA), age, race, income (using ZIP Code information), smoking status, primary language, and BMI.

Exceptions:
- The POP measure does not risk adjust for procedure type (THA, TKA) as these rates are stratified
- Due to low expected rates of occurrences, the VTE/bleeding measure will not risk adjust for VTE events alone.
  The bleeding rate in addition to the composite bleeding and VTE score will still be risk-adjusted.

Expanding the risk-adjustment model provides a distinct benefit for the RSCR eCQM over the existing NQF1550 and NQF3493 measures and reduces the concern that providers would be penalized for taking on patients who are at a higher risk of post-surgical adverse outcomes across all measures.

Discussion:
Using a systematic, iterative approach based on an environmental scan, interdisciplinary stakeholder involvement, and specifications using standard codes and EHR data routinely available in different EHR systems, our team retooled one existing quality measure and developed three additional eCQMs for orthopedic surgery. The eCQMs measure key processes (opioid prescribing practices) and outcomes (risk standardized complication rates, VTE/bleeding rates, inpatient respiratory depression). The measures address a gap in orthopedic quality measurement, while leveraging data standards and routinely available EHR data to create measures designed to support benchmarking nationally while driving local quality improvement.

Existing literature on the development of eCQMs is limited. While there are published works on eCQM development in the fields of rheumatology, oral health, as well as published works on the testing of CQMs in the orthopedic field, there are currently no published papers on the development and specifications of eCQMs in orthopedics outside of those presented by the BWH development team. This manuscript builds on the body of literature regarding eCQM conceptualization and development and aims to inform future developers and stakeholders. The measure development team acknowledges several limitations:

Stakeholder Feedback: The BWH development team received feedback from healthcare providers, payers, and patients throughout the eCQM development process through public comment solicitation, structured interviews, and advisement from a technical expert panel. A limitation of this feedback was that it was conducted solely with English speaking adults, and did not include any non-English speaking patients, despite evidence that English proficiency is a predictor of surgical decision-making and outcomes. Future stakeholder engagement with non-English speaking patients is needed to assess measure validity across a larger subset of THA and TKA patients.

RSCR (and all eCQMs): The lack of data exchange between healthcare organizations limits the usefulness of eCQMs for provider groups that do not practice within an integrated care network. Complications for the RSCR eCQM extend 90 days post index admission. Therefore, complications that are treated outside the delivery network...
where the procedure was performed will not be available, making the RSCR appear lower than if all complications were included. **VTE/bleeding:** This measure was originally designed to use a weighted scoring method where VTE events would be weighted as 2.7, and major bleeding events would be weighted as 1.0, to reflect the severity of the adverse outcomes. This was not functional within the measure authoring tool (MAT), and thus, the outcomes are weighted the same despite their differences in frequency and lethality. **POP:** During the structured interviews, respondents saw potential risks to the measure including concerns about EHR systems not being accurate sources for prescription information. Other sources of opioid prescription information include state level databases which track a patient’s use, but the patient information for these databases is not presently accessible for use in eCQMs. **IRD:** The development team was initially interested in measuring the rate of inpatient respiratory depression that was attributed to postoperative opioid use. Due to the inability to reliably attribute respiratory depression to opioid use through EHR data and the low rates of OIRD, the measure was reformatted to measure inpatient respiratory depression without an opioid-induced component. In structured interviews, interviewees shared their concern that many factors contribute to respiratory depression and therefore the measure may be better used to evaluate health care systems, rather than orthopedic surgeons. They also reported that this measure may not be an appropriate measure of care since it could be imprecise. Due to the lack of defined metrics in diagnosing respiratory depression, the BWH development team believes that the use of EHR codes and the final measure specifications are the most feasible and reliable way to quantify inpatient respiratory depression rates at the clinician group level. Despite these limitations, our TEP members agreed that given the seriousness of respiratory depression when it does occur postoperatively, that this measure is meaningful and could lead to safer care for patients undergoing THA and TKA procedures. **Risk Adjustment Model:** During public comments, respondents shared that a potential unintended consequence for the measures would be that clinicians would not take on more complex patients who are more prone to post-surgical complications out of the concern over MIPS penalties. The development team addressed these concerns through the risk adjustment model, which aims to limit the individual characteristics of the patient so that adverse event rates are reflective of the clinician group’s performance, rather than the patient population. These measures have since been tested at two geographically different healthcare systems and risk adjusted following the measure development process. The next step in this research is to submit these proposed measures to the Measures Under Consideration (MUC) List and for NQF endorsement. These proposed eCQMs have the potential to highlight areas for quality improvement in orthopedics and provide clinician groups with metrics to quantify and compare their performance with other groups, all without imposing an additional documentation burden.

**Acknowledgements:** The BWH development team would like to thank Paul Bain, PhD, MLIS, of the Harvard Countway Library for his contributions to our environmental scan and literature review during measure development.

Clinical Note Section Detection Using a Hidden Markov Model of Unified Medical Language System Semantic Types

Abstract

Clinical notes are a rich source of biomedical data for natural language processing (NLP). The identification of note sections represents a first step in creating portable NLP tools. Here, a system that used a heterogeneous hidden Markov model (HMM) was designed to identify seven note sections: (1) Medical History, (2) Medications, (3) Family and Social History, (4) Physical Exam, (5) Labs and Imaging, (6) Assessment and Plan, and (7) Review of Systems. Unified Medical Language System (UMLS) concepts were identified using MetaMap, and UMLS semantic type distributions for each section type were empirically determined. The UMLS semantic type distributions were used to train the HMM for identifying clinical note sections. The system was evaluated relative to a template boundary model using manually annotated notes from the Medical Information Mart for Intensive Care III. The results show promise for an approach to segment clinical notes into sections for subsequent NLP tasks.

Introduction

The electronic health record (EHR) is a rich source of biomedical data. With the passing of the Health Information Technology for Economic and Clinical Health Act of 2009 to incentivize the adoption of EHRs in medical practice, penetration of systems with core functionality, including clinician notes, has gone from about 27% to almost 100% of hospital systems over the past twelve years1. There is significant potential to leverage these data for the advancement of biomedical science and clinical medicine.

EHR data can be broadly separated into two categories. Structured data are stored as standardized values or codes. These include vital signs, laboratory results, medications, demographic information, problem lists, as well as diagnosis, procedure, and billing codes. The remainder of clinical data is stored in an unstructured form, such as in clinician narrative admission, discharge, and progress notes. Clinical notes contain a wealth of information that corroborates, contextualizes, and supplements what is available in a structured form. However, challenges surrounding the extraction of information from clinical notes (e.g., using natural language processing [NLP] techniques) have limited their use in large studies.

A notable portion of the EHR consists of unstructured free-text data. The clinical note is deliberately organized to enable efficient information retrieval by human readers. Each note category includes a series of expected section types. For example, the possible sections of a clinical note can be broken down into subjective information, objective information, and assessment and plan2. Subjective information is gathered using the interview and includes Medical History, Review of Systems, Medications, and Family and Social History. Objective information is obtained by the clinician’s in-person interaction with the patient or the ordering of diagnostic testing. In the clinical note, it comprises the Physical Exam and Labs and Imaging sections. The final section of Assessment and Plan represents clinicians’ summative conclusions about everything that precedes it and is where the next steps for the patient’s care are documented. Answers to individual clinical questions (e.g., the presence of chest pain), if present, can be reasonably expected to be confined to a small number of sections (e.g., Medical History or Review of Systems)3. While it is possible to further subdivide these section definitions4, in practice, those subdivisions are often combined inside a single paragraph or even within a single sentence (e.g., Assessment and Plan). Therefore, section identification at the level of granularity outlined is an effective first step to significantly increase the signal-to-noise ratio for downstream NLP tasks without significantly increasing section boundary ambiguity.

The method for note section identification for research purposes is almost exclusively performed using rule-based or machine learning approaches to identify institution-specific section headers along with formatting tokens like colons or bolded text that indicate the section header (e.g., “<b>Medications:<b>”)5. Prior work that modeled the sequence of note sections headings using a hidden Markov model (HMM) found that the majority of notes (67%) in some
clinical settings do not possess any section naming headers, and efforts to identify note sections were limited to the minority of notes that contained standardized section indicating tokens. Additional studies have reported high accuracy of granular section detection using section headers in notes to identify unlabeled sections. While this has been shown to be effective, it is challenged when either non-standard headers are used, the headers do not reflect the content that follows, or when seeking to develop generalizable approaches that can work across multiple clinical care settings with minimal training and configuration.

Generalizable approaches for identifying sections of the text using NLP tools include the identification of repeated words in adjacent text blocks and the identification of lexical chains using a thesaurus to link together related concepts. The brevity of clinical notes and lack of redundancy make direct application of these techniques that rely on repeated words unlikely to work. The most successful projects to automatically segment clinical text have used a shotgun approach of attempting to identify section breaks based on whitespace and variations in section headers along with markers for header definition such as colons and bolded type with good but not perfect accuracy. The success of this is highly dependent on the institution and EHR system-specific structure of clinical notes.

Inspired by these concepts, this study set out to use the Unified Medical Language System (UMLS) Metathesaurus to identify semantic concepts within sections of clinical text to characterize the distribution of substantive content of note sections. UMLS concepts were chosen as a domain-appropriate knowledge structure to serve as a proxy for informative information contained within note sections. The concept-based semantic types further reduced data dimensionality such that they could be modeled as a Markov process. It was thus hypothesized that a heterogeneous HMM using semantic type distribution and section transition probabilities would provide a generalizable note section detection algorithm.

Methods

Training and testing sets of admissions notes were randomly sampled from a publicly-accessible EHR dataset. The notes were then manually labeled for component sections based on content. These annotations were used to calculate the probability of transitioning from one section to another. The note text was also processed by the MetaMap NLP system to identify UMLS semantic types. Probabilities of observing the semantic types were calculated for each note section type. A subset of semantic types were selected for inclusion based on their ability to uniquely identify a note section type. Collectively, these defined a heterogeneous HMM that was trained and cross-validated on the first set of notes and tested on the second. The performance of the HMM was evaluated and compared to a template to identify note sections. The overview of these steps are outlined in Figure 1.

MIMIC-III Database

Clinical notes from the Medical Information Mart for Intensive Care III (MIMIC-III) database were used for this analysis. MIMIC-III is a publicly available de-identified dataset of intensive care patients treated at Beth Israel Deaconess Medical Center from 2001 to 2012 and includes approximately 60,000 critical care admissions. A set of 100 notes that used the single most common admission note template were randomly selected as a training set. The single most common template was selected for training in order to allow out-of-sample evaluation of different note templates to demonstrate how sensitive the HMM method is to template changes. A testing set of 100 notes was

![Image of Figure 1. Overview of the Study](image-url)
selected that comprised a variety of templates. Many of these contained no relevant changes, and those that had changes often had differences in one or two headers (e.g., “HPI:” vs “History of Present Illness:”).

Manual Annotation

A reference standard was developed to train and test the automated identification of note sections. Using written guidelines, two human annotators (KAB and INS) with clinical and informatics expertise independently identified note sections in the same two hundred clinical notes with standardized annotations at the beginning of new sections. Disagreement between the two annotators was adjudicated by a third annotator (ASE). Up to seven different section types were identified in each note. (1) Medical History was defined as including the chief complaint, history of present illness, past medical history, and review of systems if continuous with the rest of medical history. (2) Medications also included allergies if the two appeared contiguously in the note. (3) Review of systems was labeled separately if not adjacent to a medical history section. (4) Family and social history were combined into a single section type due to the fact that they are sometimes combined into a single line of text making it impossible to distinguish them at a line-level granularity. (5) Physical exam was defined to include vital sign and other “flowsheet” information in addition to the standard physical exam. (6) Labs and Imaging including any objective testing information results included in the note. (7) Assessment and Plan was defined as a summative analysis of the patient’s status at the time of note writing followed by a description of next steps for medical care.

MetaMap Text Processing

MetaMap is an NLP tool maintained by the National Library of Medicine for the processing of text for the identification of biology and medicine UMLS concepts. The full set of notes was processed using the MetaMap Docker image in batch. MetaMap was configured to use the NLMSubSyn vocabulary. UMLS concept unique identifiers (CUI) and their associated semantic types were tracked, along with their associated line number from the original note text file. Absolute and relative frequencies of semantic types identified within each section type were calculated for the notes in the training set. A subset of semantic types (n=24) were selected for the HMM that (1) occurred at least 1.5X more frequently in a single section type compared to the note as a whole, and (2) occurred in at least 90% of the sections of the type for which it is overrepresented.

Hidden Markov Model

A hidden Markov model (HMM) is a simple dynamic Bayesian network of a Markov process with underlying unobserved states that influence the observed output. There are three main parameters of an HMM. The first is an initial probability array, \( \pi \), which contains the probability of starting in each of the possible unobserved states. The second is a state transition probability matrix, \( A \), which contains the probability of changing from each possible unobserved state to another unobserved state (including remaining in the same state) after each observation. Finally, there is an observation probability matrix, \( b \), that contains the probabilities of each observation for each state. In the context of the task of note section identification, the note sections are the unobserved hidden states and the UMLS semantic types associated with MetaMap identified UMLS CUIs are the observations. The model was constrained to only allow for the identification of a state transition after the end of a new line in the note. This was accomplished by having an identity matrix, \( a_2 \), that represents the probability of state changes between observations on a single line of note text.

The parameters for the HMM were trained using the manually annotated clinical notes from the training set. The initial state probability array, \( \pi \), was defined as the proportion of notes that started with each section type. State transition probabilities for \( a \) were empirically determined on a per line basis. For each note, the transition probabilities were determined for all sections within that note with each new line being considered an opportunity for state transition. The arithmetic mean of each state transition probability was then calculated across all notes and normalized to sum to a total probability of one. Observation probabilities were also calculated within each note for each section. They were defined as the proportion of each semantic type divided by the total semantic types in each section. The observation probabilities matrix was then calculated as the mean of the probabilities calculated for each note.

Template Boundary Model

A template boundary model (TBM) was developed using the same most common admission note template applied in the training set. This model looked for the words or phrases that indicate the start of each of the corresponding note sections using regular expression matching of standardized section headers (Table 1). In the event that consecutive template sections were assigned to the same “mapped section” those were considered a single merged section.

</tbody>
</table>

TBM was also applied to the testing set. The results of this model were used to contextualize the evaluation of the HMM method and allow a comparison of each method’s sensitivity to small changes in the template.

Evaluation

Five-fold cross-validation of the HMM method was performed by randomly separating the data into five equal bins. The model was trained on four of the bins (i.e. HMM parameters were empirically determined) and subsequently tested on the remaining bin. Using this process, each original note was labeled by the HMM exactly one time. This process was performed once on the training set. The content of a note section in the reference standard was defined as the line number occurrence of an annotated section up to but not including the line of the next label or the end of the document. The average of the parameters from the five-fold cross-validation was carried forward as a single model applied to the testing set.

The performance of the identified note section boundaries was measured by the sensitivity and specificity of the content those boundaries define. The model was evaluated as the number of UMLS concepts (e.g., a proxy for the interesting data) captured by the identified section boundaries. Concepts for a given section were considered true positives if they were within the manually annotated and model boundaries for the section. False positives were defined as concepts inside the model boundaries but outside the annotated ones. Concepts outside of the model boundaries but within the annotated boundaries were considered false negatives. UMLS concepts outside of both the model and annotated boundaries were considered true negatives. Full confusion matrices were calculated using these definitions for the HMM and the TBM for both the training and testing datasets and then used to calculate sensitivity, specificity, precision, recall, and F1-score.

Results

Note Annotation Observations

Two hundred clinical notes were manually annotated into 1,336 distinct sections based on the annotation guidelines and reference standard as described above. Overall, the notes were organized and formatted in a chronological fashion from the time prior to the note being written to planned future clinical care. The notes were formatted in the original dataset such that lines were limited in length to about twelve words. As a result, paragraphs of text and even individual sentences were often interrupted by a newline character. In addition, many parts of the notes did not contain complete sentences. For example, lists were commonly employed to record medications, symptoms, and medical history not directly pertaining to the chief complaint. Each note typically began with a history of present illness and medical history. This was followed by varying combinations of Medications, Review of Systems, Family and Social History, Physical Examination, and Labs and Imaging results. Notes almost always ended with an assessment of the patient’s status and a plan going forward, including medications, testing, and follow-up care. Most of these sections contained discrete labels within the text.

There was variation in how sections were labeled, and at times they were entirely mislabeled. For example, the most commonly mislabeled sections included Medical History, and Family and Social History. These section headers were often listed out, and then the content for all three sections was merged together in the lines that followed the header labels. Another less frequent example included content from distinct sections that were embedded within one another.
(e.g., home medication list followed by medical history/surgical history, and ending with a list of more or duplicate home medications). Other observations throughout manual annotation included extra text that did not pertain to a particular section or additional notes as an addendum added at the end that included brief summaries of Medical History, Physical Exam, and Assessment and Plan written by another clinician (e.g., specialist, attending, or medical student). The annotators labeled sections based on content and not the section headers. If a section header corresponded to the following content, it was marked as the start of the section. As expected, it was evident that the unique characteristics, language, content, length, and formatting of the clinical note varied based on individual provider and specialty.

Transition State Probabilities

A transition state probability matrix was calculated using training data for each fold in the cross-validation. This was repeated five times. Mean transition probabilities after a newline character are diagrammed as a Markov process (Figure 2a). For all sections, it was found to be most common to stay within that section. Beyond that, Medical History can transition into Medications or Family and Social History. Family and Social History can be followed by Medications or Physical Exam. The remaining sections of Review of Systems, Physical Exam, Labs and Imaging, and Assessment and Plan always follow in sequential order. An example portion of the heterogeneous HMM, including both observations and hidden states, is shown in Figure 2b. Observations are UMLS CUIs converted to UMLS semantic types (e.g., Metronidazole → Antibiotic). State transitions are only allowed between observations separated by a newline character with probabilities shown in Figure 2a. Between observations without a newline character, the hidden state is maintained. The most likely path is determined using expectation maximization. A hypothetical example of this is bolded in Figure 2b as Metformin → Pharmacologic Substance (Medications) to Tobacco → Plant (Family and Social History). The most common progression of note sections is visualized as an alluvial diagram (Figure 2c). One-half of the notes followed the most common section progression of Medical History, Medications, additional Medical History, Family and Social History, Physical Exam, Labs and Imaging, and then Assessment and Plan. About one-quarter of the notes also had a Review of Systems section, most commonly between Family and Social History and Physical Exam.

Semantic Type Feature Distribution

The 24 UMLS semantic type features were calculated for all 1,366 note-sections in the reference standard. Semantic type distributions by note section type are depicted in Figure 3. The analysis of semantic type distribution represented by different sections was in line with expectations. Medications, Family and Social History, Physical Exam, Labs and Imaging, and Review of Systems all contain distinct information represented by specialized language that was expected to generate unique probability distributions.

It was found that more than two-thirds of the identified concepts within the Medications sections were “Pharmacologic Substance”, “Organic Chemical”, or “Antibiotic”. Family and Social History was dominated by “Organic Chemical”, Pharmacologic Substance”, and “Plant”, all referring to substance use habits (e.g., Tobacco). In addition, “Family Group” is significantly overrepresented, likely reflecting the common format for family history (e.g., “Father had a myocardial infarction at 64 years old”) and description of living arrangements, marital, and family status that are commonly included in Social History. Review of Systems is expectedly overweight in “Body System” and “Sign or Symptom”. Similarly, an outsized proportion of “Body Location or Region” within the Physical Exam sections is indicative of the kinds of notations that are made about the physical exam, which represents in-person observations about a patient’s body. Finally, the ambiguity presented by Medical History and Assessment and Plan was an expected challenge, but the latter includes an expectedly higher proportion of “Idea or Concept” words (e.g., “probably” and “consistent with”) that reflect the author’s thought process when assessing the patient’s condition. In addition, differentiating these two sections is accounted for by the transition probabilities matrix of the HMM.
Figure 2. Note Section Transitions. a) Markov Process, b) Heterogeneous HMM, c) Alluvial Diagram
Hidden Markov Model Evaluation

Both the HMM and TBM were used to identify note sections in two-hundred admission notes. Training was performed on one-hundred notes that used the single most common template within the MIMIC-III database. The performance of the HMM on these notes compared to the TBM is reported as five-fold cross-validation of the HMM in Table 2. Overall, both models performed well. The HMM captured greater than 85% of the semantic types in all sections, including better than 92% in Review of Systems, Physical Exam, and Assessment and Plan with the exception of Labs and Imaging, which performed relatively poorly (70%). The specificity of the HMM was at least 93% across all note section types. The HMM significantly outperformed the TBM in identifying Medical History concepts (88% vs. 75%) and significantly underperformed the TBM in identifying Labs and Imaging concepts (70% vs. 99%). The HMM modestly underperformed the TBM (Δ ≤ 10%) in the remaining note section types. Specificity was excellent for both and only significantly differed for two section types where the HMM outperformed the TBM for Family and Social History (99% vs. 93%) and underperformed the TBM for Assessment and Plan (93% vs. 100%).

The performance of the HMM compared to the TBM on the testing set is reported in Table 3. The HMM achieved a sensitivity of at least 77% across all note section categories. It performed at 84% for Medical History and Review of Systems and at least 93% for Physical Exam and Assessment and Plan. The sensitivity of the HMM outperformed the TBM in every note section category except Family and Social History; however, this was achieved by the TBM with only 20% precision. The HMM achieved very high specificity (≥ 94%) for all note section types, comparable to the TBM.

Between the training and testing sets, the HMM had an average sensitivity performance reduction of less than 3% per section type compared to a 14% degradation in the TBM. For the HMM, no single section degraded more than 8% (Family and Social History and Review of Systems), and the worst-performing section for the HMM in the testing set, Labs and Imaging, improved by 7%. Overall, the HMM performance was consistent between training and testing sets when compared to the TBM, where every section had reduced sensitivity of at least 10%, with the exception of Medical History, which was nearly unchanged.

Discussion

Admission notes from MIMIC-III represent real-world examples of clinical notes for ICU patients. The manual annotation process clearly demonstrated that while these notes possessed the expected structure that domain experience suggested, they were far from ideal. The clinical note text was commonly untidy and poorly arranged. For example, many of the Labs and Imaging sections were intended to be in a tabular format but were generally misaligned. In addition, some sections were routinely mislabeled or labeled without any relevant content to follow. In addition, there were frequent line breaks that interrupted sentences and paragraphs. These are likely artifacts of data storage processing and the result of irregular use of note templates. All of these findings reestablished the importance of note section detection informed by content rather than formatting tokens.

It is important to acknowledge that the results presented here represent a single note type tested from a single institution. Furthermore, all patients within MIMIC III were treated in an ICU, which likely both increases the complexity of the recorded information in the associated clinical notes but also necessitates structure. Significantly shorter notes that contain no underlying structure are unlikely to benefit from section detection using the methods described in this study.

The HMM method performed favorably to the TBM in several important ways. The goal of this comparison was to evaluate the model robustness to support portability to changes in templates over time or to other electronic health record systems. The most dramatic example was with Family and Social History. In this dataset, while the headings...
were consistently used, they frequently did not appropriately precede relevant content. Therefore, while the TBM appropriately found the Family and Social History section label, the section itself was essentially mislabeled. Family and Social History are particularly important as they represent the most basic form of genetic information and can impact guideline-based clinical care decisions that rely on risk stratification\textsuperscript{18}. The selected evaluation criteria account for these errors by measuring the amount of likely relevant content (i.e., the number of UMLS concepts) captured. The result of the findings presented is that the identification of Family and Social History information had very poor precision when using a method that looks for section header labels. Additionally, the HMM performed consistently from training to testing sets compared to TBM, indicating that it may be a more portable method for note section detection across different templates and note types.

When considering the NLP tasks that are downstream of note section identification, the HMM results are particularly promising. Two of the three note section types for which the HMM performed the worst are for data that are relatively low yield in clinical notes. Both Medications and Labs and Imaging data within notes are often copied from structured sources or dedicated reports. These data are likely more useful in the structured form from which they were derived than extracted from clinical notes.

Despite these findings, the methods presented have significant room for improvement, and analyzing common errors can inform future model development. Improved detection of candidate section transitions would improve the accuracy of the model by decreasing the number of state change decision points. This could be accomplished with additional text preprocessing to, for example, reformat the notes so that narrative text that is broken up into multiple lines intra-paragraph and intra-sentence is considered as a single block inside which transitioning of states cannot occur. In addition, staging the identification of sections by starting with an HMM that only considers the three categories of “Subjective”, “Objective”, and “Assessment and Plan,” and then further processing of each of those into component sections may improve performance.

The promising results of this study suggest that clinical note sections can be identified using an HMM based on UMLS semantic types associated with MetaMap identified UMLS CUIs. The relatively standard organization of clinical notes and the expected information contained within each section is both the motivation for identifying clinical text sections and the reason why these methods worked. It is likely that these methods would be portable across EHR systems, as preliminary testing on an additional corpus of publicly available notes from MTSamples.com demonstrates better performance than reported here. The ability to identify note sections across EHR systems and medical specialties using minimal training data in this way would enable the development of tools to aggregate clinical data about an individual patient across health systems. For example, the aggregation of sparsely recorded information like Family and Social History could be collected and synthesized into a single best summary for a patient. This information may be more likely to be recorded by a primary care physician but could then be made available to physicians during all of a patient’s clinical encounters. In addition, the note section contains contextual information about the meaning of the underlying information. Most importantly, distinguishing between Medical History and Assessment and Plan is needed in order to assemble a chronology of a patient’s clinical information. For example, a medication that appears as part of a standard Medications section is generally confirmed as active therapy, while a medication that appears in the Assessment and Plan could go unfilled.

All code written for this paper is available through GitHub (http://github.com/aeisman/NoteSectDetect).

Conclusion

The hidden Markov model and results presented are the first step in the development of a generalizable method for the identification of sections based on content in clinical notes. The findings demonstrate that semantic types associated with MetaMap identified UMLS CUIs differ among clinical note sections, and the probability of observing consecutive content within notes can be used to determine note sections. Additional work is required to improve the performance of these models and test this method on a variety of note types across different healthcare settings.

Abstract The wide availability of near infrared light sources in interventional medical imaging stacks enables non-invasive quantification of perfusion by using fluorescent dyes, typically Indocyanine Green (ICG). Due to their often leaky and chaotic vasculatures, intravenously administered ICG perfuses through cancerous tissues differently. We investigate here how a few characteristic values derived from the time series of fluorescence can be used in simple machine learning algorithms to distinguish benign lesions from cancers. These features capture the initial uptake of ICG in the colon, its peak fluorescence, and its early wash-out. By using simple, explainable algorithms we demonstrate, in clinical cases, that sensitivity (specificity) rates of over 95% (95%) for cancer classification can be achieved.

1 Introduction

The wide availability of near infrared (NIR) light sources in interventional medical imaging stacks enables non-invasive quantification of perfusion by using fluorescent dyes, typically Indocyanine Green (ICG). As a result, fluorescence-guided surgery, where ICG is utilized e.g. for lymph node mapping and identification of solid tumors, has become common practice. Interrogation of tissue and vasculature using ICG has also found application in the assessment of anastomotic complications and the prediction of suspected cancerous tissue. The prediction of cancerous tissue is not sufficiently useful currently due to false positive rates and problems of interpretation.

It has been reported that ICG accumulates in cancers, which can offer a means of differentiation between healthy and malignant tissues, however grossly obvious differences that are detectable by the human eye can take hours to appear. In contrast, attempts to leverage the short-time differences in fluorescence behaviour, namely how long it takes for fluorescence to reach its peak and at what rate it subsequently decays, which requires on the order of only 10 minutes of observation has been shown to be feasible by exploiting the bio-physics of perfusion processes.

Since we are primarily interested in perfusion dynamics, i.e. the evolution of fluorescence in specific tissue over time, the task is one of surgical video classification. This task cannot be readily translated to an image classification problem for several reasons, precluding the use of existing methods. Although containing many individual images, each surgical video represents only a few sufficiently distinct images and results in significant duplication when used as a training set. Indeed, most of the frames of the NIR video are near duplicates when compared e.g. by using perceptual hashing.

In our approach, we refine the bio-physical two-compartment model of ICG dynamics for the purposes of simplifying computation and improving interpretation of results. Our contributions differ from previous work in the following important aspects: (1) The number of features used is greatly reduced from previous models and their significance is obvious. (2) Feature values have clear meanings such as the slope of the initial uptake of ICG, the time it takes to reach peak perfusion, and the rate of decay of ICG once the peak is reached (this last feature is – to the best of our knowledge – absent from the previous literature). These features can be estimated from visual inspection of the fluorescence time-series addressing interpretability of results. (3) Inter-patient variation is taken into account by setting each feature in relation to a healthy reference region in the same patient.

Related Work. Cancer angiogenesis has been recognized to lead to abnormal vasculature, characterized by higher internal pressure, wide inter-endothelial junctions, high number of trans-endothelial channels and a discontinuous basement membrane, in comparison with normal, healthy tissue. Cancer detection methods based on analysis of multispectral videos have become popular with the advent of advanced intra-operative fluorescence imaging systems.
and progress in image processing. We consider them in three broad categories: (1) observation by the surgeon of perfusion in the colon (2) image classification using Deep Learning (DL), and (3) quantitative analysis of bio-physical models based on perfusion patterns.

Observation of perfusion patterns by surgeons is common practice for anastomoses. However, the changes in the perfusion needed to discriminate cancer are not easily detected by visual observation. Considerable time needs to elapse, in the order of days, for easy visual discrimination, and this still remains prone to error, rendering application during surgery problematic.

Deep learning, a sub-discipline of artificial intelligence, has been applied for cancer screening using images from mammography and histology. Deep learning methods typically require enormous numbers of labelled training examples for each class to estimate model parameters. Cancer screening is observed to require on the order of tens of thousands of mammograms with known pathology. A further drawback of deep learning, which we wish to avoid in the presented approach, is the lack of explainability inherent to the complex path between inputs (i.e. images, videos, annotations, etc) and classifications.

Mathematical models describing the bio-physics of perfusion provide an alternative method of fluorescence analysis. Perfusion quantification based on estimating time-series of ICG fluorescence intensities, and then extracting a number of so called time-to-peak (TTP) features directly from the time-series is well represented in the surgical literature. TTP features have direct physical meaning and have been successfully applied to perfusion quantification on animal, and for predicting anastomotic complications after laparoscopic colorectal surgery. By exploiting models of the underlying perfusion process, bio-physical methods require vastly less annotated image data than deep learning methods and use more clinically recognizable features.

The premise of bio-physical modeling for perfusion imaging is that differences in ICG inflow during a relatively short timeframe of minutes after injection known as the wash-in phase, and ICG outflow during the beginning of the venous outflow, termed the wash-out phase, can serve as a marker for tissue distinction. Relevant to cancer, ICG inflow over a wash-in phase could disclose valuable discriminative signatures. It is also noted that most malignant tumors are characterized by “increased interstitial pressure from leaky vessels” and “relative absence of intra-tumoral lymphatic vessels”, suggesting that fluid “could pool” in the malignant tumor over time, causing the retention of the tracer, leading to differences of ICG outflow during wash-out. These behaviors are different between cancerous tissue and benign tumors and healthy tissue.

The bio-physical model proposed in generalize models proposed in by modeling ICG intensity time-series as a response of a generic second-order linear system with exponential input, which is a sum of one real and two complex exponentials, to allow for oscillating behaviors observed in ICG time-series estimated from videos of human tissue perfusion. The coefficients and exponents of these exponential terms form a set of features.

To date there are no commercially available systems to aid in the characterization (benign vs malignant) of colorectal lesions. Endoscopic adjuncts such as narrow band imaging (NBI) have been shown to help differentiate lesions but only in the hands of experts and require considerable user interpretation. Combining NBI with AI interpretation has been reported however this was to characterize small polyps of the colorectum as either hyperplastic (non-neoplastic) or adenomatous (neoplastic) polyps and was not used to identify malignancy. Large multicentre studies consistently demonstrate the limited diagnostic accuracy of conventional endoscopy, most especially for early malignancies where accuracy may be as low as 39%.

2 Dataset

Following full Institutional Approval (1/378/2092), colorectal tumors from 16 patients with known rectal lesions undergoing an examination under anaesthesia for either diagnostic or surgical planning purposes were imaged transanally for up to 30 continuous minutes following Indocyanine Green (ICG) administration (0.25mg/kg i.v) using a Pinpoint (Novadaq, Stryker) near infrared (NIR) imaging system. The resulting video is multispectral: the NIR image is stored separately from the visible light image, see Figure 1 for an example. The frame rate is 29.95 FPS.

Representative tissue samples were obtained through biopsy or excision in keeping with standard clinical practice. Subsequent histopathological analysis of specimens, along with specialist colorectal clinician input, facilitated retro-
Figure 1: Example video frame: the upper panel shows the visible light, the lower panel shows the NIR image.

Figure 2: Tracking, i.e. compensation of motion and deformation in the videos, is challenging: the frames on the left illustrate regions having drifted from their original locations, likely due to reflections and lack of textures. The frames on the right show an example of successful tracking. The lesion on the left turned out to be benign, whereas the one on the right is malignant.

spective annotation of tissue regions within each video (“cancer”, “benign” or “healthy”), resulting in 5 patients with cancerous regions, and 11 patients with benign lesions. Quantitative fluorescence plots over time for regions of interest based on video annotations were subsequently created for analysis using a bespoke tracker: movement of patient and camera as well as deformations, reflections, etc have to be compensated for in order to collect fluorescence in one region of tissue (as opposed to one location within the image) over time, see Figure 2 for an illustration. The tracker will be the subject of subsequent publications; we stress however that its performance was assessed for each video and regions were discarded if tracking was not deemed precise enough; for the present dataset, 3 out of 180 tracked ROIs were discarded because of imprecise tracking.

Videos were considered suitable for inclusion if stable mucosal views of both tumor and adjacent healthy/control tissue were successfully tracked for the duration of ICG ingress, peak and at least 8 minutes of ICG outflow.

3 Methods
3.1 Video Processing

The underlying assumption to all what follows is that fluorescence intensity is proportional to the ICG concentration in the tissue, which has been shown in the literature for the concentrations commonly encountered. Following this assumption, the brightness in the NIR image can be interpreted as a relative measurement of ICG concentration.

From each available video \( p \), between 3 and 8 fluorescence time-series are extracted in the following steps: (i) a clinical expert identifies areas of healthy tissue and areas of concern, (ii) in each area, depending on its size, between 1 and 4 rectangular regions of interest (ROIs) are drawn. Typically, 4 ROIs are drawn on the area of concern, and 4 ROIs are drawn on the healthy tissue. (iii) The ROIs are tracked through the video for as long as they are visible. This time interval has to start before ICG arrives in the tissue under observation and has to include at least the peak fluorescence and 8 minutes thereafter. The tracking is performed in the visible light video, since the only changes there are due to movement, deformation, occlusions etc, and ICG is not visible there. (iv) For each ROI \( r \) and each included time step

\[ \text{by that we mean the absolute concentration is not available, however if a region at time } t_1 \text{ appears twice as bright as the same region at } t_0, \text{ we may conclude that the ICG concentration in that region has doubled between } t_0 \text{ and } t_1. \]
Figure 3: Example profiles, with circles and vertical dashed lines indicating the detected peaks and latencies, solid lines are smoothed, dashed lines indicate the original, noisy data. While in some cases, the collected data is pretty smooth already (left), in some cases it is so noisy that even discerning a clear peak is hard; yet other cases have initial peaks which are likely due to camera movement and/or adjustments of internal camera parameters. Incidentally, the orange curves correspond to healthy reference regions, whereas the blue curve in the left panel corresponds to a cancer, and the remaining curves to benign lesions.

The result is a collection of time series $I_{p,r}(t)$, where $p$ ranges from 1 to 16 (the number of patients in our dataset), $r$ ranges from 1 to the number of ROIs tracked in the specific patient (typically 8), and $t$ ranges from 0 seconds to up to 30 minutes, depending on how long ROI $r$ in patient $p$ was in view.

3.2 Peak and Latency Estimation

The resulting time series can be quite noisy, see Figure 3 for a few examples. It is hence necessary to smooth the data before proceeding with the detection of peaks and the estimation of the latency. By “peak” we here mean when the fluorescence in each region reaches its highest value, and by “latency” we mean the point in time when fluorescence starts rising beyond the initial background fluorescence.

The smoothing is done using a Savitzky-Golay filter\textsuperscript{29} of order 5 with window length 99. These values were chosen by manually annotating peak and latency in a small subset of our data and optimizing with respect to average estimation error. The peak detection is done using its SciPy\textsuperscript{30} implementation, whereas the latencies $L_{p,r}$ are detected using a custom detector considering the smoothed derivative of the curves and finding its first “robust” zero crossing.

Since medical imaging devices are typically not designed to be measurement instruments, but rather to present a readily interpretable image to the user\textsuperscript{31,32}, it is clear that absolute NIR brightness is not meaningful: it depends on the distance of the ROI to the camera, the distance from the ROI to the center of the frame, and most importantly on the camera parameters, which are typically chosen to optimize contrast and overall visual representation\textsuperscript{31,32}. To counteract this, every ROI’s brightness is normalized by its peak brightness, so that the peak value equals 1 for each of them.

3.3 Feature Design

The features are chosen in two steps: First, the following characteristic numbers are chosen for each ROI individually:
The time to peak (TTP\(_{p,r}\)) is simply the time difference between when the peak is reached and the latency \(L_{p,r}\).

The upslope \((U_{p,r})\) is computed as \(U_{p,r} = \frac{1-I_{p,r}(L_{p,r})}{TTP_{p,r}}\), i.e. it is the average slope between initial ICG arrival and the peak.

The downslopes \(DX\) are the average downslopes between the peak and \(X\) seconds further, so \(DX_{p,r} = \frac{1-I_{p,r}(L_{p,r}+TTP_{p,r}+X)}{X}\). We included \(DX\) for \(X \in \{20, 50, 80, 100, 160, 250, 400\}\) seconds in our initial feature set, but only the most discriminative values of \(X\) will be used in the final classifier.

Since we noticed that estimating the downslope based on a single time point might lead to very noisy estimates, see e.g. the middle panel of Figure 3, a more robust feature was introduced by estimating the downslopes of a window around \(L_{p,r}+TTP_{p,r}+X\) seconds and taking the median of those downslopes:

\[ DX_{p,r,avg} = \text{median}_{x \in \text{Window}} D(X + x)_{p,r}, \quad \text{Window} = \{-15, -13, \ldots, 13, 15\} \text{seconds} \]

The time ratio \(TR\) is included as well. It is the ratio between \(TTP_{p,r}\) and when \(I_{p,r}(t)\) reaches half the peak values, see Figure 4.

While \(U\) and TTP relate to the uptake of ICG, the \(DX\) relate to the decay of ICG fluorescence; \(TR\) is a measure of the temporal inhomogeneity of the initial uptake.

Once this first set of features is obtained, inter-patient variation can be addressed by relating the features of each ROI to a healthy reference value in the same patient. In particular, for a feature \(F\), we define its patient-normalized value \(f\) to be

\[ f_{p,r} = \frac{F_{p,r} - \text{median}_{\text{is "healthy"}} F_{p,s}}{\text{median}_{\text{is "healthy"}} F_{p,s}}, \]

in other words, we are choosing the median value (as an average that is robust to outliers) of a feature across a patient’s healthy tissue as a reference value, and define each feature as its percentage difference to that reference value.

This puts into numerical terms the intuition that “benign” growths would have similar perfusion patterns as “healthy” tissue, whereas “cancer” tissue should deviate from that. As an illustration, consider Figure 5: the normalized downslope feature concentrates around 0 for benign regions, whereas it concentrates away from 0 for the cancerous regions; for other features, e.g. the time-to-peak TTP, that appears to not be the case, hence it is necessary to consider all features in the feature selection process.

### 3.4 Classification Algorithms and Feature Selection

While the data acquisition required addressing technical challenges in the realm of computer vision, and the feature extraction and design required domain insights, the classification itself is now a rather standard binary classification problem, with feature selection as a subproblem: Given the features of a region for which the pathology is unknown,
we want to assign the label “benign” or “cancer” to it. Additionally, we want to explore which small subset of features achieves the best performance.

Considering the scarcity of data and the justified desire for simple, interpretable algorithms in the context of digital health, we restrict ourselves to a subset of available machine learning (ML) algorithms. In particular, we exclude neural networks from consideration, and evaluate support vector machines (SVMs), naive Bayesian classifiers, generalized additive models (GAMs), decision trees, nearest neighbors, and logistic regression. These standard algorithms are well-described in the literature and have simple to use, efficient Python implementations.

Furthermore, we restrict the number of finally used features to two, for: (a) this enables us to draw decision boundaries, see Figure 6 (b) with a dataset as small as ours, there is no justification for using high-dimensional feature spaces.

3.5 Feature Selection

We selected the best pair of features in terms of achieved sensitivity, specificity, and accuracy by a two-step procedure:

- In a first step, decision trees and SVMs using the full set of 34 features defined above were trained, and recursive feature elimination (RFE) was performed to arrive at a much smaller set of best-performing features. Those were \{d_{250\text{avg}}, d_{400\text{avg}}, tr, TR\}.

- In the second step, an exhaustive search over pairs of features was performed, by training classifiers for the 6 possible pairs of two chosen from the 4 features identified in the previous step.

In all cases, performance was assessed by a k-fold cross-validation strategy where a portion of the training data is reserved and used to test the model after hyperparameter optimization; this is detailed in Section 4.

Care also needs to be taken to prevent leakage from training into testing sets: Since ROIs from the same patient often have similar characteristics, splitting into testing and training sets was done on the patient level, i.e. all of a patient’s ROIs will always be either in the training or the testing set, but never in both. Experiments were run with 20 random splits of training and test data sets and the mean of the performance metrics are reported for sensitivity, specificity and accuracy respectively.

4 Results

Performance of the interpretable machine learning models was assessed by first selecting 12 patients to be the training set, and setting the remaining 4 patients aside as the test set. Each ML model was then tuned to the training set in an inner 5-fold cross validation procedure (i.e. the remaining 12 patients were split into 5 folds, 4 of which were used to train the classifiers, and the last fold was used to assess performance), and evaluated by its performance on the test set. This process was repeated 20 times (there would be 1820 ways to split 16 into groups of 12 and 4), and the average of each metric was reported as the classifier’s performance. Table 1 shows the best model performances with all pairs of
Table 1: For all feature pairs, best performing algorithms for 3 metrics and the average metric (Accuracy + Specificity + Sensitivity)/3. NB = Naive Bayes, NN = Nearest Neighbors, DT = Decision Tree, GAM = Logistic Generalized Additive Model, LogReg = Logistic Regression.

Figure 6: The decision boundary of a naive Bayes classifier based on the feature combination $d_{250_{avg}}$ and $d_{400_{avg}}$ and a decision tree based on $d_{250_{avg}}$ and tr. Each plot can be interpreted as follows: For a given ICG brightness curve, compute or estimate the features and locate the point in the plot. The deeper the shade of red, the higher the classifier’s confidence in “cancer”, and the deeper the shade of blue, the higher the confidence in “benign”. The dots denote the data used to train the classifiers (a random selection of 12 patients).

The classifier with the best average of all considered performance metrics is a naive Bayes classifier using the features $d_{250_{avg}}$ and $d_{400_{avg}}$, which achieves an Accuracy/Sensitivity/Specificity of 0.953/0.950/0.958. To illustrate the resulting classifiers and their interpretable nature, we computed the decision boundaries for this best classifier, and, for comparison, a decision tree using the features $d_{250_{avg}}$ and TR, see Figure 6.

Conclusions
We stress a few important points:

1. While the process of preparing the data and training the algorithms is complex, the resulting algorithms them-
selves are so simple that the predicted pathology can be computed in one step from a simple tabulation of a
ROI’s brightness over the course of around 7 minutes.

2. The more traditional features TTP and $U$ do not appear in our selection of most discriminative features, however
two of the novel downslope features derived from $D_{250}$ and $D_{400}$ do appear. TTP is of course still necessary
to compute $DX$ (recall that it is the average slope between TTP and TTP + X seconds).

3. The training set is very limited, hence while numbers in excess of 90% are exciting and encouraging, we caution
that significantly more videos will be necessary to make assessments with any confidence.

To summarize: We proposed to characterize dynamic perfusion patterns by a number of easily interpretable features
(e.g. the slope of the initial uptake of ICG, the time it takes to reach peak perfusion, and the rate of decay of ICG
once the peak is reached). These features can be estimated merely by visual inspection of the fluorescence time-series
addressing interpretability of results, and computed by hand or in a spreadsheet. For validation of the proposed features
we implemented an experimental framework combining a tracking algorithm, basic peak and latency estimation
algorithms (which could be replaced by visual inspection of the selected data) and classification algorithms from stan-
dard machine learning open source tools. Experiments on a corpus of 16 suspected colorectal cancer multispectral
endoscopic videos (5 confirmed cancer/11 confirmed benign lesion) captured during surgical procedures, showed that
using only 4 of the proposed features is discriminant for benign and malignant tissues; reducing the number of features
to 2 is seen to decrease performance, but not dramatically, while lending itself to a simple visualization of the decision
boundaries between benign and malignant tissue.

The method of tissue characterization described here has many potential uses. Immediate uses include guiding the
operator to the tissue locations most likely to yield a diagnostic biopsy as well as the identification of tumor margins.
Following further refinement of the technique, confident characterization of colorectal lesions at the time of initial
encounter would accelerate the patient towards definitive care, whether that is proceeding with local excision (e.g.
Trans-anal minimally invasive surgery (TAMIS) in the case of benign or early stage malignancy), or more extensive
surgical resection.

Abstract Despite impressive success of machine learning algorithms in clinical natural language processing (cNLP), rule-based approaches still have a prominent role. In this paper, we introduce medspaCy, an extensible, open-source cNLP library based on spaCy framework that allows flexible integration of rule-based and machine learning-based algorithms adapted to clinical text. MedspaCy includes a variety of components that meet common cNLP needs such as context analysis and mapping to standard terminologies. By utilizing spaCy’s clear and easy-to-use conventions, medspaCy enables development of custom pipelines that integrate easily with other spaCy-based modules. Our toolkit includes several core components and facilitates rapid development of pipelines for clinical text.

Introduction

Retrospective clinical research often relies on data extracted from electronic medical record (EMR) systems using natural language processing (NLP) adapted for clinical language. Despite a wide range of existing solutions, code reuse is challenging because new system development projects face the labor-intensive task of connecting isolated modules into cohesive cNLP pipelines. Over the years, the need for reuse and reproducibility has been met with a number of frameworks and toolkits.1 Java-based general architectures, such as UIMA2 and GATE3, have provided a strong foundation for a number of highly successful cNLP toolkits and general purpose reusable systems such as cTAKES, CLAMP, Leo, and HITE4–7. As a platform-independent and straightforward programming language, Java has been the primary environment for most cNLP applications of the last 20 years even prompting re-implementation of tools previously written in other programming languages to improve accessibility8,9.

While Python programming language is celebrating its 30-year anniversary, in the last few years its usage has exploded as it had become one of the most popular languages of data science.10–14 The wider NLP, machine learning, and data science community’s shift towards Python is fueled by its capability of interactive environments to explore data and experiment with approaches while avoiding a common cycle of compiling code and reloading data15. The machine learning ecosystem in Python is vibrant and growing, including state-of-the-art training methods and deep learning models.

Until recently Natural Language Toolkit (NLTK) has been the leading platform for general text processing in Python.16 Actively supported by a dedicated team since 2000, NLTK is comprised of a number highly functional NLP libraries for rule-based and machine learning-based text analysis. While NLTK has enabled hundreds of successful research and educational projects, its approach to text processing as lists of strings and lack of a unifying architecture have hindered its ability to scale to large datasets.

In contrast, spaCy+ provides a robust architecture for building and sharing custom, high-performance NLP pipelines by taking an object-oriented view of text. It is non-destructive, supports seamless integration of statistical and machine-learning methods with rule-based NLP, and allows for the creation of custom components for specialized tasks. Powered by the strength of Cython, an optimizing static compiler for Python that generates very efficient C or C++ code, spaCy allows achieving exceptional speed of performance. Similar to UIMA approach in Java, spaCy provides a framework for modular plug-and-play construction of custom NLP pipelines. Since its inception in 2015, spaCy universe has gained a robust, highly-active, and growing community of contributors of open source modules, state-of-the-art models, and end-to-end systems developed with or for the framework.

Recognizing the need to adapt processing to different domains, several models and toolkits have been introduced targeting specialized text, among them scispaCy that handles scientific and biomedical sublanguages17. While scispaCy includes custom tokenization rules, biomedical concept identification, and a variety of pre-trained dependency parsing

*https://spacy.io/*
and named entity recognition (NER) models, the differences between clinical and biomedical language hamper its ability to achieve optimal performance on clinical narrative. To confront the particular challenges posed by medical text, a team at Virginia Commonwealth University created MedaCy, a medical text mining framework built over spaCy to facilitate the engineering, training and application of machine learning models for medical information extraction\textsuperscript{18}. Neither scispaCy nor MedaCy provide adequate support for rule-based system development beyond the functionality natively provided by spaCy. Despite a wide range of machine learning applications, rule-based algorithms still comprise a large proportion of successful academic and commercial cNLP projects\textsuperscript{19, 20}.

To bridge the gap between the existing functionality and the needs of the clinical research community for easy-to-use clinical text processing that combines statistical and symbolic methods, a team of enthusiastic cNLP practitioners at the Veterans Health Administration and University of Utah developed a spaCy-based library of core components targeting medical text called medspaCy\textsuperscript{†}.

**Methods**

**Framework Overview**

MedspaCy is designed to utilize spaCy’s application programming interface (API) while only minimally expanding upon it where needed. This minimal expansion of spaCy’s API ensures each component is usable standalone or as one part of a larger spaCy pipeline that may incorporate components from other sources. Figure 1 illustrates the interconnection of medspaCy components into an end-to-end system through a common API. Once the toolkit reached acceptable maturity, we made it available through PyPI with the command `pip install medspacy`.

![Figure 1: Overview of medspaCy architecture.](image)

All information generated by components is directly accessible through the use of spaCy’s attribute extension functionality. For example, a default spaCy attribute of a named entity is accessible using `ent.like_num` attribute, a medspaCy attribute utilizes the custom extensions such as `ent..is_negated`. Attribute extensions are registered at the `Doc`, `Span`, or `Token` levels, depending on the component to create a variety of useful tools for analyzing data after medspaCy processing is complete.

The components included in medspaCy offer both a default initialization and a large number of optional customization

\textsuperscript{†}https://github.com/medspacy/medspacy
parameters. This allows components to be quick to set up, learn, and use to develop prototypes while also being fully customizable for more specific needs. Resources, such as curated rule sets or knowledge bases, may be shared with the community and utilized across projects. Figure 2 is an illustration of an example pipeline using medspaCy. Since the spaCy API allows for modular components, there are many possible pipelines where users could insert alternative components, such as scispaCy AbbreviationDetector or other spaCy-compatible rule-based or machine learning-based modules.

**Figure 2:** Example of a text processing pipeline that utilizes medspaCy and other spaCy-based components.

**MedspaCy Components**

MedspaCy has a growing list of integrated components that allow building end-to-end systems for clinical text processing.

**Tokenization**

The primary advantage of spaCy’s approach to tokenization is that it is non-destructive, which preserves all whitespace and punctuation information enabling complete reconstruction of the original text. The major drawback of the default spaCy tokenizer for clinical text processing is that it is not trained on clinical text. Additionally, it has a variety of rules designed to handle text sourced online, including many rules that mitigate excess tokenization of URLs. These rules prevent splitting sequences of alphanumeric characters and punctuation into multiple tokens. However, URLs are relatively uncommon in clinical text but typos and using punctuation to delineate document structures are common. The tokenizer included in medspaCy implemented custom rules to handle punctuation and inconsistent use of whitespace that are common in clinical notes.

**Sentence Detection**

Due to the limited purpose of clinical language to document and succinctly communicate information about a specific patient, sentences in clinical text are characterized by telegraphic grammar with omitted subjects and the propensity to use long lists for present or absent conditions and prescribed medications\(^ {21} \).

Sentence segmentation in clinical language is hindered by frequent use of templated and tabular text, abundance of concept-value pair statements, and inconsistent use of punctuation. Since the text is meant to be read within a specific user interface of the EMR, space, tab, and new line characters are utilized to indicate sentence or section boundaries as well as for visual indication of grouped text, such as in case of templates and tabular text. Syntactically significant whitespace complicates the traditional approach to text processing that ignores existence and length of whitespace in text. To correctly identify the context of target concepts from clinical text, a clinical-domain sentence boundary detector is essential, because many downstream components work at the sentence level. Commonly used sentence detectors trained on non-clinical text typically do not perform well on clinical text data.\(^ {22} \) To make medspaCy more capable of performing cNLP, we adopted a high-performance, rule-based sentence detector for clinical text – PyRuSH, which is the Python version of Rule-based sentence Segementer using Hashing (RuSH)\(^ {22} \). Relying on rules for tokenization allows easy adaptation of the tokenizer to a new setting without extensive retraining.
Section Detection

Clinical documentation has a well established data format for different document types. Logical Observation Identifiers Names and Codes (LOINC) Document Ontology outlines hundreds of document types that vary by subject domains, role of the author, setting, type of service described, and document kind\textsuperscript{23}. At each intersection of these axes, a clinical document has a specific structure that is either learned through apprenticeship (medical students learning from practice) or specifically prescribed by guidelines\textsuperscript{24,25}. The same statement in different sections of the same or different documents might have very different meanings. For example, a document type called Progress Note has Subjective, Objective, Assessment, Plan sections, and Procedure Report has Findings and Impressions sections. Depending on which section it is mentioned in, a clinical condition may be experienced by a patient in the past, may be happening at the time when the note is written, or the patient may be at risk for experiencing it in the future. These sections may or may not be explicitly labeled with a variety of section headers fully spelled out or abbreviated.

Breaking documents into relevant sections is often a core part of cNLP, especially as documents grow in length and complexity. medspaCy includes an implementation of clinical section detection based on rule-based matching of the section titles with default rules adapted from SecTag\textsuperscript{26} and expanded through practice. The sectionizer contains several other features beyond simple section title identification. If desired, the sectionizer can interact with the attributes of entities, such as changing the temporality attribute of all entities in the “Past Medical History” section. The medspaCy sectionizer is also capable of creating hierarchies of sections and subsections within the document and preserving them in a traversable tree structure.

Concept Extraction

Clinical concept extraction through concept mention detection and concept encoding is one of the most prominent tasks of clinical text processing.\textsuperscript{19} Similar to NER, concept extraction employs either manual rules or trained statistical models to identify specific spans of text from a clinical document and labeling them with pre-defined clinical concepts. Several utilities are included in medspaCy for targeted concept extraction which extend existing spaCy rule-based functionality. Rules defining concepts specify the text pattern to be matched, semantic category, and additional metadata about a concept. In addition to integrating existing pattern-matching functionality provided by spaCy, medspaCy incorporates additional regular expression features, such as accepting multi-token regular expressions, and allows directly specifying entity attributes, such as temporality or standard vocabulary codes. Enabling additional regular expression matching ensures greater compatibility with existing cNLP resources and knowledge bases as regular expressions are commonly used in other frameworks and languages.

UMLS Mapping

Clinical text processing systems frequently rely on comprehensive indexing of the narrative text to a standard vocabulary. The Unified Medical Language System (UMLS)\textsuperscript{27} is the most comprehensive standard terminology that is typically used as the basis for clinical concept extraction. Aiming to enable UMLS concept extraction with minimal environment configuration, medspaCy adapted QuickUMLS to spaCy framework. The existing system QuickUMLS was selected as a concept mapping solution due to its speed and matching accuracy that are comparable to other existing systems\textsuperscript{28}. It allows efficient approximate dictionary matching by leveraging an implementation of the SimString library.\textsuperscript{29} Modifications were made to QuickUMLS so that its algorithm could be contained in a spaCy component. UMLS licensing does not allow redistribution of the databases, therefore, medspaCy is distributed with resources generated from a publicly available UMLS sample.\textsuperscript{5} MedspaCy documentation includes instructions on how to create QuickUMLS resources after installation. An additional contribution of medspaCy is a better support for QuickUMLS and its dependencies for Windows operating system. While our implementation of QuickUMLS in Windows requires Anaconda and some additional installation steps, other operating systems such as Linux and MacOS can perform extractions with the provided small UMLS sample immediately following installation.

\textsuperscript{1}https://www.nlm.nih.gov/research/umls/new_users/online_learning/Meta_006.html
Contextual Analysis

Extracting contextual properties of clinical concepts is an essential step of typical cNLP systems. Negation, temporality, certainty, and experiencer are the most useful contextual features for entities extracted from clinical text. The ConText algorithm\textsuperscript{30} asserts attributes by linking entities with linguistic modifiers within a contextual window, typically a sentence. Previously implemented using Python in pyConText\textsuperscript{NLP}\textsuperscript{31}, the algorithm was adapted to spaCy\textsuperscript{API} with extended attributes. MedspaCy implements the ConText algorithm with a set of default rules that can be customized as needed. ConText rules take advantage of pattern matching and also allow the user to control the behavior of the modifier by defining properties such as directionality in the text and custom linking logic. Several attributes, such as negation, are registered by default, but attributes can be customized by users to allow for use case-specific semantic categories.

Utilities

Assisting with development of complete end-to-end systems, medspaCy provides a variety of utilities to support deploying pipelines and analyzing output of text processing:

- pre- and post-processing utilities that help developers transform simple methods into components compatible with spaCy pipelines.
- a component that converts a spaCy Doc to a dictionary-based format that is directly convertible to Pandas, SQL, CSV, or other tabular format when added to the end of an existing medspaCy pipeline. It supports output for all attributes and spans for entities, sections, and context.
- a pipeline controller for deploying medspaCy on large quantities of data. It facilitates batching documents on both input and output and a wrapper that handles standard database operations through \texttt{pyodbc} (Python ODBC bridge), such as creating tables and write queries given a set of desired columns, which allows medspaCy to deploy faster.

Visualization

The visualization tools included in spaCy’s have been adapted to display the results of the integrated medspaCy components. There are two types of visualization included (Figure 3): the first highlights extracted entities, contextual modifiers, and section titles in the text. The second represents the ConText algorithm by drawing directed arrows between entities and their linked modifiers. These visualizations can be used to present a model’s final output or to explain the logic of a model. During development, visualizing intermediate results can assist with debugging. Updating a model, testing on text, and inspecting the results with the visualizer can be done rapidly when used in an interactive setting such as Jupyter Notebook.

Use Cases

Multiple operational and research oriented projects within the U.S. Department of Veterans Affairs (VA) have utilized medspaCy. The rapid development supported by medspaCy has been essential to several projects aiding the VA’s COVID-19 pandemic response.
**Chief Complaint Surveillance**

One of the earliest applications utilizing some of these components in a spaCy pipeline is a system which is used for enhanced syndromic surveillance in VA. This system processes presenting symptoms recorded during emergency department triage such as "n/v/d" (i.e. “nausea / vomiting / diarrhea”) or "c/o cp+sob" (i.e. “complains of chest pain and shortness of breath”) to extract UMLS concepts. This pipeline has been running in an operational capacity for biosurveillance since early 2019. It was leveraged in early 2020 in response to the COVID-19 pandemic to identify potential patients under investigation before the existence of laboratory testing for SARS-CoV-2 or the term COVID-19 was adopted. This pipeline performs text pre-processing using a subset of regular expression patterns from the Emergency Medical Text Preprocessor (EMT-P)\(^{32}\), and maps text spans to standard vocabulary concepts using the QuickUMLS component.

**COVID-19 Surveillance**

Another operational project used medspaCy to identify VA patients who have been tested for COVID-19 outside of the VA network when no structured lab results were available\(^{33}\). This pipeline classifies clinical documents which likely contain a mention of positive COVID testing so that they can be prioritized for manual chart review. Between January 1 and June 15, 2020 the system had processed documents for over 3 million patients and had resulted in over 36% of all identified COVID positive patients being identified by this method alone. An evaluation of the system demonstrated precision and recall of 82.5% and 94.2%, respectively. As terminology related to the virus changed over time, it was imperative to add to concepts and patterns nearly every day. Iterative development of this system with medspaCy permitted putting the system into practice by January 21, 2020 and has been continuously operational throughout the pandemic, having processed over 63 million clinical documents one year after initial deployment.\(^8\)

**VA COVID-19 Screening**

As the COVID-19 pandemic spread, VA facilities implemented standardized COVID-19 screenings for all visitors and employees. All interactions with Veterans are logged using a specific document format that quickly became one of the most frequent documents entered into the VA EMR in 2020. Veterans in inpatient care or community living centers often had multiple COVID-19 screenings recorded each day.

A medspaCy pipeline was developed to identify the screening as a standalone document or as a subsection of a larger document and then to extract up to 17 different possible screening questions and the associated responses including community- or travel-based exposure to COVID-19, previous COVID-19 tests or diagnoses, or specific COVID-19 symptoms.

This pipeline has processed 6.8 million screening documents for 914,000 Veterans who have received a COVID-19 test. The dataset is available to VA researchers in the VA COVID-19 Shared Data Resource.\(^{34}\)

**Inpatient Nursing Templated Text Processing**

Several national VA standard operating procedures have been put into operation during the COVID-19 pandemic mandating use of standardized inpatient nursing shift assessments. While the assessments are presented to users as forms, the data are stored as the raw text conversions of templated questionnaires with their answers, thus, much of the information is not automatically retrievable. The medspaCy sectionizer is being utilized for the automatic extraction of information from these semi-structured documents (Figure 4). Given an empty version of each template, a utility module is used to automatically generate sectionizer rules. The sectionizer applies those rules to identify each question in the template as section header and extracts of all template answers captured as the section body.

**Veteran Suicide Risk and Intervention Analyses**

Several capabilities of medspaCy were used to rapidly summarize insights from Veterans, family members and organizations who responded to a request for information on how to improve suicide prevention. This survey was performed as part of the President’s Roadmap to Empower Veterans and End a National Tragedy of Suicide (PREVENTS) task force to better understand risk factors and approaches to end Veteran suicide\(^{35}\). A total of 9,040 open ended responses

\(^8\)https://spacy.io/universe/project/cov-bsv
needed to be analyzed and their insights summarized to allow a report of findings to be delivered to the task force within 3 months. Several capabilities in medspaCy made this project possible within the requested deadline, such as iterative rule development, exploratory data analysis, and visualization of text extraction. The project was also able to leverage existing knowledge resources from UMLS, including concepts related to mental health, medication and treatment. These insights were utilized by the task force as material to inform development of the PREVENTS.

**Homelessness and Housing Stability Identification**

Social determinants of health including homelessness are important factors in patient health and are often only documented in free text. The VA partners with community organizations through the Supportive Services for Veteran Families (SSVF) program to provide rapid rehousing and temporary financial support to veterans who are homeless or at risk of becoming homeless. A pipeline is being developed using medspaCy which extracts mentions of homelessness and housing stability from clinical texts. This information is then aggregated to infer a patient’s housing stability over a period of time and will be used to evaluate long-term outcomes of SSVF participants and identify at-risk individuals who could benefit from enrollment in the program.

**Education**

Besides supporting operational or clinical application, medspaCy’s simple interface and low barrier to entry makes it useful for education. Local, national, and international workshops and tutorials have utilized medspaCy to illustrate clinical text processing. A recent multi-day intensive course on clinical data science targeted to medical students used medspaCy as part of its curriculum. This course introduces medspaCy in one of the first sessions so that the remainder of the workshop can be devoted to experiential learning where students create rules and modify components to develop systems for processing clinical documentation. A simple installation process and a common programming interface enables students with little programming experience to quickly apply NLP to clinical data.

**Future work**

There are many additional components and applications possible in the next steps for medspaCy. One potential area of development is releasing medspaCy pipelines which include components, resources, and pre-trained models for specific cNLP tasks. These could also be created from publicly available resources such as MIMIC-III, shared tasks such as i2b2, or ontologies constructed during previous research. Released models could include a broad range of clinical domains, including adverse drug event detection, infectious disease surveillance, and radiology reporting.

While most of the existing medspaCy components support rule-based systems, future work could include additional utilities for machine learning. This could include word embeddings loaded as part of a default pipeline or utilities for feature extraction from text. Such improvements would allow users to more fully leverage both statistical and rule-based cNLP.

**Conclusion**

By improving the accessibility to high-performance NLP solutions optimized for clinical language, we aim to improve the productivity of cNLP development and reduce development burden for projects that require the use of rule-based

---

1. https://github.com/Melbourne-BMDS/mimic34md2020_materials
NLP or the integration of rules with other NLP methods. Unlocking new data elements through clinical information extraction will enable researchers to find answers to questions previously inaccessible for investigation.

A Machine Learning Pipeline for Accurate COVID-19 Health Outcome Prediction using Longitudinal Electronic Health Records

Alice Feng

1The Harker School, San Jose, California

Abstract

Current COVID-19 predictive models primarily focus on predicting the risk of mortality, and rely on COVID-19 specific medical data such as chest imaging after COVID-19 diagnosis. In this project, we developed an innovative supervised machine learning pipeline using longitudinal Electronic Health Records (EHR) to accurately predict COVID-19 related health outcomes including mortality, ventilation, days in hospital or ICU. In particular, we developed unique and effective data processing algorithms, including data cleaning, initial feature screening, vector representation. Then we trained models using state-of-the-art machine learning strategies combined with different parameter settings. Based on routinely collected EHR, our machine learning pipeline not only consistently outperformed those developed by other research groups using the same set of data, but also achieved similar accuracy as those trained on medical data that were only available after COVID-19 diagnosis. In addition, top risk factors for COVID-19 were identified, and are consistent with epidemiologic findings.

Introduction

COVID-19 is a serious respiratory disease caused by a new type of coronavirus (SARS-Cov-2) and has put a strain on the global healthcare systems. As of March 8, 2021, there are more than 116 million confirmed infections worldwide, where more than 28 million cases are in the United States with a death rate of 1.78% which translates to 505K death due to COVID-191. In addition, there are 18 million veterans in the US who are at higher risk than the general population for severe COVID-19 illness. The death rate of veteran COVID-19 patients is 4.6%2, which is significantly higher than that of the general population. Epidemiology studies have shown that there are several factors that increase a COVID-19 patient’s risk of developing into a severe disease even death3,4,5. Hence, it is of urgent need to efficiently identify and protect at-risk individuals, especially veterans, through accurate predictive models, and effectively allocate limited healthcare resource such as vaccination to mitigate the burden on healthcare systems.

Many studies on COVID-19 prediction models were published in the past year, however, most of them were prognostic models built on suspected or confirmed COVID-19 cases, and relied on COVID-19 specific medical data such as lab tests, symptoms, and chest imaging. In addition, most models only predict COVID-19 mortality risk. There have been few studies that predict several COVID-19 health outcomes using past Electronic Health Records (EHR) routinely collected from the general population6. There was no study specifically addressing the veteran population. We filled in the gaps in this study.

In this project, we designed a novel machine learning pipeline to predict COVID-19 related health outcomes and identify the risk factors of different health outcomes using the synthetic veteran EHR data provided by the VHA (Veterans Health Administration) Innovation Ecosystem and precisionFDA COVID-19 Risk Factor Modeling Challenge7. Synthetic data mirroring the real veteran population were provided for privacy and liability concerns8. The longitudinal EHR data from 147451 patients who may or may not have COVID-19 include what are routinely collected during clinic visits, such as demographic information (age, gender, race, income, address, marital status etc.), allergies, education, immunization, medication, medical histories, insurance care plans, and many other information. The predicted health outcomes included COVID-19 infection status, mortality status, controlled ventilation status, days hospitalized and days in ICU.

Methods

1. Project goal

The 147451 patients’ EHR were split into two sets with 80% used as the training data set and 20% used as the test data set. The COVID-19 related health information (COVID-19 related symptoms, diagnosis, outcomes etc.) was withheld in the test data set. Our goal was to build predictive models from the training set to accurately predict the COVID-19 health outcomes for the test set. During this process, we also identified risk factors for COVID-19 illness.
as part of feature selection for the model training where we chose the top features that contributed most to the health outcomes. In particular, we developed a unique machine learning pipeline which included data cleaning, initial feature screening and vector representation, followed by various modules for feature selection, model training, and model evaluation.

2. Data analysis and data cleaning

First, we analyzed the EHR data extensively and designed an effective data cleaning algorithm to filter out data that may result in skewed or biased model. In machine learning, it is important to do data cleaning to remove data that are not relevant or may cause bias or skew during training. Based on our data analysis, we applied a data specific cleaning algorithm to remove the following problematic training data. 85944 records remained after data cleaning.

1. 25% of patients were dead before Jan 1, 2020. We consider these patients died of reasons other than COVID-19 since the first COVID-19 case in the United States occurred after Jan 1, 2020. They were removed as they did not offer any COVID-19 related information.

2. 0.5% of the records have conflicting data types and were removed.

3. Some patients had positive then negative PCR COVID-19 test records. They were recovered COVID-19 patients. We removed ‘COVID-19 negative’ test results from these patients as recovery was not studied in this project and these ‘negative’ test results were misleading.

4. A few patients were hospitalized due to COVID-19 but lacked positive COVID-19 PCR test records. Their COVID-19 status might have been confirmed through other methods such as imaging. We consider them having positive COVID-19 tests.

5. 1% data had conflicting condition code and descriptions, and were removed.

3. Initial feature screening

Next, we did an initial feature screening on the training data. Each patient was represented by a feature vector which included patient unique ID and the features a patient had, i.e., patient information from EHR including demographics, medical conditions, etc. In order to improve model training stability and reduce computational complexity, we first selected a subset of the features based on the following rules.

1. We selected features that were most relevant. Hence, health insurance provider, revenue, payer’s information, organization were not selected.

2. We selected features that can be more readily quantified in the feature matrix. Hence medical imaging, addresses, insurance plan were not selected.

3. We removed features that have constant values across all samples.

4. We also removed features that are highly correlated to other features to reduce data redundancy.

4. Vector representation

We then transformed the raw data into feature vectors. The goal is to minimize the distance between the targeted vector and the predicted vector. Many machine learning algorithms require that the numerical values of each feature can be compared against each other and a valid distance can be defined to reflect the closeness between the values. Thus, an optimized feature vector representation is critical to achieve the optimal model performance. Based on this principle, our vector representation algorithm

1. used frequency for medical condition, allergy, medication, immunization, medical procedure;

2. used One-Hot Encoding for categorical variables such as marital status, race and gender, so as to expand those categorical values into a series of binary numbers;

3. used the latest record for ‘observations’;

4. transformed the raw birthdate into a numerical feature for age.

5. Feature normalization

Features with very large values may dominate the model training. In addition, gradient descent, used in many machine learning algorithms, converges much faster with normalized features. Hence we normalized the features by removing each feature’s mean and scaling each feature to unit variance.
6. Feature selection through ANOVA
Coupled with model training, the significance value of each feature was calculated using t-test through Analysis of Variance (ANOVA) for each health outcome and reflected the feature’s impact on the health outcome. We tested both FWE (family-wise error rate) and FPR (false positive rate) modes of ANOVA and chose the one with better performance. In the end, about half of the features were removed due to their low significance.

7. Model training
We adopted different machine learning strategies for different health outcomes.

(1) Binary status predictions such as COVID-19 infection status, mortality status and ventilation status were classification problems, and we experimented with algorithms such as Gradient Boosting Machine (GBM) classifier, AdaBoost classifier, Random Forest (RF) classifier, K-Nearest Neighbor (KNN) classifier and ensemble learning.

(2) Numerical predictions such as days hospitalized and days in ICU were regression problems, and we experimented with algorithms such as GBM regressor, AdaBoost regressor, RF regressor, KNN regressor, and ensemble learning.

We chose these machine learning strategies based on machine learning literatures where these algorithms performed well in similar settings. In general, boosting algorithms combine the results from a series of weak prediction models to make the final prediction. Random Forest combines the results of many individual decision trees to make the final decision. KNN classifies data points based on the similarity of the points.

Each algorithm has a set of hyper-parameters, which were optimized through 5-Fold Cross Validation with Grid Search. In particular, the performance of the algorithm given a grid point was evaluated through 5-Fold Cross Validation to reduce the risk of overfitting. Here, the 5-Fold Cross Validation split the training data set into 5 folds and used four folds to train the model and the remaining one fold to test the model, then rotated through the training/testing folds in five iterations. The average performance over five iterations was used as the performance of the algorithm for that grid point. After traversing all grid points, the optimal set of hyper-parameters was selected for that algorithm.

As the last step of model training, the algorithm was trained again over the entire training data using the optimized set of hyper-parameters to get the final model.

8. Model testing
Eventually, we chose three models with best cross validation performance on the training data and predicted the COVID-19 health outcomes for the testing data. For each patient in the testing data, we predicted the probability of COVID-19 infection, probability of mortality, probability of using controlled ventilation, the length of hospitalization and the length of ICU stay, due to COVID-19. The predictions were evaluated against the ground truth of the testing data. AUROC (Area Under Receiver Operating Characteristics Curve) for classifiers, RMSE (Root Mean Square Error) and C-index for regressors were used as the performance metric. ROC (Receiver Operating Characteristics) curve is a graph showing the performance of a classification model at all classification thresholds, while AUROC measures the accuracy of the classifier. C-index measures the goodness of fit for binary outcomes in a regression model. The features with top significance values were selected as the high-risk factors for each health outcome.

Results

1. Raw data analysis
Our statistical analysis of the veteran EHR training data showed the following statistics (Table 1).

2. Initial feature screening

After initial feature screening, 687 features (Table 2) were used in the feature vector for each patient.

Table 2 A total of 687 initial features were used in the feature matrix.

3. Model performance

For COVID-19 positive status, mortality status, and ventilation status predictions, Figs. 1-3 and Table 3 compare the ROC curves and AUROC of our models using several machine learning algorithms based on cross validation. The algorithms with the best performance were GBM, AdaBoost and an ensemble model of GBM and AdaBoost.

For days hospitalized and days in ICU predictions, the RMSE of our models are compared in Table 3. GBM, AdaBoost and an ensemble model of GBM and RF performed the best.

In Table 4, our top 3 models (marked in blue) were compared with other 31 models submitted by other research groups in terms of AUROC, RMSE and C-index. Only the top models were included for brevity.

In Tables 3 and 4, Ensemble (G+A) is Ensemble of Gradient Boosting and AdaBoost. Ensemble (G+R+A) is Ensemble of Gradient Boosting, Random Forest and AdaBoost. Ensemble (G+R) is Ensemble of Gradient Boost and Random Forest.

Discussion

1. High-risk factors

Even though the top risk factors for each health outcome are not exactly the same, they cover the same range of issues: age, diabetes, metabolic syndromes (hypertension, high blood sugar, abnormal cholesterol levels), cancer (especially breast cancer, prostate cancer, lung cancer), heart disease, and chronic kidney disease. These risk factors are consistent with published epidemiological findings. In this study, gender, race or income did not show high significance. The reason that age did not show up as a high-risk factor for days in hospital or in ICU is because the other illnesses shown in Table 5 have a more direct impact. Being old but healthy will not cause longer hospital or ICU stays.

2. Model analysis

A total of 34 models were submitted to the VHA Innovation Ecosystem and precisionFDA COVID-19 Risk Factor Modeling Challenge. Table 4 shows that our models (marked in blue) consistently outperformed almost all other 31 models in every category (only the top models were included for brevity). Detailed results are published on the modeling challenge website. We believe the unique machine learning pipeline we developed were crucial in achieving the best models, which included thorough data cleaning, systematic initial feature screening, optimal vector representation, feature normalization, methodical choice of k-Fold Cross Validation, feature selection mode selection, and exhaustive testing of combinations of different settings.

3. COVID-19 positive status prediction

The health outcome “COVID-19 positive status” was removed from the modeling challenge, since all submitted models had low AUROC around 0.52. For example, our models could only achieve AUROC of about 0.54 (Fig 3, Table 3). This suggests that the given EHR data only is not a good indictor of a person’s chance of contracting COVID-19. Combining other information may provide better correlation such as a person’s daily activity, if wearing a mask and keeping social distance.

4. Scope of prediction

Most prior work only identified COVID-19 mortality risk factors and predicted mortality probability. However, with good accuracy, our models predicted a wider scope of health outcomes including mortality, controlled ventilation, days in hospitalization, and days in ICU. These health outcomes are of great interests to healthcare systems, for example, Veteran Health Administration, so that they can predict if their facilities have enough hospital beds, ICU beds, or ventilation equipment, and better prepare for possible shortage. The ability to predict these health outcomes is also more useful than only identifying risk factors, as these predictions are based on a patient’s holistic medical
history, demographic info and social variables; hence are more accurate and provide more information than using risk factors only.

5. **Mortality prediction**

For mortality prediction, other published COVID-19 predictive models have AUROC range from 0.69-0.9. All these models relied on symptoms, lab results, chest images after patients were diagnosed or suspected of COVID-19. Our model provides relatively high AUROC of around 0.84, was built entirely on longitudinal EHR data, without the need for confirmed or suspected COVID-19 test, and without using imaging or any COVID-19 specific tests. This makes our model more advantageous as it predicts the outcome well before a patient contracts COVID-19 and can provide protection for high-risk patients well in advance.

6. **Significance of longitudinal EHR**

As stated above, the ability to use longitudinal EHR data in accurately predicting several critical COVID-19 health outcomes make our models stand out among thousands of COVID-19 prediction studies.

7. **Reliability of our models**

The health outcome of the EHR testing data were not given to us. The AUROC, RMSE and C-index in Table 4 were calculated by VHA and precisionFDA using our predictions and the ground truth of the testing data. The good AUROC and RMSE/C-index values demonstrated the reliability of our models.

8. **Implication for veteran and general population**

The models were built on synthetic veteran EHR data generated by Synthea specifically for VHA for this challenge, hence the synthetic EHR mirrors the real veteran population in terms of demographics, medical history, social determinants, etc. Thus, our models are one of the first COVID-19 predictive models addressing the veteran population. In addition, even though the final models are data specific, our machine learning pipeline can be applied to the real patient data for the general population. In fact, our models are being validated using real patient data from VHA and precisionFDA and the results will be available soon.

9. **Future work**

We would like to work on the following topics in the future.

1. Applying our models to real veteran EHR data is underway.
2. We would like to test more machine learning algorithms to see if better performance is achievable, such as Bayesian Network and Support Vector Machines.
3. It would be interesting to divide the training data into separate age groups, for example, age 70+, 40-70, or 40-, then train the model for each age group, and see if the prediction is more accurate.
4. We are also interested in adding each person’s genomic data in the predictive model.
5. Making a software tool to calculate a person’s COVID-19 risk score would be quite useful.
7. Predict a person’s chance of catching COVID-19 using EHR and other relevant information.

**Conclusion**

In this paper, we described innovative machine learning strategies to accurately predict a holistic set of COVID-19 health outcomes and identify COVID-19 risk factors. In particular, we designed a machine learning pipeline which was trained and evaluated on synthetic EHR data. The health outcomes that can be predicted from our pipeline include mortality status, controlled ventilation status, length of hospitalization and length of ICU stay. For mortality and controlled ventilation status, our predictive models can achieve AUROC of around 0.8-0.84. For days hospitalized and days in ICU, our models can achieve RMSE of 5.7 and 1.5, C-index of 0.63 and 0.75, respectively. Our models consistently outperformed those from other research groups. The top risk factors we identified include age, diabetes, metabolic syndromes, cancer, heart disease, chronic kidney disease and smoking. Our results are helpful for providing advanced guidance to protect high-risk individuals especially veterans, and mitigate the burden on healthcare systems. This project also demonstrates that longitudinal EHR data can be successfully employed to provide a holistic prediction of an individual’s health risk based on past health records, which is critical for emerging infectious diseases control such as COVID-19.

Abstract

Medical scribes have become a widely used strategy to optimize how providers document in the electronic health record. To date, literature regarding the impact of scribes on time to complete documentation is limited. We conducted a retrospective, descriptive study of chart completion time among providers using scribes at our organization. A total of 148,410 scribed encounters, across 55 different clinics, were analyzed to determine variations in chart completion time. There was a significant variance in completion time between specialty groups and clinics within each specialty. Additionally, chart completion time was highly variable between providers working in the same clinic. These patterns were observed across all specialties included in our analysis. Our results suggest a higher level of variability with respect to chart completion when utilizing scribes than previously anticipated.

Introduction

The implementation of electronic health records (EHRs) has led to many positive outcomes, including improved efficiency in healthcare delivery and enhancements to care because of provider access to complete and up-to-date information.¹ ² However, EHRs have also led to some unintended consequences like provider burnout, over-documentation, and stress.³ ⁴ Health care professionals have some of the highest levels of burnout compared to other professions and the use of EHRs has been implicated as one of the possible factors contributing to burnout.³ ⁴ ¹¹ Because of the EHR and documentation requirements, many providers experience EHR fatigue and note bloating.¹² ¹³ Providers are spending an exorbitant amount of time doing computerized provider order entry and after-hours charting; this phenomena is known as “pajama time”, where providers are spending time working, at the EHR, after business hours.³ ⁶ ⁷ ⁹ ¹⁰ One study noted that for a patient encounter, providers spend an average of 16 minutes and 14 seconds using the EHR; the average patient visit is 15 minutes, so providers are often spending more time documenting in the EHR than they are spending with the actual patient.¹⁰ The majority of this time spent in the EHR is distributed, relatively equally, around three domains: orders, documentation, and chart review. With the excessive time spent in the EHR, both during and outside of work hours, providers have issues creating a work-life balance – many wish they could spend more time with patients.³ ¹³ ¹⁴

There are multiple ways to tackle the inefficiencies of the EHR and reduce the volume of time providers spend with the EHR. Medical scribes are one proposed way to alleviate physician documentation burden.⁴ Scribes have been aiding in documentation for centuries, but were not part of the medical field until 1975 when they were deployed as nursing scribes.¹⁸ With the massive increase in EHR use in the early 2000s, the scribing industry has risen in popularity. In today’s terms, a medical scribe is usually an unlicensed member of the clinical care delivery team who documents the patient encounter for providers in real-time, so that providers can spend more time with the patient and less time in the EHR. Besides documentation, research has suggested that medical scribes can also aid in information gathering and data entry.¹⁹ It has been demonstrated that medical scribes may decrease provider EHR-time, increase patient and provider satisfaction, improve workflow efficiencies and boost billing and reimbursement through the optimization of coding.²¹ ²⁸

A systematic review and meta-analysis by Gottlieb et al. [2021] found that changes in satisfaction, patient throughput, and revenue observed with the use of scribes was nearly consistent across the literature. Their analysis consisted of 562,682 patient encounters from 39 different studies. They observed that providers could see more patients per hour and that the use of a scribe resulted in increased relative value units (RVUs), a measure of the relative economic value of the medical services provided.²⁸ Seven of the nine studies that investigated provider perceptions when working with scribes reported increases in satisfaction. Of the 18 studies that looked at the patient view of scribe use, reports had varying findings. Some reports suggested that scribes did not change patient satisfaction, while others found increases in patient satisfaction when providers used scribes. One important thing to note about this study is that even though the studies consisted of 562,682 encounters, there was such heterogeneity regarding both study design and measures used, that the authors could not perform a meta-analysis on all of the data elements, such as provider satisfaction.²⁸

While research has suggested that scribes can decrease provider burnout by decreasing EHR documentation burden, there is a gap in the literature on whether using scribes leads to better chart closure and documentation. This is of particular concern, considering that there have been mixed results as to the quality of scribed documentation. One
study showed that scribe notes have a higher documentation quality than non-scribed notes. Other studies noted variability in the accuracy of the scribed note. Some institutions have looked at chart closure time with scribe use.

One outpatient ophthalmology clinic used audit logs of EHR data to investigate the scribes’ impact on clinical documentation; their results showed that providers who used scribes had overall less documentation time, but were spending more time documenting after the visit when using a scribe. Another study conducted in an outpatient oncology department reported that providers who used scribes spent less time documenting at the end of the day compared to providers who did not have scribes. A recent meta-analysis found that scribes had a varying impact on documentation completion, with studies ranging from positive to no impact. In another study, there was no difference between providers who used scribes and providers who did not use scribes when it came to chart notes that were incomplete after 72 hours. One potential reason for these varied results is that the vast majority of the studies investigating chart closure time only include one or very few clinics or specialties. These studies may not account for varying workflows and thus researchers cannot compare or contrast chart completion time between different groups. Thus, there is a need to conduct large-scale quantitative studies using multiple clinics, specialties, and subspecialties that examine how scribes impact provider chart closure time.

Oregon Health & Science University (OHSU) piloted a “home grown” scribe program in 2011 for the Center for Women’s Health. In 2015, it became a formal internal scribe program, which has since expanded to include over 80 clinics across OHSU. The size, duration, and breadth of the program is uniquely positioned to perform a large-scale quantitative analysis of the impact of scribes on provider documentation patterns. Thus, the goal of this study was to use EHR data to determine the impact of scribes on chart closure time across the institution, and determine factors associated with differences in completion time.

Methods

Setting and Participants. This study was conducted at a large academic medical center in Portland, Oregon. We included data from the EHR (EpicCare; Epic Systems Corporation, Verona, WI) for all ambulatory encounters that occurred between 2015 through 2019, where a medical scribe contributed to documentation. The OHSU Scribe Program almost exclusively services outpatient clinics. Thus, we only included encounters that occurred in outpatient settings. We excluded encounters if they remained unclosed at time of data collection. Encounters scheduled on Saturday or Sunday were excluded from our sample to minimize the effect of potential workflow differences between weekday and end weekend clinic service. We excluded scribes coupled with advanced practice providers because of the small sample size. Finally, to minimize irregularities due to providers who do not regularly see patients, we only included encounters belonging to physician-scribe dyads if they had completed documentation for at least 100 encounters together. This study was reviewed and approved by the institutional review board at OHSU (STUDY00017599).

Data Extraction and Processing. We extracted encounter log data from the EHR, for all ambulatory documentation, where actions on patient records were linked to an EpicCare user identifier (ID) of a medical scribe. We collected the following encounter-level concepts: patient ID, visit ID, physician ID, and scribe ID. Additional meta-data about the specialty and subspecialties of outpatient clinic providers were also extracted. We created a categorical variable to identify the outpatient clinic specialty groups included in our analysis: medicine, surgery, obstetrics and gynecology (Ob-Gyn), and pediatrics. These groups were defined based on high-level differences between the workflows of the specialties. We then generated a set of identifiers to capture the nesting of scribes within physicians, the physicians within clinics, and the clinics within specialty groups.

Descriptive Statistics. For each nested level of analysis, we calculated the median and interquartile range of time to complete chart notes by finding the difference between the scheduled visit date and the date the encounter documentation was completed by the physician. Finally, we also determined the percentage of charts that were completed according to organizational policies: “on time” documentation was closed in less than 14 days, “late” documentation was closed within 14 to 28 days, and “delinquent” documentation was completed sometime after 28 days.

Statistical Analysis.

Descriptive statistics were provided for physicians, scribes, and physician-scribe dyads across our entire sample (Table 1). Continuous variables with normal distribution were presented as mean ± standard deviation, while non-normal variables were reported as median [interquartile range]. We then included data from medicine specialty clinics to illustrate the trends repeatedly observed for documentation completion time across all specialties and clinics in our sample (Figures 1 and 2). Kruskal-Wallis tests were used to compare the mean chart completion time of three or more
groups (i.e. specialty, clinic, and provider). Where significant, a Dunn’s post hoc test was carried out on each pair of specialty groups. P-values were adjusted using Bonferroni correction. The frequencies of categorical variables (chart closure type) were compared using Fisher’s exact test, when appropriate. Descriptive and inferential statistics were performed in R v4.0.3 (R Foundation for Statistical Computing, Vienna, Austria). Unless otherwise noted, we set a level of significance of p < 0.05 for all hypothesis testing.

**Results**

**Sample Characteristics.** The purpose of this study was to examine chart completion time of attending physicians using medical scribes across a variety of clinical environments. The final sample consisted of 148,410 ambulatory encounters across 55 different outpatient clinics (Table 1). Care clinics were grouped into one of four general specialties which included medicine (69,209; 47%), surgery (48,448; 32.5%), Ob-Gyn (21,326; 14.5%), and pediatrics (9,427; 6%). The types of visits accounted for in each specialty group are included in Table 2.

Our analysis included a total of 129 physicians and 127 scribes (Table 1). On average, physicians had worked with 3±2 scribes in our sample. Scribes had a mean employment length of 14±10 months and worked with anywhere from 1 to 9 physicians. We included a total of the 325 physician-scribe dyads in our final analysis. Of these dyads, 161 (50%) worked in medical specialties clinics, 76 (23%) worked in surgical, 65 (20%) worked in Ob-Gyn, and 23 (7%) worked in pediatrics. On average, dyads worked together over a 10 [6, 17] month period and documented 296 [159, 525] encounters together.

**Chart Completion Time.** Time to complete chart notes was highly right-skewed and observed a log-normal distribution. Less than half of all chart notes (72,306; 49%) were complete within 24 hours. The median number of days to complete encounter documentation was 0.95 [0.11, 5.9] days and ranged from 0.00069 to 854 days. Finally, 132,700 (89%) of the 148,410 charts were closed on time according to organizational policies. Of the remaining, 11,734 (8%) of the completed records were considered late, while 3,976 (3%) were delinquent.

**Chart Completion Time by Specialty and Clinic.** Chart completion time was most consistent (least spread) in pediatrics with a median chart completion time of 1 [0.3] days (Figure 1). Surgery had the lowest median completion time (0 [0.5] days), while Ob-Gyn had the highest (1 [0.10]). Difference in mean ranks of time to complete chart notes were highly statistically

Abbreviation: Ob-Gyn, obstetrics and gynecology.

**Figure 1.** Days to Complete Chart Notes by Specialty Group.

Abbreviation: Ob-Gyn, obstetrics and gynecology.

The upper and lower ends of the boxes indicate the first and third quartiles. The horizontal line inside the box indicates the median and the square indicates the mean. The whiskers indicate values within 1.5x the interquartile range from the upper or lower quartile (or the minimum and maximum value if within 1.5x the interquartile range of the quartile).

The mean ranks of time to complete chart notes were different between groups (p < 0.0001). Brackets over bars indicate specialty groups that were statistically significant; **** indicates p < 0.0001.
significant between specialty groups (p < 0.0001) with significant follow-on differences between each of the group-pairs (p < 0.0001).

We next sought to determine whether a similar variance was present within a given department. Overall, each specialty demonstrated a high degree of variance between their subspecialty clinics. As an exemplar, data from the medical specialty clinics are found in Figure 2. Here, the number of days to complete chart notes was also highly variable. The

**Figure 2.** Days to Complete Chart Notes Within Medicine Specialty Clinics.
Each medicine clinic is represented on the x-axis by their ID (M1-25). The dashed, black line represents the overall sample mean.
Statistical components of the boxplots are explained in the first footnote to Figure 1.

The median number of days to complete chart notes ranged from 0.03 to 18 days. For some clinics, like M22 and M23, the distribution of days to complete chart notes was highly skewed, with a substantial number of encounters closed after an extended period.
We next wished to determine whether this variance existed within given outpatient clinics. To explore the differences in completion time between providers within the same clinic, we limited the analysis to specialty clinics with at least five scribe-using providers (Figure 3). Overall, differences in mean ranks of completion time for these four clinics were highly statistically significant between groups (p < 0.0001) and multiple comparison tests suggested that each clinic’s completion time was statistically significantly different from each of the others (all adjusted p-values were <

**Figure 3.** Days to Complete Chart Notes for Physicians Within Medicine Specialty Clinics of Five or more Providers.
Each medicine clinic is shaded in gray and represented above the x-axis by their IDs (M4, M10, M11, and M18 correlate to Figure 2). Each provider within a given clinic is represented on the x-axis by their ID (P1).
Statistical components of the boxplots are explained in the first footnote to Figure 1.
More importantly, within each clinic, there was a highly statistically significant difference in completion time between providers (p < 0.0001 for each clinic), suggesting that the observed variability seen across clinics is driven by variability at the individual provider-level.

Visit Day of Week & Days to Complete Chart Note. We next sought to determine what factors may explain some of the inter- and intra-provider variance and initially focused on the encounter day of the week. The total number of encounters that occurred each weekday was relatively similar. The highest number of encounters took place on Thursday (35,244; 24%), followed by Tuesday (33,100; 22%). In contrast, the lowest number of encounters occurred on Fridays (24,062; 16%), Monday (27,848; 19%), and then Wednesday (28156; 19%). The number of days to close chart notes was statistically significantly different across each day of the week that encounters were scheduled (p < 0.0001). Encounters that occurred on Thursdays and Fridays had a notably higher average number of days to complete chart notes than the other days of the week (Figure 4). Encounters that occurred on Thursdays and Fridays also had lower percentages of chart notes that were not completed “On Time” compared to the other days of the week (Table 3).

Chart Closure Day of Week & Days to Complete Chart Note. The number of charts closed each day of the week decreased throughout the workweek: Monday (29,646; 20%), Tuesday (28,969; 20%), Wednesday (27,7701; 19%), Thursday (25,4151; 17%), and Friday (19,1761; 13%). Providers can complete documentation on the weekends and our results suggest that around one in ten chart notes were completed on either Saturday (6,450; 4%) or Sunday (10,984; 7%). For charts where documentation was completed on a Saturday or Sunday, the number of days to complete the chart note was nearly double that of charts completed during the week (Figure 5). When chart documentation was completed on a Saturday or Sunday, the number of delinquent or late closures was higher than all other days of the week (Table 3).

Discussion

Previous literature regarding the use of medical scribes support their implementation as they are purported to help mitigate providers’ burdening challenges of EHR documentation.27 Despite the appeal of their intended usefulness as documentation assistants, qualities of the timeliness of documentation in the company of a medical scribe remains largely unreported. This study is among the first to quantitatively capture the variation in documentation completion time among physician-scribe dyads and the first to do so over such a wide collection of medical specialties and subspecialties. It is also the first

to explore how documentation completion time manifests across multiple levels of a nested sample of clinics, physicians, and scribes, which provides insight into where causes of variation may arise.

One of the most interesting findings is the wide variance between the major clinical specialty groups and time to complete chart notes. The inconsistency in documentation completion time throughout these groups is not surprising considering the previously reported differences in workflows and EHR use among specialists and primary care physicians. Among scribe users, this variation is also understandable, given that the previous literature suggests that different specialties may not utilize their scribes in the same way. When examining documentation completion time between clinics within specialties, we found that this variability existed within the different subspecialty clinics and providers using scribes within the same clinic. This emphasizes that a large degree of variance that we observed is most certainly linked to characteristics at the individual provider level. Our findings highlight a need to develop strategies to manage variation among scribe users. Organizations need provider-specific training that can be applied during scribe implementation and additional tools, such as a dashboard or data visualization system, which can allow them to identify ineffective users of scribes for intervention.

Many factors may influence the widely observed provider differences in chart completion time. One factor that we were able to consider in this analysis was whether documentation completion time was different depending on the day of the week that a visit takes place or the day of the week on which charts were closed. Day of the week may affect completion time as some providers may be more or less likely to perform documentation activities after-hours or on weekends. Our findings suggest that charts are completed at different rates of time depending on the day of the week of a visit. Furthermore, charts that are closed later in the workweek will have an increasingly higher number of days to complete documentation than those completed earlier in the week. More importantly, our data suggests that at least 10% of scribe-generated chart notes are still being completed during “pajama time”. This significant fraction of notes, finalized on weekends, had the longest amount of time between the visit date and the closure of chart notes – documentation completed on Sunday took over double the time to complete chart notes compared to those closed during the workweek. It should be noted that this is currently only assessing weekend “pajama time” and we did not assess after-hours weekday work, which was likely also present, suggesting this may be an even greater effect.

However, the idea that, even with scribe utilization, providers are facing after-hours documentation may explain why there are conflicting results on reports of how scribe use impacts provider documentation behaviors.

It is likely that additional factors are influencing the large degree of variance with chart completion time among providers who use scribes. The degree to which providers must correct a scribe-generated note is another likely factor influencing the variance we observed in this sample. First, there may be underlying variability in the quality of the scribe-generated note. Previous simulation studies have suggested that scribe-generated notes contain a wide variance in both note structure and content, as well as discrepancies in their accuracy. While all scribe-generated documentation requires a thorough review by the supervising physician, the inconsistency of notes produced by scribes may inevitably influence the amount of time a physician must expend to review, edit, and sign-off on their chart notes. This is further complicated by previous literature regarding the underlying provider-level variance in the specific content, type of content, and amount of content that is included in encounter chart note documentation. Workflow analysis may be another useful tool that can be used in future studies to ascertain granular details of the influence that scribes have on provider chart hygiene.

Perhaps the largest driver to the degree of oversight providers maintain over scribe note content is the nature of the specific relationship they have with their scribe. Previous work carried out by our group and others have found numerous subthemes that play into this relationship and allow for effective and efficient interactions between the scribe and provider. One critical subtheme that has been identified in the research is the “quality of scribe-provider relationship” and the aspect of trust. Findings suggest that the longer the provider and scribe work together, the higher the level of trust in the relationship can become. This higher degree of trust may be associated with less oversight in the completion and correction in content of the note. Future research should investigate if and how scribe-generated chart notes differ regarding both content and quality of the documentation. Additionally, it would be helpful to determine if the content or quality of the documentation depends on the amount of time taken to complete the chart note.

It is helpful to consider these findings in the context of the limitations of this study. First, our analysis only includes a single, academic medical center, limiting the generalizability of our findings. Likely, the incentives that underlie physician documentation hygiene at an academic medical center are different from that of private practice physicians. For example, the salary of physicians working in private practice may be directly tied to reimbursement claims, which require a completed chart note before the submission of a claim is possible. For academically based physicians, salary
is often tied directly to faculty appointments as opposed to claims reimbursement, which may influence their timeliness to complete documentation. Furthermore, our institution recruits and trains their scribes, who are almost uniformly pre-professional students. Individuals from many different professional groups can serve as scribes (medical assistants, nurses, etc.), and further, a large fraction of scribes are trained and supplied by independent organizations. It will be important in future studies to determine the impact these factors have on completion time and documentation hygiene. This study did not account for the chart completion behaviors of physicians before receiving a scribe. It is possible that some of the physicians who received scribes already had poor documentation hygiene, and thus self-selecting for those providers most likely to be given a scribe in the first place, which may have influenced some of the variance observed in our findings. Further, we did not directly analyze how much of the variation we observed in this study occurred because of the presence of a scribe, and we were unable to account for the impact of confounders. Therefore, while multiple explanatory factors may influence chart completion time, there is a chance that the results presented here are attributable to other ongoing factors that were not captured by this analysis. As a result, it is difficult to know how much of a provider’s documentation completion time is associated with the presence of a scribe or these other unaccounted-for factors.

Conclusion

This study assessed a gap in knowledge on how quickly physicians complete documentation while using medical scribes. Across clinical specialties and outpatient clinics, there was substantial variation in the time to complete encounter documentation, and this variation persisted across physicians using scribes within the same clinic. Our findings suggest that individual provider behavior may drive the variation in completion of clinical documentation and that scribes may have little impact on regulating the time to chart completion. Because this variation has the potential to undermine the justifications for the use of scribes, it is important that scribe-users understand this aspect of the physician-scribe dynamic and that interventions are developed to educate scribe-users to take full advantage of the assistance with clinical documentation. It should be noted that clinical documentation in the United States is, on average, almost four times as long as those in other countries; an important factor that has driven the utilization of scribes. This work also brings to the fore a larger issue of institutional and regulatory requirements for documentation. Organizations must consider how matching physician-scribe dyads will achieve the overall goal of scribe implementation, while also recognizing the limitations that scribes will have in altering poor EHR users’ underlying behavioral deficits.

Acknowledgment and Funding

We wish to acknowledge Dr. Joan S. Ash, James Becton, Robby Bergstrom, and Dinesh Neelapala for their contributions to this research. This project is supported under contract grant #R01HS025141 from the Agency for Healthcare Research and Quality (AHRQ), U.S. Department of Health and Human Services. The results from this paper are from the authors and do not represent the views of AHRQ or the U.S. Department of Health and Human Services.

Abstract

After the emergence of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) in 2019, identification of immune correlates of protection (CoPs) have become increasingly important to understand the immune response to SARS-CoV-2. The vast amount of preprint and published literature related to COVID-19 makes it challenging for researchers to stay up to date on research results regarding CoPs against SARS-CoV-2. To address this problem, we developed a machine learning classifier to identify papers relevant to CoPs and a customized named entity recognition (NER) model to extract terms of interest, including CoPs, vaccines, assays, and animal models. A user-friendly visualization tool was populated with the extracted and normalized NER results and associated publication information including links to full-text articles and clinical trial information where available. The goal of this pilot project is to provide a basis for developing real-time informatics platforms that can inform researchers with scientific insights from emerging research.

Introduction

Immune correlates of protection (CoPs) are measurable aspects of the immune system that indicate an individual may be protected from becoming infected1. In-depth knowledge of CoPs is essential to understanding immune responses to infectious diseases. CoPs can inform the efficacy of vaccine trials or provide an estimate of individual level immunity after previous infections1-3. With the emergence of novel pathogens such as severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), identification of CoPs has become increasingly important.

Over the past year since the emergence of SARS-CoV-2, new literature regarding SARS-CoV-2 and the resulting illness, coronavirus disease 2019 (COVID-19), is being published at a rapid pace3. Many studies have attempted to identify aspects of the immune system that may correlate with or directly confer protection against SARS-CoV-2, and several vaccine candidates have been approved for emergency use around the world4-8. Even with this research, the CoPs against SARS-CoV-2 remain ambiguous.

The vast amount of preprint and published literature provides an opportunity to gain a better understanding of potential CoPs against SARS-CoV-2. However, identifying publications relevant to SARS-CoV-2 CoPs using basic keyword searches oftentimes bring back thousands of results, making it challenging for researchers to easily stay up to date on information regarding CoPs against SARS-CoV-2. Several systems currently exist to extract COVID-19 and SARS-CoV-2 related literature from broader sources, but none are specific to literature relevant to CoPs9-12. There are also several open source natural language processing (NLP) models trained on biomedical text and literature13-15; however, these models have neither been trained to classify CoP relevant literature nor identify CoPs. Customization of existing machine learning methods, such as document classifiers and NLP, can be employed to fill this gap.

This pilot project aims to leverage existing machine learning tools to develop a pipeline that allows for quickly informing individuals of the current literature related to potential CoPs against SARS-CoV-2. To accomplish this, we identified literature related to CoPs against SARS-CoV-2, extracted relevant entities from the manuscripts, and visualized the results in a user-friendly tool. To the best of our knowledge, this is the first study focused on extracting and classifying potential CoPs against SARS-CoV-2 from biomedical literature. This will facilitate upkeep of knowledge on the status of CoPs against SARS-CoV-2 in both preprints and publications for researchers and administrators in related fields of study.

Methods
Data Curation

To identify potential CoPs against SARS-CoV-2, we downloaded the planned outcome measurements for the 252 COVID-19 vaccine trials documented on ClinicalTrials.gov on October 5, 2020\textsuperscript{16}. 113 of the 252 vaccine trials’ planned outcome measurements contained potential CoPs. We manually extracted and curated a list of these CoPs, which was reviewed by two subject matter experts (Table 1).

Table 1. Potential immune correlates of protection (CoPs) against SARS-CoV-2 and the count of appearances in planned outcome measurements from clinical trials extracted from COVID-19 vaccine trials on ClinicalTrials.gov\textsuperscript{16}; n = 113.

We then used this list and words synonymous with protection to generate keyword search queries in the National Institutes of Health (NIH) Office of Portfolio Analysis’ iSearch COVID-19 Portfolio, an expert-curated source for publications and preprints related to COVID-19 and SARS-CoV-2\textsuperscript{11}. We accessed the iSearch COVID-19 Portfolio from 10/16/2020 to 11/4/2020 to identify articles discussing CoPs and generated a COVID-19 dataset of articles relevant and non-relevant to CoPs against SARS-CoV-2 for the classification task. We tried several search queries such as the following: \((antibod* \text{ OR } T-cell~1 \text{ OR } B-cell~1 \text{ OR } "natural killer" \text{ OR } immunoglobulin \text{ OR } Ig*) \text{ AND } (*neutraliz* \text{ OR } protect*)\).

Since most of our queries yielded thousands of results, we limited our results to articles with an assigned PubMed ID (PMID) and the source listed as “Peer Reviewed (PubMed)”. For example, the query above, when filtered to only “Peer Reviewed (PubMed)”, resulted in 4,961 articles. We focused on primary literature with original results by excluding publication types such as reviews, editorials, meta-analyses, and letters. Articles were then randomly selected for manual annotation. After reviewing the first set of 100 articles, we identified only 12 articles as relevant. Due to this low number, we then considered only articles with an iSearch generated relevance score of at least 0.4 (range 0.0 – 1.0) to increase the number of relevant articles. We also filtered to articles with an abstract length of at least 20 words and less than 1,000 words to control for unlabeled or mislabeled publication types of non-primary literature. Finally, we combined each article’s title and abstract into a single document. We will refer to document in place of title and abstract going forward.

Two annotators (SLF and SJ) read and manually labeled each document in the COVID-19 dataset as either relevant or non-relevant to the topic of CoPs against SARS-CoV-2 using doccano, an open-source text annotation tool with features such as text classification and sequence labeling\textsuperscript{17}. Inter-annotator agreements (IAA) were periodically calculated, and an annotation guideline was maintained to track the annotation process.

The IAA was initially 0.53 but grew to 0.70 after discussion between the annotators and edits of the annotation guideline. Further discussion and finalization of the annotation guideline resulted in a final IAA of 1.00.

The publication dates of the articles from iSearch ranged from November 2019 to November 2020. After manually annotating COVID-19 literature, 426 documents were included in the COVID-19 dataset with 55 labeled as relevant to CoPs against SARS-CoV-2 and 371 labeled as non-relevant. Since the COVID-19 dataset was heavily skewed towards non-relevant documents, we expanded our search for literature related to CoPs predating the pandemic from the years 2000 to 2019 to increase the number of relevant documents and reach our final COVID-19 + non-COVID-19 dataset used for machine learning classification.

We used several phrases in PubMed such as correlates of protection and vaccine immunity to find relevant primary articles. We then utilized PubTator Central, a web-based system providing automatic annotations of biomedical terms,
to download the titles and abstracts from the PMIDs of our searches\textsuperscript{18}. The process of manually annotating documents described above was repeated for this set of documents.

We identified another 458 relevant documents and 402 non-relevant documents from literature related to other diseases and published between 2000 and 2019 for the non-COVID-19 dataset. The final COVID-19 + non-COVID-19 dataset used for the classification task had 1009 documents: 513 relevant and 496 non-relevant.

\textit{Machine Learning Classifier}

We developed a machine learning model to classify documents as either relevant or non-relevant to the topic of CoPs. Each document from the final COVID-19 + non-COVID-19 dataset described above was preprocessed by separating special characters from words and converting text to lowercase using code adapted from the Convolutional Neural Networks for Sentence Classification\textsuperscript{19}. We also removed English stop words from each document using scikit-learn’s TfidfVectorizer’s stop words parameter\textsuperscript{20}.

We then applied a train-test split of 80/20 to the COVID-19 + non-COVID-19 dataset. After fitting TfidfVectorizer to the training dataset, both the training and test datasets were transformed to a matrix of term frequency-inverse document frequency (TF-IDF) features\textsuperscript{20}. The following machine learning models from scikit-learn were used: LogisticRegression, RidgeClassifier, Perceptron, PassiveAggressiveClassifier, KNeighborsClassifier, LinearSVC (L1 and L2 regularization), SGDClassifier (L1, L2, and elastic net regularization), MultinomialNB, BernoulliNB, and ComplementNB. In addition, we used an ensemble method, VotingClassifier, that uses a majority rule voting of the machine learning models just described\textsuperscript{20}. For model evaluation, we computed the accuracy and the average precision, recall, and F1 scores on the test dataset. In addition, we calculated a repeated stratified k-fold cross validation (5 folds and 3 repeats) with the test dataset and used accuracy as the evaluation metric. Hyperparameter tuning was not performed on the selected model.

\textit{Named Entity Recognition}

We built a custom named entity recognition (NER) model to identify and classify specific words and phrases in documents relating to CoPs. Through this model, we aimed to identify four unique entity classes: CoPs; assays used to measure CoPs; animal models used in the study, including human patients; and vaccines specified in the documents.

To construct a training and test dataset for model building, we manually identified and classified all pertinent entities within an NER dataset, a subset of the final COVID-19 + non-COVID-19 dataset, using doccano\textsuperscript{17}. An annotation guideline for entity recognition was written during the annotation process.

Two annotators (SLF and SJ) independently annotated 20 documents, resulting in an IAA of 0.74. The annotators discussed and resolved all discrepancies, with any changes added to the annotation guideline. The remaining documents in the NER dataset were split into two groups, annotated independently by one annotator each, then reviewed by the other annotator for consistency.

To build the customized NER model, we fed the annotated NER dataset into a standard NLP pipeline based upon the “en\_core\_sci\_lg” model from the Python package scispaCy and tweaked using additional tools from the Python package spaCy\textsuperscript{15, 21}. The annotated NER dataset was pre-processed using a tokenizer, parts-of-speech (POS) tagger, and parser, then piped through the customized NER. During training and testing, precision, recall, and F1 scores were used for model evaluation.

Several steps were taken to optimize the NER model. First, we added extra suffixes ([,], [0-9], [-], [.] and infixes ([ ] to the tokenizer to fix a misalignment problem with the text. We tested two different training options for the model: k-fold cross validation and an 80/20 train-test split of the NER dataset. We also varied the number of iterations used during training to find the best model fit. Additionally, we added a post-processing rule after the NER to identify any mention of “human(s)” and classify it as an “animal” entity because “human(s)” was not originally included when annotating for the NER.

For the final processing, text was fed into the NLP pipeline. The tokenizer, POS tagger, and parser pre-processed the text, then the customized NER extracted and classified entities of interest. The entity ruler identified any instances of “human(s)” and the model outputted annotated text, with the entities of interest identified and classified (Figure 1).
Interactive Visualization

In collaboration with the Analytics, Visualizations, Insights, & Data Science team within the Office of Cyber Infrastructure and Computational Biology (OCICB) at the National Institute of Allergy and Infectious Diseases (NIAID), NIH, we built an interactive Tableau dashboard to highlight the output of our models.

To populate the Tableau dashboard, we downloaded the documents and their metadata from all preprint and published papers in the iSearch COVID-19 Portfolio published between 11/1/2019 and 12/31/2020 (accessed 12/31/2020). We ran these iSearch documents through our finalized classifier and NER models. Only documents that had a predicted probability score of at least 0.5 from the classifier were considered relevant to CoPs against SARS-CoV-2 and, thus, kept for additional analysis. We used the default predicted probability score of 0.5 as our minimum threshold since this value captured all the relevant documents in a dataset consisting of only COVID-19-related literature. To allow for easy visualization, we cleaned all entities to reflect a more harmonized term using regular expressions and fuzzy string matching. For example, all instances of mouse-related entities, such as mice, humanize mouse, etc., were categorized simply as “mouse”. To accurately clean the vaccine entity data, we used categories identified in the Milken Institute Vaccine Tracker. Regular expressions were also used to extract any clinical trial IDs in the documents. Hyperlinks were generated for DOIs, PMIDs, and clinical trials IDs.

Software

All analyses were conducted using Python version 3.7.3, scikit-learn versions 0.23.2 – 0.24.1, scispaCy version 0.3.0, spaCy version 2.3.2, and Tableau Server version 2020.2.4. Training of the classifier and NER models were done on NIH and NIAID high performance clusters (HPC), Biowulf and Locus respectively.

Results

Classifier for Information Retrieval

We used the final COVID-19 + non-COVID-19 dataset to test several classifiers and determined accuracy for the various algorithms. All the tested classifiers and their performance are enumerated in Table 2. The ensemble majority voting classifier performed similarly to other models such as the SGDClassifier with L2 (accuracy of 98.51% and 98.02%, respectively). The models used for the classification task all had a median accuracy of at least 85% (Figure 2). We had several models with high accuracy and consistent performance from repeated stratified k-fold cross validation. Therefore, we decided to use the SGDClassifier with L2 regularization for all subsequent steps.

Figure 2. Accuracy of machine learning models from repeated stratified k-fold cross validation on classification task.

We assessed the SGDClassifier model on the COVID-19 dataset, with 371 non-relevant and 55 relevant documents. Note that the model was trained on all 55 relevant documents and 94 non-relevant documents from this dataset. Our model achieved an accuracy of 90.1%. The model identified all the relevant documents in the COVID-19 dataset. Of the non-relevant documents, the model incorrectly classified 42 documents as relevant (Table 3). Overall, the performance of the model on correctly identifying the relevant documents had a precision of 56.70%, recall of 100%, and F1 score of 72.37%.

NER
We trained and tested the final NER model using 165 relevant documents from the final COVID-19 + non-COVID-19 dataset; 105 of these documents were related to COVID-19, while the remaining 60 were related to other diseases.
From these documents, we manually annotated 184 assays, 278 animals, 515 vaccines, and 1290 correlates. To build the model, we split these documents so 80% were in the training dataset and 20% were reserved for testing. We trained the model over 100 iterations of the training dataset.

We evaluated NER model performance using F1 scores, precision, and recall for the overall model as well as each entity class (Tables 4 & 5). Model performance was most affected by number of publications (Table 4).

**Interactive Visualization**

A total of 98,065 preprints and publications were available on the iSearch COVID-19 Portfolio published between 11/1/2019 and 12/31/2020 at the time of download (Figure 3). The classifier identified 2,409 research articles as relevant to CoPs against SARS-CoV-2. This iSearch dataset was used to populate the dashboard.

**Figure 3.** The final project workflow in which preprint and published documents from the OPA iSearch COVID-19 Portfolio were run through the customized machine learning classifier and named entity recognition models.

Currently, the Tableau dashboard has three visualizations: a summary table, class comparison charts, and a class comparison treemap. The summary table includes the 2,409 research articles from the iSearch dataset identified as relevant by the classifier and related data. In this table, users can filter on publication date, publication type, source of publication, title, first author, last author, author affiliation, entity class, and relevance score. Each paper is marked “Yes” if it contains any of the entity classes. Hyperlinks are also provided to allow users access to the full text of each paper at its original source or in PubMed. Users can also view any clinical trials related to publications via hyperlinks to ClinicalTrials.gov (Figure 4). The class comparison charts provide a visualization of the total instances of each type of entity within each class and allows for filtering on any entity types by clicking on a specific bar, as well as all the filters available to the summary table (Figure 5). The class comparison treemap is a visualization similar to the class comparison charts, but with the treemap format and a corresponding bar chart. (screenshot not shown).
The visualized results are currently available for internal use only and, as such, are housed behind NIAID’s firewall. Public access may be available in the future.

**Discussion**

With the rapid growth of COVID-19 literature, keeping up to date on emerging research for topics such as the CoPs to SARS-CoV-2 has been challenging. In this pilot project, we implemented open-source machine learning methods to build a classifier to identify literature relevant to CoPs against SARS-CoV-2, constructed a custom NER model to extract entities, and visualized the results using a dashboard.

To address the influx of COVID-19 literature, many resources and NLP solutions have been or are being developed to organize this information and address high priority scientific questions within the medical and research...
communities. For example, the Semantic Scholar team at the Allen Institute for AI and partners have provided CORD-19, a free resource of more than 280,000 scholarly articles on SARS-CoV-2. The Semantic Scholar team have also created several NLP tools to explore the large corpus of COVID-19 literature, such as SPIKE-CORD that extracts important information and SciSight which visualizes associations between concepts appearing in the literature. The National Center for Advancing Translational Sciences at the NIH has developed the OpenData Portal, an interactive dashboard that provides SARS-CoV-2 datasets and associated manuscripts in real-time as well as user-friendly heatmap visualizations that permit direct comparison of compounds and repurposed drugs across multiple different assays. Efforts to either cluster or categorize similar articles include the Allen Institute for AI’s SPECTER and LitCovid’s assignment of broad categories (i.e. Treatment and Mechanism) to relevant articles. Additional groups have applied existing NER models trained on biomedical or clinical text while others have created their own NER models. For example, Wang et al. used the CORD-19 corpus to create a model called CORD-NER that covers 75 fine-grained entity types. However, none of these resources and tools are specific to CoPs against SARS-CoV-2, highlighting the need for additional tools and visualizations that are more domain-specific such as our own.

For both the classification and NER tasks, we initially considered only COVID-19 related publications for training a machine learning model. However, we did not accrue a large enough corpus to train and test machine learning models. The lack of relevant research articles was likely related to the status of vaccines at the time of our search in October 2020 but may also have been affected by the initial exclusion of preprints from our dataset. To address our small dataset, we extended our search for papers of CoPs back 20 years to include the first SARS-CoV outbreak in 2002 and the MERS outbreak in 2012. By including research articles of other coronaviruses, we hoped to capture CoPs that may be pertinent to SARS-CoV-2. In addition to these coronaviruses, we identified relevant research articles from different infectious diseases such as HIV, influenza, Ebola, malaria, and measles. The diversity of infectious diseases within our dataset may have provided a wider variety of CoPs compared to a SARS-CoV-2-only dataset.

Even though there are existing tools like LitSuggest to classify and retrieve relevant articles, we proceeded to train our own classifier using scikit-learn. After training several models on our COVID-19 + non-COVID-19 dataset, we tested our selected model, a L2 regularized linear model with stochastic gradient descent learning, on our COVID-19 dataset. Overall, the model had an accuracy of 90.1%. However, it is important to note that part of this dataset was used to train the model. We reviewed the documents of the 42 false positives and found most of these documents initially had differing decisions regarding relevance between the two annotators. Despite the low precision (56.7%), we were more focused on the recall (100%) since our main intent was to ensure we did not exclude any relevant papers.

Our NER model did reasonably well with an overall F1 score of 74.01%. Performance of the NER model, especially of entity classes like vaccines, may be improved by adding more documents that contain these entities. As described above, the number of manually labeled entities was heavily skewed towards CoPs. We did observe that entity classes like vaccines could pose a challenge for any NER model. The format of vaccine names may not allow for vaccine entities to be distinguishable from other entities that use a combination of hyphens and alphanumeric characters, such as “ChAdOx1 nCoV-19”, a vaccine name, compared to “SARS-CoV-2 nucleoprotein ELISpot”, an assay. With the latest version of spaCy v3.0 and the addition of transformer-based features, we may observe additional gains in the performance of the NER model.

Currently, the data feeding the interactive visualization tool is static. Addressing this limitation is important since the Tableau dashboard does not display any new findings regarding CoPs after the publication date 12/31/2020. We are working on a solution with the OCICB at NIAID to make the visualization dynamic. Part of the solution will be to download the latest research on a daily and weekly basis from either the iSearch COVID-19 Portfolio or another source such as CORD-19. Another limitation of our pipeline is that we applied the NER model to only the titles and abstracts of relevant articles. It is very likely that we missed other CoPs or other entities that would have been described further in the full text of the paper. Lastly, our pipeline does not provide context as to whether the identified CoPs were positively or negatively correlated with protection against SARS-CoV-2. This knowledge is important for determining the true protective value of CoPs, such as CD4+ T cells, since it not yet conclusive in the literature which CoPs have an effect.

Despite some of these limitations, our project allows the user to view all research related to the topic of CoPs. We provide several options to not only perform keyword searches but also filter the data to specific articles based on publication date, author name, author affiliation, publication source, publication type, entity class, and entity category.
For example, a user can filter to the companies of three vaccines currently authorized for use in the United States, Pfizer, Moderna, and Janssen, by using author affiliation. With the entity class comparison charts, a user can observe co-occurrence of entities within the literature and explore any similarities and differences among entities (ex. CoPs by vaccine type). We hope that this visualization of data extracted from biomedical literature can provide key insights and trends in CoPs against SARS-CoV-2 until there are consensus definitions for CoPs in the scientific community. The Tableau dashboard may help to fill this information gap while human CoPs data accumulate to benefit vaccine developers, regulatory agencies, and ultimately the public.

**Conclusion**

In this pilot project we developed a user-friendly visualization tool for individuals to stay up to date on the latest literature related to the CoPs against SARS-CoV-2 as well as give individuals key scientific insights from emerging research. To create this dashboard, we employed machine learning and NLP methods with open-source software. We identified research articles relevant to CoPs against SARS-CoV-2 with a machine learning classifier and extracted terms of interest within the titles and abstracts via a customized NER model. Our next steps are to make further improvements to the visualizations and add new features based on user feedback. In addition, we plan to automate the update process of the dashboard by pulling in new publications on a daily or weekly basis.

**Funding**

SLF and SJ were supported by an appointment to the National Institute of Allergy and Infectious Diseases (NIAID) Emerging Leaders in Data Science Research Participation Program. This program is administered by the Oak Ridge Institute for Science and Education through an interagency agreement between the U.S. Department of Energy (DOE) and NIAID. ORISE is managed by ORAU under DOE contract number DE-SC0014664.

Identifying Opioid Use Disorder from Longitudinal Healthcare Data using a Multi-stream Transformer

Abstract

Opioid Use Disorder (OUD) is a public health crisis costing the US billions of dollars annually in healthcare, lost workplace productivity, and crime. Analyzing longitudinal healthcare data is critical in addressing many real-world problems in healthcare. Leveraging the real-world longitudinal healthcare data, we propose a novel multi-stream transformer model called MUPOD for OUD identification. MUPOD is designed to simultaneously analyze multiple types of healthcare data streams, such as medications and diagnoses, by attending to segments within and across these data streams. Our model tested on the data from 392,492 patients with long-term back pain problems showed significantly better performance than the traditional models and recently developed deep learning models.

1 Introduction

Early identification and engagement of individuals at risk of developing an opioid use disorder (OUD) is a critical unmet need in healthcare1,2. Individuals with OUD often do not seek treatment or have internalized stigma about OUD that limits identification through traditional means, such as screening and clinical interview3. Significant disparities limit access to treatment for OUD resulting in less than 20% of all individuals with OUD receiving any form of treatment in the past year4. While there are currently tools developed to predict aberrant behavior when prescribing opioids5 or to predict OUD from a general primary care population7, there are only a few clinical tools, such as the Opioid Risk Tool5, developed for assessing the risk of OUD. Typical clinician workflow does not allow for comprehensive OUD screening, but available administrative and clinical data have the potential to help clinicians identify and screen higher risk patients providing an opportunity for primary care professionals to play a greater role in increasing OUD detection, treatment, and prevention. Healthcare data are a growing source of information that can be harnessed together with machine learning to advance our understanding of factors that increase the propensity for developing OUDs as well as those that aid in the treatment of the disorders8,9. In healthcare data, patients’ outcomes and treatments are collected at multiple follow-up times. Tools developed to analyze longitudinal healthcare data and to extract meaningful patterns from these ever growing data are critical in addressing real-world public health emergency including but not limited to OUD.

Analyzing real-world data is a complicated task with multiple computational challenges including high dimensionality, heterogeneity, temporal dependency, sparsity, and irregularity10. In particular, healthcare (and claim) data are typically collected from multiple sources, and the subsequent data analysis requires simultaneous analysis of the temporal correlation among multiple streams such as medications, diagnoses, and procedures. Deep learning models have demonstrated great potential in addressing some of these challenges and creating promising longitudinal healthcare data analysis tools. Among them, Doctor AI11, RETAIN12, and DeepCare13 modeled multiple data streams including medications, diagnoses, and procedures using Recurrent Neural Network (RNN) models such as Long-Short Term Memory models (LSTMs)14. Doctor AI concatenated multi-hot input vectors to predict subsequent visit events11. RETAIN used two separated RNNs to generate attentions at the visit level and the variable level as well12. These applications demonstrate that RNNs are promising in longitudinal and sequential healthcare data analysis, since RNNs are capable of extracting contextual information from past time steps and pass this information forward; this helps to efficiently model long-term dependencies in input streams15. Nevertheless, the network architecture and design preclude RNNs from processing long streams in a reasonable amount of time16. Attention mechanism was introduced in RNNs to increase their capacity in capturing long range dependencies more efficiently16-18. Attention-based models
bridge the gap between different states in RNNs using a context vector. Successful applications of multiple attention layers led to the transformer model\textsuperscript{19}, which removed recurrence in RNNs relying entirely on the attention mechanism.

The transformer is a type of attention-based deep learning models originally proposed for natural language processing (NLP) tasks such as machine translation\textsuperscript{19}. Later, transformers have been applied on longitudinal EHR data\textsuperscript{20} to predict patients’ outcomes in the future. There are already several models that have been successfully applied on EHR data without significantly changing the network architecture or loss\textsuperscript{21–23}. Of course, the typical transformer's structure can be altered to better fit the special needs of solving healthcare problems\textsuperscript{20, 24}. Choi et al. proposed a transformer model for healthcare data analysis by utilizing the conditional probabilities calculated from the encounter records to guide the self-attention mechanism in the transformer\textsuperscript{20}. BEHRT\textsuperscript{24} was developed based on BERT\textsuperscript{25}, a popular transformer model for NLP tasks, for analyzing EHR data. BEHRT considers the patients’ existing diagnoses and demographic data to predict their future diagnoses. Similar to RNNs, transformers have been modified to model multiple data streams. Li et al developed a two-stream transformer to analyze both time-over-channel and channel-over-time features in human activity recognition tasks\textsuperscript{26}. Two parallel, yet separate transformers were used to handle two input streams. Another multi-stream transformer has been developed to generate effective self-attentions for speech recognition\textsuperscript{27}. They parallelized multiple self-attention encoders to process different input speech frames. Gomez et al. developed a multi-channel transformer for sign language translation using one self-attention encoder\textsuperscript{28}. Their model finds the attentions across three different channels, i.e. hand shapes, mouthing, and upper body pose. A more recent work\textsuperscript{29} showed that “transformer is all you need” by using multiple transformer encoders. The encoded outputs can be concatenated using a joint decoder that enables simultaneous model training. There are also works that analyze multi-stream data using transformer by simply stacking or parallelizing multiple transformer models\textsuperscript{30, 31}.

Although the recently developed transformer models showed promising performance, especially on handling multiple data streams, the potential of applying transformers on healthcare data analysis has not yet been fully explored. One of the major limitations is the lack of capacity to model multiple data streams within the self-attention layer. The transformer was originally designed to process one data stream, which is mostly an order of words in a NLP task, at a time. The modified transformers either can only handle multiple streams at intra-stream level or they are not suitable to solve OUD identification problem as a real-time task where only previous clinical events can be used to make a decision at a specific time point. Here, OUD identification is a complex data analysis task that includes not only finding long term effects of prescription opioids such as morphine and fentanyl, history of diagnoses such as mood disorders, but also the hidden associations between patient’s prescriptions and diagnoses, since these input streams are highly correlated with each other. Identifying the relationships within and between input streams may reveal hidden patterns leading to an increased classification ability and interpretability for OUDs. Moreover, the medication application patterns and the interactions between medications across different visits as well as the patient’s diagnoses patterns throughout his/her medical history may carry important information that should be extracted in order to develop precise and sensitive OUD identification tools.

This study proposes a novel transformer model called Multi-stream Transformer for Predicting Opioid Use Disorder (MUPOD) to analyze longitudinal healthcare data collected from multiple sources and predict the onset of OUD. First of all, MUPOD is capable of analyzing multiple data streams, such as medication and diagnosis, simultaneously and

\textbf{Figure 1:} Data preprocessing and patient representation. EHR data are first converted to an enrollee-time matrix $X(P, T, F)$. Then, the data are fed to LSTM models to encode the medication and diagnosis streams separately.
extracting associations within and between the streams. Second, MUPOD utilizes attention weights within and across data streams to interpret the classification results. In our experiment, MUPOD successfully captured the complex associations within and between multiple streams including medications, diagnoses, and demographic information, and predicts the onset of OUD precisely.

2 Materials and Methods

Data Set

The large-scale administrative records in the IBM (formerly Truven Health Analytics) MarketScan Commercial Claims\textsuperscript{32} database were used to train and test both baseline models and MUPOD. Data include person-specific clinical utilization, expenditures and enrollment across inpatient, outpatient, prescription drug and carve-out services. The database contains about 30 million enrollees, a nationally representative sample of the US population with respect to sex (50% female), regional distribution, and age.

We extracted medications, diagnoses and demographic information of 682,402 patients who have at least one diagnosis of OUD (ICD-9: 304.0x, 305.5x and ICD-10: F11.xxx; where x can be any code) from 2009 to 2018. The hypergeometric\textsuperscript{33} test was used to identify sub-cohorts of OUD with high statistical significance of whether a population consists the richest information of OUD. We identified an OUD sub-cohort (p-value 0.00) with 229,214 patients who had at least one Clinical Classification Software code (CCS) of 205 (patients with Spondylosis; intervertebral disc disorders; other back problems). This sub-cohort was defined as the case cohort. Note that CCS 205 has already been shown to be a prevalent diagnosis in OUD patients in the literature\textsuperscript{34, 35}.

The case cohort (OUD positive and CCS 205) was matched with a subpopulation of OUD-negative patients called the control cohort. All the individuals in the control cohort have the same back pain diagnosis (CCS 205) but do not develop OUD. We first matched cases and controls based on age and sex. Second, we matched them based on the opioid medication use duration. Specifically, we grouped every opioid medication with a therapeutic class generic product identifier (TCGPI) of 65x as opioid medications. Buprenorphine and Methadone were excluded as they are often used as a treatment for opioid overdose. Next, we randomly sampled OUD-negative patients who have the matched age and gender with the case ensuring that the averaged opioid use ratio between case and control is almost equal.

Table 1 shows the characteristics of cases and controls regarding age, sex, top-10 most frequent medications and top-10 most frequent diagnoses. The diagnoses and the medications were classified using CCS codes and Generic Product Identifier codes (TCGPI) respectively. We grouped opioid analgesics, anticonvulsants (neuromuscular agents), musculoskeletal therapy agents, and antianxiety agents based on the first two digits of their TCGPI codes as 65x, 72x, 75x, and 57x, respectively. The rest of medications were classified using the first 6 digits of their TCGPI codes (from left to right). The variables presented in Table 1 have already been reported as OUD risk factors in the literature\textsuperscript{34, 36}. Especially, diseases including “Other connective tissue disease”, “Other nervous system disorders”, “Essential hypertension”, “Mood disorders”, “Other non-traumatic joint disorders and Anxiety disorders” have been found to be more prevalent diagnoses among OUD patients than normal people\textsuperscript{34}. Note, since we matched the case and control cohorts based on age, sex and analgesics-opioid use, these three variables have similar statistical characteristics across both case and control cohorts. However, the distributions of other variables vary across the case and control cohorts and can be utilized by our deep learning models to discriminate OUD-positive patients from OUD-negative individuals.

Data Pre-processing

For each of the enrollees in the case and control cohort, his/her medications and diagnoses between Jan 2009 and Dec 2018 and demographic records were extracted. In total, we extracted 78,136,935 medication records and 143,275,864 diagnoses records. The original format of the prescription and professional service encounter claims in IBM MarketScan data is a table where each row is a visit and columns are enrollee ID, date of visit, and prescription/diagnoses. If an enrollee has multiple visits, each visit will occupy a row in the table. To facilitate further study of the temporal patterns in the data, we converted the data into an enrollee-time matrix $X(P, T, F)$ where each $x_{i,j} \subseteq F$ is a set of medications or diagnoses (from feature space $F$) associated with enrollee $p_i \in P$ at time slot $t_j \in T$, where $P$ is the
Table 1: Distributions of age, sex, medication, and diagnoses in case and control patients. Top 10 diagnoses and medications are provided. The numbers indicate the number of patients who had at least one such diagnosis or medication.

enrollee set and $T$ is the set of monthly slots between Jan 2009 and Dec 2018. We excluded patients from $X(P, T, F)$ if the number of valid entries is less than 3.

The goal of data representation is to learn a function: $f_R : X \rightarrow \mathbb{R}^d$, where $d$ is 10 in this work and it shows the dimension of the representation to which each input stream is mapped, $X \in \{M, D\}$, and $M$ and $D$ are medication and diagnosis, respectively. To train the function $f_R$, LSTM was adopted. The outputs from all LSTM hidden states were used to represent both the OUD case and control cohorts. The general schema of the data pre-processing and representation is shown in Figure 1.

**MUPOD Architecture**

MUPOD is a transformer-based deep learning model designed to analyze $n$ highly correlated healthcare data streams simultaneously. To minimize ambiguity, the algorithm is described for a single patient and for $n = 3$. Each patient can be represented by $p = (S, y)$ in which $S$ is a set of input streams and $y$ is the target label. Herein, three input streams are considered: 1) medication tuples $(T, M)$ in which $t_i$ is the $i^{th}$ time step and $M$ is a list of medications that the patient is prescribed with at time $t_i$, 2) diagnoses tuples $(T, D)$ where $t_i$ is the $i^{th}$ time step and $D$ is a list of
diagnoses assigned to the patient $P$ at time $t_i$, 3) demographic tuples $(T, G)$ in which $t_i$ is the $i^{th}$ time step and $G$ is the demographic information of patient $P$ at $t_i$.

This study uses the encoder part of transformer to identify the associations between medication and diagnosis across time and detect the onset of OUD. Medications $M$, diagnoses $D$, and demographics $G$ are fed to the model in parallel. The first step is to incorporate the temporal patterns of the data stream into the encoder’s inputs using positional encoding. The embedding layer in the transformer is replaced by the proposed LSTM based representation layer. This change has two computational advantages. Firstly, it deals with challenges in the input data such as variable dimension and data sparseness, which is common in longitudinal healthcare data. Secondly, it extracts hidden parameters and transforms the original input into a new feature space where cases and controls are better separated than in the original feature space.

The encoded input streams are plugged into the attention layer to generate Query, Key, and Value matrices for each input stream. For example, medications $M$ are fed to a set of fully connected layers to generate $M_Q$, $M_K$, and $M_V$, representing the query, key, and value matrices for the encoded medication stream for patient $P$. Let $X, Y \in \{M, D\}$, the Query, Key, and Value matrices are used to find the attentions across these three input streams:

$$Attention(X_Q, Y_K, Y_V) = \text{softmax}(\frac{X_QY_K^TY_V}{\sqrt{d_k}})$$

Note, the $d_k$ is the same as the original transformer. Figure 2a describes how the data flows through the different layers of MUPOD. The raw medication and diagnose streams are first represented in the representation layer (the intermediate outputs of the LSTMS models in Figure 1). The temporal information is then encoded into the represented streams in the temporal encoding layer. The encoded streams are processed in the MUPOD’s multi-stream encoder layer. This novel multi-attention layer is further described in more details in Figure 2b. In the figure, $X_Q$, $X_K$, and $X_V$ represent query, key, and value matrices for stream $X$ ($X \in \{M, D\}$). All possible combinations of the streams are used to determine the attention weights between different visits and across streams. Attentions are then passed through a set of dense layers to generate outputs. For example, given two data streams $M$ and $D$, we can generate three combinations i.e. $MM$, $MD$, and $DD$. 

---

**Figure 2**: MUPOD architecture. $X_Q$, $X_K$, and $X_V$ represent query, key, and value matrices for the input stream $X$, where $X \in \{Medication, Diagnoses\}$. $\text{Att}_{XY}$ represents the attention weights between different records across input streams $X$ and $Y$, where $X, Y \in \{Medications, Diagnoses\}$. $O_{XY}$ represents the outputs, which capture the associations between the input streams $X$ and $Y$. The demographic information is plugged into the system before the last layer and in the classification layer.
The reconstruction layer receives the relevant outputs and maps them to appropriate format for the next layer as described in Equation 2. For example, only the outputs relevant to the medications \( M \) including \( O_{MM} \) and \( O_{MD} \) are used to reconstruct the medication stream appropriate to be fed into the next encoder layer:

\[
f : O_{XX}, O_{XY} \rightarrow \hat{X}
\]

\[
\hat{X} = [\text{Concat}(O_{XX}, O_{XY})]W_x + b_x
\]

where \( O_{XX}, O_{XY} \subset \{O_{MM}, O_{MD}, O_{DD}\} \), \( \hat{X} \in \{\hat{M}, \hat{D}\} \), \( X, Y \in \{M, D\} \), \( W_x \) and \( b_x \) are trainable reconstruction weight and bias matrices. The two reconstructed matrices generated by the last encoder layer are fed to classification layer to make the final decision for the current patient \( p \) as \( \text{Softmax}([\text{Concat}(\hat{M}, \hat{D})]W + b) \).

### Experimental Results

All the deep learning models in this work were deployed on the TensorFlow platform\(^9\) and were trained using eight GeForce GTX 1080 GPUs. The original transformer model, LSTM models, Linear Regression (LR), Random Forest (RF)\(^{10}\) and Support Vector Machine (SVM)\(^{11}\) were compared with MUPOD as baselines. We used 314,504 samples for training, 38,776 samples for validation and 39,212 for testing the models. All results reported in this paper are on the test set. We optimized all models using a random search policy across hyper-parameters of each model. A grid of hyper-parameters values was set up and 10 random combinations of the hyper-parameters were selected to train the models.

The optimized SVM model uses a RBF kernel function and the optimum value for the parameter \( C \) is 0.0039 in this model. The optimized linear regression model uses the L2 norm with \( C = 0.0625 \) in penalization and the sag algorithm as its solver method. The optimum number of trees in the random forest model is 1600 and the optimum value for maximum number of levels in a tree is 40. For the LSTMs, their learning rates were randomly set to \( 10^n \) where \( n \in \{-2, -3, -4\} \). The batch size was randomly selected from \( \{64, 256, 512\} \) and the number of iterations was randomly selected from \( n \times 10^3 \) where \( n \in \{10, 50, 100, 200\} \). The regularization parameter for LSTM models was randomly selected from \( 10^n \) where \( n \in \{-4, -5, -6\} \). The number of hidden neurons for the LSTMs in the representation layer was fixed to 10; because the outputs of these LSTM models were the inputs to MUPOD and the inputs to our model have to be of a fixed dimension (the dimension of our model in this paper is 20: 10 for medications and 10 for diagnoses stream). However, the number of hidden neurons for the other LSTM model used as a baseline (refer to Table 2) was randomly selected from \( 2^n \) where \( n \in \{3, 4, 5, 6, 7, 8\} \).

Table 2 compares the classification performance of MUPOD with LR, RF, SVM, LSTM and the original Transformer model. We used the same train, validation and test data to train, validate and test all models in Table 2 except for the SVM model. Due to the hardware and time limitation we had to train and test this model using 10,000 randomly selected samples. Note, the LSTM model in Table 2 is trained using medication, diagnosis and demographic data. We concatenated the vectors of medication, diagnosis and demographics in each time step and formed a single vector which was fed to this LSTM model. We dynamically unrolled the LSTM model based on the input sequences' lengths and applied a fully connected layer and an argmax function on the last output of the unrolled LSTM model to make the final decisions. The hyper-parameter search space for this LSTM was the same as explained earlier in this section. We used a randomized 5-fold cross validation to tune LR, RF and SVM models. The LR, RF and SVM were trained on the static data and the LSTMs, transformer and MUPOD were trained on the longitudinal data. To create static data for LR, RF and SVM, the longitudinal data was converted to a new format \( Y(P, L) \), where \( P \) is the complete list of patients, and \( L \) is a vector including aggregated values for all medication, diagnosis and demographic features across time steps (from Jan. 2009 to Dec. 2018). In fact, we counted the frequencies for each medications and diagnoses and concatenated these frequencies with demographic information of the patients to create \( L \). Transformer is the original encoder block of the transformer model\(^{19}\). We concatenated the vectors of medication, diagnosis and demographics and fed them to the original encoder block of the transformer model. Then, a fully connected layer and softmax function were used to perform the final classifications. In Table 2, MUPOD has the highest accuracy (0.775), precision (0.741), F1-score (0.790) and AUC (0.871). These results indicate that our proposed model captures important factors in the medication, diagnosis and demographic data and provides an increased power to detect the development of OUD, while LR, RF, SVM, LSTM and original Transformer appear to miss such factors.

In addition, we tested the models' performances on three imbalanced test data sets with the ratio of OUD-positive samples to OUD-negative samples set to 0.1, 0.2 and 0.5. OUD is an uncommon event and the ratio of OUD-positive to OUD-negative patients in patients who have used Opioid prescriptions at least 3 times is 3.2% in the data set. Therefore, we conducted the experiments in Table 3 to simulate the performance of the models on imbalanced datasets as well. Table 3 shows the model performances on imbalanced test sets. Table 3 shows that MUPOD maintains higher performance on all imbalanced test sets compared to all baselines in terms of precision, F1-score and AUC. Note, we did not show accuracy in Table 3, because this measure is not informative when assessing algorithms on imbalanced data.

We examined the relationships between the medication and diagnosis streams by aggregating the attention weights in the first layer of the model for all the records of each individual and visualized the results. While it is still unclear whether attentions can be used to explain deep learning models\[^{33,44}\] attention weights have been used extensively to assess feature importance\[^{24,42}\]. In particular, the aggregated attentions across all the records of the same patient may be useful to identify important relationships between his/her prescriptions and diagnoses. In the visualization, a rectangular node represents a medication type and an oval node represents a diagnosis code. We divided the accumulated attention weights to “moderate” and “strong” based on pre-defined thresholds (i.e. moderate: \( 0.3 \sim 0.6 \), and strong: \( \geq 0.6 \)) that were selected by visually inspecting the distribution of accumulated attention weights. The moderate and strong connections are represented using dashed and solid lines respectively. The lines of an OUD-negative patient are colored black, while the lines of an OUD-positive patient are colored red.

Figure 3b shows the attention weights computed with MUPOD on one OUD-positive and one OUD-negative patient. The cosine similarities of the medication and diagnosis streams of the two patients are 0.85 and 0.27, respectively, indicating that they have different diagnoses but similar medication records. The connections belonging to the positive and negative patients are well separated. Besides, almost all the strong connections are from the OUD-positive patient, while all the moderate connections are from the OUD-negative patient. Similarly, Figure 3c shows the attention weights on one OUD-positive and one OUD-negative patient. The cosine similarities of the medication and diagnosis streams of the two patients are 0.71 and 0.93, respectively, indicating that they have very similar diagnoses and medication records. Although they have similar records and similar connections between medication and diagnoses nodes, the strengths of attention are different for the OUD-positive patient versus the OUD-negative patient and MUPOD was able to correctly classify these two samples. Note that ONTJD and Opioid are collected with both the OUD-positive
(a) Medication and diagnoses abbreviations and full names.

**Figure 3:** Attention weights. Rectangular nodes represent medications and oval nodes represent diagnoses. Solid, dashed and dotted edges respectively mean strong, moderate and weak connections. We used abbreviations for medications and diagnoses, and provided the full names in (a).

(b) A pair of OUD-positive and OUD-negative samples that have different diagnoses but similar medication records.

(c) A pair of OUD-positive and OUD-negative samples that have very similar diagnoses and medication records.

link (red) and the OUD-negative link (black), indicating the ONTJD-Opioid is often observed on both cases. Figure 3 shows that the attention weights in MUPOD can be used to: 1) discriminate OUD-positive from OUD-negative patients and 2) reveal the relationships between medications that the patient has been prescribed with and the diagnoses he/she has been diagnosed with. These attention weights can further be accumulated across all patients in the cohort to create more generalized conclusions and OUD risk factor identification.

**Conclusion**

OUD is a public health crisis costing the US billions of dollars annually in healthcare, lost workplace productivity, and crime. In this study, we developed a multi-stream transformer model to analyze the long-term impact of medication application pattern, diagnosis history and demographic information, and to explore the associations within and between these streams of patients' data. Our proposed model was able to predict the onset of OUD more effectively compared to baseline models including RF, SVM, LSTM and original transformer model. We discovered that the associations between medication and diagnosis streams are key factors that improve power to predict the development of subsequent OUD.

There are some limitations in our approach. First, the current model relies on patient demographic information and limited subset of medications and diagnoses as features. Incorporating more detailed diagnostic and medication information such as daily dose of opioid could refine the relationship between medications and diagnoses, and create more accurate OUD identification tools. Furthermore, this work only considered a cohort of 196,246 OUD patients who has been diagnosed with the OUD ICD9 or ICD10 codes at least once, ignoring all the undiagnosed OUD patients. For example, more than 224K patients in Truven have been prescribed with Buprenorphine or Methadone but without having any OUD diagnoses. These patients may be undiagnosed OUD patients and could be included in our future work. Second, the current approach cannot predict/estimate risks because the medication application patterns and the diagnosis history of patients that may lead to the increment of OUD risk has not been studied. Third, the explainability of MUPOD was explored using a few representative samples. However, more analysis and correlation analysis using more sophisticated methods such as heatmaps are needed in the future to interpret the model more efficiently. In the future, we will extend our model to address the aforementioned problems such as incorporating more medication and diagnosis features as well as the Morphine Milligram Equivalent (MME) information in MUPOD. The rationale is, given a patient who is constantly on the same type of medication for a while, the variation of the dosage may indicate whether the medication is still effective for the patient.

Despite the limitations of the model, the current approach adds detail to our understanding of the factors that may be important to the development of OUD. Our hope is that a more thorough understanding of the relationships between medications and diagnosis will eventually enable clinicians to identify individuals at risk for OUD at an earlier stage,
and ideally, perhaps even prevent OUD.

Abstract

Findings from randomized controlled trials (RCTs) of behaviour change interventions encode much of our knowledge on intervention efficacy under defined conditions. Predicting outcomes of novel interventions in novel conditions can be challenging, as can predicting differences in outcomes between different interventions or different conditions. To predict outcomes from RCTs, we propose a generic framework of combining the information from two sources - i) the instances (comprised of surrounding text and their numeric values) of relevant attributes, namely the intervention, setting and population characteristics of a study, and ii) abstract representation of the categories of these attributes themselves. We demonstrate that this way of encoding both the information about an attribute and its value when used as an embedding layer within a standard deep sequence modeling setup improves the outcome prediction effectiveness.

1 Introduction

Randomized controlled trials (RCTs) act as a key source of information about intervention outcomes. An RCT in behavioural science usually captures information on the demographic characteristics of each cohort group in the study, the interventions at a broad level defining a general configuration of each cohort, and a configuration for measuring the outcome values, i.e., some measure of the success for each cohort. A predictive model learned from a set of existing literature could potentially find applications in predicting what is likely to happen for new combinations of cohort groups characteristics, interventions, and outcome measurement settings, which could then provide useful insights to facilitate the process of systematic review. In addition to help compiling systematic reviews, a predictive model may potentially be useful for policy makers to help prescribe a set of behavioural policies that are likely to be helpful to trigger a behaviour change for societal benefits of a target group of people with a given set of characteristics.

Our Contributions. The objective of the paper is to investigate how effectively can the outcome of a behaviour change RCT be modeled in terms of its characteristics comprising mainly the population settings (the whom), interventions (the what) and outcome measurement criteria (the how). We emphasize that the novelty of the paper is not to develop a new neural end-end architecture for the RCT outcome prediction task, for which we employ an end-to-end neural architecture comprising of bidirectional LSTMs, a model that has been met with considerable success in sequence problems such as those of Natural Language Processing.

The novelty of our work rather lies in enriching the embedded input vectors of an end-to-end neural model with additional useful information, the source of which, in our problem, is the ontology of behaviour change attributes, which in addition to the text features proves effective in improving the downstream task of modeling the outcome of an RCT. In particular, our predictive model relies on a novel approach of leveraging information from two sources, namely the annotated text and a document-level co-occurrence relationship between the entities in a behavioural science ontology.

2 Related Work

The work related to text mining for RCTs spans domains from Natural Language Processing to medical informatics. Much of this literature begins with information extraction, which can then be used for summarization, automating (parts of) systematic reviews, or prediction. Early work on extraction from RCTs looked at elements from PICO, and initially classified sentences according to that framework. Instead, a corpus was annotated with PICO entities to

*The study actually uses PIBOSO, which is an extension of PICO.*
The study similarly extract entities but use a much larger inventory of entities taken from the Behaviour Change Intervention Ontology. This and other work has been undertaken to help in automating systematic reviews of RCTs1, 2, 8, 15, which rely on accurate information extraction.

Not much research has yet been carried out on predictive tasks on RCTs. Related to our use case of behaviour change and smoking cessation, the articles16, 17 showed the feasibility of regression approaches to predict the percentage of quitters but this work does not extend to the number of papers and entities that we cover. Probably the closest work to ours is from18. Like our second task of pairwise classification, they look to infer the findings of an RCT based on its intervention, comparator, and outcome entities.

Among existing work that combines text and graph embeddings, joint embeddings of text and relations was employed for link prediction in a knowledge base19. More similar to our embeddings, the authors of20 learn embeddings over a co-occurrence graph of entities and compare them to word embeddings, but they do not explore how those can be combined. A graph-based framework was proposed in21 to incorporate non-local co-occurrences in modeling the semantics between words. While their objective was to improve the effectiveness of word embedding with the help of additional relationships between terms, the objective of our work is to model the relationships between the features in our data with the help of an ontology.

A popular approach towards predictive tasks, such as relation prediction on entities is to use graph convolutional networks22. However, a graph convolution network is suitable for scenarios when an individual instance is modeled as a graph23. In our case, the relations are defined at the level of features and not at the level of each RCT instance. Hence, we leverage the relational information between the features only during the pre-training phase24, so as to generate an enriched set of input vectors to help improve an end-end neural model.

3 Problem Formulation

Ontology Overview. For this study we use the Behaviour Change Intervention Ontology (BCIO) comprised of hundreds of entities at multiple levels of classification25. Lower-level entities, being more granular, define the features used in our study. Different from25, this paper is not concerned with automated extraction of the values of these entities from the papers, but rather assuming that such values have been extracted, to predict the outcome behaviour values and estimated effects given these values.

An RCT as a set of entity-value pairs. A randomized control trial (RCT) study on behaviour science in our dataset usually contains multiple study arms. Each study arm forms an instance for classification and is associated with an outcome value. We represent each document \( d \in \mathcal{D} \) as a set of entity-value pairs. More specifically, an input document \( d \) is a set of 2-tuples of the form \((a, x_a)\), where \( a \) is one of the entities from the BCIO and \( x_a \) is the value associated with the entity, i.e., \( d = \{(a, x_a) : a \in A, x_a \neq \emptyset\} \). The cardinality of the set \( d \) is the number of different entities for which there exists an annotated value. In addition to the semantic type of an entity, each attribute is also associated with a value-type which is also a part of the ontology, and is one of categorical, numerical, or text.

The value of an entity \( a \) (i.e., \( x_a \)), corresponding to an RCT arm, is annotated by a human expert by highlighting the span of text. In our predictive approach, we consider the string (text span) corresponding to each entity value, generally speaking, as a multi-set (bag) of words. The values of each entity are encoded differently depending on the detected type of their annotated span (text, numeric or categorical). For example, each word of a text value is converted to its embedded representation, whereas a numerical token or a categorical value is appended as an additional dimension to a dense vector input (we will revisit this later in the section on outcome value prediction).

Discretizing RCT outcomes. We assume that in each arm, the relationship between the outcome value and the set of features is given by a function of the form \( y(d) = \phi(d) \), where \( y(d) \in [0, 100] \) denotes the percentage outcome value. For the sake of readability, from here we refer to a study arm of an RCT as a document (denoted by \( d \)) in a collection of such arms (denoted as \( \mathcal{D} \)).

https://github.com/HumanBehaviourChangeProject/ontologies
https://www.ebi.ac.uk/ols/ontologies/bcio
The two types of prediction tasks we address correspond to those of a) predicting a discrete interval or range of outcome values, and b) predicting the relative comparison between two studies. Both these tasks require transforming the real valued $y(d)$’s into discrete ones. First, we split the range of $y(d)$, i.e., $[0, 100]$ into a number of intervals. We set this number to 7 to achieve a reasonable degree of discriminability.

We use discrete ranges for the outcome value prediction to simplify the interpretation of the results, e.g., low, moderately low etc. In practice, prediction of a continuous outcome value should be accompanied by a confidence interval, which can be difficult to interpret or even unreliable. Instead of attempting to predict a single exact value, we fix the intervals and try to figure out a relative notion of the likelihood of a low or a high outcome. In our experiments, we also report linear regression results in our experiments, i.e. where the outcome value is directly predicted as a continuous variable.

The start and end-points for each interval constituting a partition of $[0, 100]$, is determined from the distribution of the outcome values in the training set (i.e. the values corresponding to input instances that are known to a model), i.e.,

$$
\mathcal{R}(y(d)) = [0, 100] = \bigcup_{i=1}^{k} [a_i, b_i], \text{ s.t. } a_1 = 0, \quad b_k = 100, \quad a_{i+1} = b_i, \quad Pr[X < a_i] \leq \frac{100i}{k}.
$$

Setting $k=7$ in Equation (1) partitions the range of $y(d)$’s into 7 intervals, where the start of the $i^{th}$ interval is specified by $i^{th}$ 100/7 $\approx$ 14 percentile computed over the distribution of the $y(d)$ values (the percentile points indicating the cut-off points in the cumulative distribution function in Equation (1)). Partitioning the range of the outcome values this way seeks to achieve a uniform binning of the values and mitigate effects of any class priors for the classification task. Each $y(d) \in \mathbb{R}$ is converted to a class label $z(d) \in \mathbb{Z}$ pointing to the index of the interval in which $y(d)$ falls, the intervals being defined as per Equation (1).

**Use-case for Point-wise and Pair-wise Models.** We now describe how the point-wise and the pair-wise models, trained on the input-output associations of existing RCT studies, could potentially be used in practice by an RCT practitioner. In both the point-wise and the pair-wise case, an RCT practitioner would want to know what is likely to happen for a new combination of whom, what, and how features. These features may be entered into a prediction system in the form of attribute value pairs. In the point-wise case, the user would want to obtain a predicted outcome value percentage range on the target population and interventions specified under certain settings independent of a reference point. Instead of intending to obtain a predicted range, for the pair-wise case, an RCT practitioner would want to know if the new combination of input (test) features is likely to increase the success percentage in comparison to a reference study that already exists in the literature.

### 4 Outcome Value Prediction

#### 4.1 Model Overview

Figure [1] shows a standard deep sequence classification model, comprised of stacked layers of LSTMs the hidden states of which lead to a softmax layer of 7 classes into which the outcome value is classified as per Equation (1). This so-called bi-LSTM is a standard neural network architecture that has been met with success in domains that feature an input sequence such as time series or sentences in Natural Language Processing. The novelty lies in defining the scope of the input to this predictive model. More concretely, the input is a set of attribute-value pairs of the form $(a, x_a) \in d$ as annotated in document $d$. The raw input is transformed into a dense vector comprising a pretrained global information about the attribute itself and its text value. Additionally, if the value-type of an attribute is numerical or categorical, its value (a real number or an integer representing the category value) is appended as an additional dimension to the concatenated vector representation comprised of a) the attribute relation and b) the text information. Formally, we denote the transformation from a set of attribute-value pairs to that of dense vectors as

$$
\psi : a, x_a \mapsto \mathbb{R}^{k_f} \times \mathbb{R}^{k_t} \times \mathbb{R},
$$

where each vector corresponds to two distinct subspaces of sizes $k_f$ and $k_t$ (and an additional one for the numerical value). The first subspace (of dimension $k_f$) corresponds to the relations between the entities, whereas the second one (of dimension $k_t$) corresponds to word semantics. The attribute-value set for each arm of a document, $d$, is transformed
Examples of Input Transformation. To illustrate how the attribute-value pairs annotated in a RCT are transformed into inputs to the network of Figure 1, let us look at the following example annotations from a sample paper on smoking cessation studies from our dataset (the example annotations are also shown as the text highlighted in a document at the bottom-left of Figure 1).

Example 1: For an annotated value (text-span) of ‘(% female) 63.3%’ for the ‘gender’ attribute, after tokenizing the string into ‘female’ and ‘63.3’, we obtain the pretrained vector representation of the word ‘female’. We concatenate the word vector ‘female’ with the node vector representation of the attribute ‘gender’, and append the number ‘63.3’ as an additional dimension.

Example 2: For the sample I attribute with value ‘encouraged to set a new quit date’, either the average is computed over vectors (specifically, pre-trained skipgram on PubMed) for the constituent words ‘encouraged’, ‘to’ etc., or the context vector (specifically with Bio-BERT) is obtained for the entire piece of text. This context vector is then used substituted into the $k_t$ dimensional subspace of Equation 2. The other part (the $k_f$ dimensional subspace) is substituted with the node vector for the attribute ‘goal setting’. The additional dimension for the numerical value in this example is 0 (since no number exists in the annotated text instance).

4.2 Textual Context Vector Representations

In this study we investigate two different ways of obtaining the vector representation of the textual context around an instance of an attribute occurrence. These two methods correspond to exploring different granularity for embedding text, one at the level of words and other at the level of sequences of words. Both these approaches are trained on large volumes of unannotated text. While word2vec learns a set of linear transformation parameters for each word to predict its context, BERT captures term semantics with the help of a transformer architecture trained by arbitrarily masking words from text segments.

In our work, we specifically use pretrained word2vec (skipgram) vectors trained on PubMed abstracts. These pre-trained vectors are of 200 dimensions, i.e., $k_t = 200$ in Equation 2. We used zero vectors used for out-of-vocabulary words (8.9% of our dataset). As the context vector, we used the pre-trained Bio-BERT model. The vocabulary of the Bio-BERT is initialized from the larger BERT model of and then fine-tuned on PubMed abstracts. The dimensionality of the feature vectors for the Bio-BERT model is 768, i.e., $k_f = 768$ in Equation 2.

https://bio.nlplab.org/
Embedding of context text is potentially useful to semantically associate/dissociate instances of different/same feature types (e.g., to discover that while two different interventions can be semantically related, the values for the two instances of the same intervention attribute may in fact be semantically different from one another). Next, we describe how we obtain the vector representations of the entities.

4.3 Learning Node Representations

Motivation. One of the limitations of modeling the outcome value as a (predicted) function value of the set of input feature values (comprising numerical, categorical and text features) is that the predictions are likely to be less effective for a sparse feature space. In the context of our problem, sparsity of the feature values is caused due to a wide range of different population characteristics, or interventions used in the studies, e.g., some studies report the average age of a cohort, while others use median age. Moreover, a predictive model assumes that the features are independent. However, in the context of our domain of behavioural science reports, correlations do exist between the entities. For example, if some interventions are likely to work well on a cohort of young people (with lower values for minimum age), they are also likely to work well on cohorts with lower mean age. As another example, sets of interventions are also correlated with each other, e.g., intuitively speaking, ‘psychological counseling’ often works well with ‘continuous monitoring’.

Embedding nodes as vectors has been reported to improve downstream prediction tasks for the biomedical domain, such as modeling interactions between genes, diseases and drugs. In our case, via embedding nodes as vectors we intend to model the correlations between features of different types. For the purpose of graph construction we group the BCIO entities into broader types for who (P) what (I) and how (Q).

Graph Construction. The first step in our proposed approach is to construct an undirected graph \( G = (V, E) \) intending to capture the co-occurrences between different feature instances. Each node in this graph is represented by a tuple \( v(t, a, x_a) \), \( a \) being an attribute of type \( t \in \{P, I, Q\} \). Formally,

\[
V = \{(t, a, x_a) : \exists (a, x_a) \in \mathbf{x}_d, \ d \in \mathcal{D} \},
\]

where \( t \in \{P, I, Q\} \) and the node set, \( V \), is thus comprised of nodes of unique types with unique values. While constructing a node corresponding to an attribute, only its categorical or numerical value is included as a part of the node. We exclude the string (text span) of the annotation for an attribute because including it would make the graph too fine-grained (e.g., one node for each possible value of an intervention ‘goal setting’). This would lead to sparse edge relations between its nodes, which in turn would not be conducive for modeling the inter-attribute relations. Note that the text information is eventually used in the downstream prediction task because it constitutes a separate subspace of the input vectors (Equation 2). Next, we define the edges in \( G \) as follows. Formally, an edge exists between a pair of nodes corresponding to the values of entities of type \( t \) and of type \( t' \) (\( t, t' \in \{P, I, Q\} \) \( t \neq t' \)), if these values are observed in the same RCT arm (document). To model the likelihood of a correlation between pairs of attribute-values, we set the weight of an edge \( e \), \( w(e) \), to reflect the relative number of times such associations between the feature values are observed across a number of different documents in the collection.

Node Embedding. After constructing the graph \( G = (V, E) \) from a given collection of documents \( \mathcal{D} \), the next step in our proposed method is to obtain a dense vector representation for each node of \( G \). Specifically, we applied the random walk based node2vec algorithm to learn the vector representation of each node. The choice of visiting a next node in node2vec is controlled by two parameters, namely a) the (inverse) return parameter, \( p \), which if set to a low value makes it more likely for the walk to return to \( t \), and b) the in-out parameter, \( q \), which if set to a high value makes the walk unlikely to visit nodes that are not adjacent to \( t \). A low value of \( p \) and a high value of \( q \) is thus likely to make the walk more compact. Specifically, for our experiments, we tie the two parameters by setting \( q = 1 - p \).

In our case, after applying node2vec on the weighted graph of Equation 3, attribute-value combinations that are likely to be correlated to each other will be embedded close to each other, because these nodes are likely to be more reachable from each other with a random walk using the edge weights as probabilities.
5 Modeling RCT Comparisons

We now extend the point-wise prediction framework to learn a comparison function between a pair of RCTs. A practical use-case for this pairwise situation arises when an RCT practitioner wants to compare a new combination of population, intervention and outcome settings with reference to an existing study, which we call the reference study involving a target population. The intention of the predictive model in this case is predict if a new combination of interventions is likely to increase the success ratio in comparison to another study, which is different from predicting if the relative comparisons between two arms of the same study yield significant differences.

For pairwise modeling of RCTs, the input is a pair of RCTs. The attribute-value pairs of each RCT is transformed to a variable length sequence of embedded representations of concatenated node and word vectors identical to the input transformation of Equation 2 (Figure 1). The pairwise prediction model employs a Siamese type architecture, where we feed in a pair of RCTs as input. The training phase makes use of the annotated attribute-value pairs of existing RCTs reported in the literature. The encoded representation of the LSTM layer for both studies is then concatenated before applying a sigmoid layer. During training, the ground-truth label between a pair of RCTs is 1 if the outcome value of the first element of the pair is less than that of the second, or 0 otherwise. The network is trained with all combinations of pairs of the form $(d_1, d_2)$ from the training set. A pair $(d_1, d_2)$ is used in the training set in a unique ordering, i.e., inclusion of $(d_1, d_2)$ excludes $(d_2, d_1)$, which means that the total number of pairs used for training is $|D|(|D| - 1)/2$. In the testing set, one of the elements of each pair is a new combination of PIQ features, unseen in the training set, whereas the other is from the training set (i.e., a previously seen reference study).

6 Evaluation

Dataset. For our experiments, we focused on the domain of the smoking cessation behaviour change RCTs reports the compilation of such a dataset (called HBCP) of behaviour change RCTs focused on smoking cessation; however, their dataset is mainly targeted towards addressing information extraction from RCTs. Since we focus on a different task, that of predicting outcomes of RCTs, we construct an extended version of the HBCP dataset for our experiments. Different for our classification task the RCT instances are constructed as described in Equation 2. Each study includes a number of study arms corresponding to a fundamental unit of a study, i.e., a particular population group with certain characteristics and a set of interventions applied on the group. Outcome values are reported separately for each arm and a single RCT can have multiple arms.

Our extended dataset comprises a set of 513 RCTs (PDF documents) on behaviour change for smoking cessation. The annotation schema of our dataset follows the ontology and the guidelines defined in . A team of in-house domain experts annotated a total of 7451 attributes of different types from the set of 513 PDF documents. Table 1 presents an overview of our dataset.

**Figure 2:** Parameter sensitivity effects of Text+N2V (Bio-BERT) for point-wise outcome value classification for different context sizes. It can be observed augmenting pre-trained feature relationship information as a part of the input produces substantially better results in comparison to the Text-Only and the Text+N2V-1Hot approaches (shown as the two constant lines).

**Figure 3:** Parameter sensitivity measured in terms of RMSE (lower the better) of Text+N2V (with Bio-BERT) for point-wise outcome value regression for different context sizes. A comparison with Figure 2 shows that regression results are more sensitive to parameter variation effects.

**Setup.** To assess the effectiveness of the graph-based approach for the point-wise and the pairwise prediction tasks, we compare our proposed approach of joint embedded input representation (text and attribute-value nodes) with two ablation baselines\(^*\). As the first ablation baseline, we employ a standard one-hot encoding of each attribute node coupled only with its numeric value (i.e., \(k_f\) being number of unique attributes, \(k_t = 0\) in Equation 2), which is equivalent to standard linear regression and multi-class classification (for the continuous or the interval prediction). Note that this baseline neither uses information from the text around the context of the attribute instances, nor does it use an embedded representation of the attributes themselves. We name this baseline ‘Values-only’.

The second ablation baseline, Text-Only, does not use any information from the attribute-value pair co-occurrences, i.e., we feed in as input vectors to the network of Figure 1 (and its pairwise equivalent) an aggregation (average) of word vectors, each of dimension \(k_t\) (see Equation 2), from the annotated text spans. For a numeric value, e.g., mean age of a population, we feed in its value as an additional dimension in the input vector along with the word vector representation of its context. We used two different ways of obtaining the feature vectors for the text, namely a) Skipgram, where we used pre-trained skipgram vectors of dimension 200 (i.e. for this baseline \(k_t = 200\)), and b) Bio-BERT, where we used the pre-trained Bio-BERT model\(^*\) to obtain \(k_t = 768\) dimensional representation of the context text.

The third ablation baseline, Text+N2V-1Hot, employs a one-hot encoding of the attribute-values nodes (Equation 3). This baseline treats each graph node as independent ignoring the co-occurrence relations between the edges. The two different text embedding approaches lead to two different settings for the one-hot experiments with different feature dimensions (for the text part).

To test the approaches, we employ 5-fold cross-validation. The intervals to induce the class labels are computed on each training fold instance (Equation 1). For pairwise classification, training proceeds with pairs from the training fold. The test instances are constructed by pairing up each RCT from the test fold with each from the train fold, the objective being to predict if a new study, for which the outcome is not known, is likely to yield a higher or a lower outcome compared with an existing one.

---

\(^*\) Implementation of the point-wise and pairwise models, along with the dataset would be made publicly available. [https://huggingface.co/emilyalsentzer/Bio_ClinicalBERT](https://huggingface.co/emilyalsentzer/Bio_ClinicalBERT)
Table 2 summarizes the best results obtained with each method for the point-wise and the pairwise tasks. We observe that a value-only based approach (similar to a simple linear regression or a multi-class classification) produces not too effective results. We observe from the bottom part of Table 2 (‘Text+N2V’) that leveraging information from the co-occurrence likelihoods between the behaviour science attributes in the form of embedded node representations improves significantly (t-test with 95% confidence) the effectiveness of both the point-wise and the pairwise tasks in comparison to the corresponding text-only approaches (e.g. compare the ‘Skipgram Text-Only’ results with ‘Skipgram Text+N2V’ ones). Moreover, the results also improve in comparison to the approach when the node attribute features are treated as independent one-hot vectors (e.g. compare ‘Bio-BERT Text+N2V’ results with ‘Bio-BERT Text+N2V-1Hot’ ones). The pairwise case yields slightly better results when skipgram vectors are combined with the node embeddings.

Parameter Sensitivity. In addition to presenting the best results for each method in Table 2, we now investigate the effects of varying the parameters of node2vec for obtaining the embedded vectors that are concatenated as inputs to the architecture of Figure 1, i.e., parameters - the context size (ws), dimension of embedding (kf), and the return/in-out node2vec parameters (p, q). We explore the parameter space only for the most effective combination method of Table 2 i.e. the ‘Text+N2V’ with the Bio-BERT embedding.

Figures 4 and 5 report parameter sensitivity for the multi-class classification and regression tasks, respectively. From Figure 4, we observe that smaller values of p (and thereby larger values of q = 1 − p) usually result in better outcome value prediction. As per Equation 4, small values of p (and large values of q) are likely to yield locally compact walks. In the context of our problem, this means too much exploration on the co-occurrence graph may introduce noise in the form of false long-chain dependencies across entity values of different types.

For the pairwise case, we explore the parameter space for the combination of node vectors with skipgram vectors (since this configuration produced better results than the Bio-BERT ones). Figure 4 shows trends that are similar in nature to that of Figure 2 i.e., the optimal results are obtained for smaller values of p.

### 6.1 Prediction with Uncertainties

In this section, we investigate the feasibility of a more pragmatic approach where only a small subset of the documents in a collection is annotated with the attribute-value information. This scenario also tests how effectively can a prediction system, trained on a subset of the collection (called the seed set), may subsequently be used to make predictions for newly created research articles on behaviour change (i.e., those for which no manual annotations are available).

For each unannotated documents, we employed the unsupervised information extraction method to automatically extract a set of attribute-value pairs, given its text as an input to the extractor. The prediction system is then trained on a mixture of both manually annotated (hence, clean) and automatically extracted (hence, uncertain) data.

To conduct experiments for predictions with uncertainties, from our static collection of annotated documents, we first use only a fraction of the data as the seed set (signal), and then employ the extractor to automatically infer the attribute values from the remaining set (noise). Figure 5 shows how does the effectiveness of our prediction model (Text + N2V) is affected by the use of automatically extracted values (the RMSE values are averaged over 5-fold CV test splits). The red line plots the RMSE values obtained only with the seed data, whereas the blue line, for each fraction of the seed
data, displays the results obtained by augmenting the seed data with extracted information from the remaining fraction of the data.

It is seen that too small or too large a seed set (i.e. \( \leq 10\% \) or \( \geq 60\% \)), the use of additional uncertain data, in the form of automatically extracted attribute values, is not able to outperform the results obtained with clean data only. However, it is seen that using about 20\% of clean data, coupled with 80\% additional (potentially noisy) data improves the overall outcome value prediction effectiveness. This implies that knowledge gained from new RCTs in the form of extracted attribute-value pairs can potentially be injected into our prediction system for improving its effectiveness.

7 Conclusions

We investigated how effectively can we automatically predict outcomes from RCTs on behaviour change studies. The novelty lies in encoding an RCT instance as a combined representation of the embedded textual context of annotated values coupled with the embedded representation of the relations between attribute-value instances. Our experiments demonstrate that this way of modeling the inputs outperforms the cases which make an oversimplifying assumption that such attribute-value instances are independent. A broader impact of our work is that it shows that the outcome value of a behaviour change study can be predicted within satisfactory levels of accuracy, which implies that AI systems can potentially be used by policy-makers in implementing a set of behaviour change policies (interventions) on a target population.

In future, we would like to investigate outcome prediction for RCTs with automatically extracted attribute values from documents.

Abstract

In this paper, we examined informatics challenges and opportunities related to emergency department visit data during public health emergencies. We investigated the impact of COVID-19 pandemic on the volume and acuity of adult patients visiting the emergency department (ED) of a medical center in Arizona during the pandemic compared to the pre-pandemic period. We performed a negative binomial regression analysis to understand how different public health-related mandates and statewide business opening/closing orders in Arizona affected the daily emergency department visits. The results of this study show that the average daily ED visits decreased by 20% during the COVID-19 pandemic in comparison with the same period in 2019. In addition, the business closure order had the most impact on emergency department visits in comparison to other public health mandates.

Introduction

As the COVID-19 pandemic developed and intensified throughout the United States in the early part of 2020, state governments and healthcare systems enacted a range of mitigation strategies and operational changes to address the increasing number of infections in the community. Initial public health strategies recommended avoiding unnecessary healthcare utilization to decrease virus spread and to ensure that there is enough capacity to handle spikes in COVID-19 cases [1]. In addition, different public health-related mandates, including the stay-at-home order, business closures, and mandatory wearing masks were implemented to prevent and mitigate the spread of the virus [2]. While the number of patients who visited Emergency Departments (EDs) due to COVID-19 significantly increased, health systems noticed a change in ED visits for acute care unrelated to COVID-19 [3]. Accordingly, the pattern of ED visits changed with the spread of COVID-19 in 2020. In this regard, collecting, sharing, and analyzing ED volume data are necessary for improved coordination of care and distribution of resources during high utilization times. An example of using available ED resources equitably was the Boston Marathon Bombing, where trauma patients were appropriately distributed such that trauma centers in the Boston metropolitan area were not overloaded. By recognizing spikes in patient arrivals during either mass casualty events or public health outbreaks, each hospital could call in backup providers, offload the least sick of the inpatients, and be better prepared for a potential surge of sick patients in a more timely and appropriate manner. Conversely, recognizing drastic decreases in volume ahead of time in a metropolitan area could serve as a warning or alert that something large is happening such as a new wave of pandemic or fear of becoming sick from the healthcare system. However, there are several issues relating to the ED volume data elements that have not been examined in the literature. In addition, to the best of our knowledge, the change in the pattern of ED volume and acuity, as well as the impact of public health-related mandates and state-wide business opening/closing on ED visits due to the COVID-19 pandemic, are yet to be studied in detail while considering regional factors. Therefore, in this study, we seek to answer the following questions.

1) What are the challenges of collecting, coordinating, and sharing ED volume data elements and recommendations to address those challenges?

2) How did the COVID-19 pandemic affect ED visits and acuity (in terms of Emergency Severity Index (ESI) level at triage, admissions, and specific ED activations) in a single regional hospital compared to the pre-pandemic period?

3) How did different periods of the COVID-19 pandemic in Arizona, as defined by different public health-related mandates and statewide business openings/closings, affect daily ED visits in a single regional hospital?

* Equal contribution
Background

The United States declared a national emergency on March 13, 2020, in response to the COVID-19 pandemic. Afterwards, states imposed stay-at-home orders to prevent the spread of COVID-19 and relieve the burden on the healthcare system, which influenced the number and type of ED visits. Several prior studies have examined the impact of the pandemic on ED visits. We provide a review of results from these studies, along with data limitations, and other informatics challenges.

Hartnett et al. [4] investigated the effect of the COVID-19 pandemic on ED visits in the United States from January 1, 2019 to May 30, 2020. They found that ED visits in the United States declined 42% during the pandemic. They also demonstrated that ED visits associated with the patients aged less than 14 years, females, and Northeast region had the sharpest decline after the pandemic. Additionally, they showed that the proportions of infectious disease-related ED visits during the early pandemic period in 2020 were four times higher than those in the same period before the pandemic in 2019. Adjemian et al. [5] presented an update on Hartnett et al.’s [4] report; they compared the effect of the pandemic on ED visits in the United States during December 20, 2020–January 16, 2021 with those during a pre-pandemic period (December 15, 2019–January 11, 2020). According to Adjemian et al.’s [5] report, ED visits were 25% lower in December 2020-January 2021 than in the same months the previous year. In addition, Adjemian et al. [5] showed that, during the pandemic period, higher proportions of ED patients, particularly pediatric patients, are seeking treatment for mental and behavioral health issues.

Although these previous studies on the effect of COVID-19 on ED volume in the United States (i.e., [4] and [5]) show a decline in ED volume during the pandemic, there are life-threatening conditions that always require immediate emergency care, even during the pandemic. In this regard, Lange et al. [6] conducted a study of ED visits for three life-threatening acute health conditions, including myocardial infarction, stroke, hyperglycemic crisis, in the United States immediately before and after the declaration of the COVID-19 pandemic as a national emergency. They reported that ED visits for each of these health conditions declined after the declaration of the COVID-19 pandemic as a national emergency. The US ED volume data included in [4-6] were from National Syndromic Surveillance Program (NSSP) that collaborates with programs across CDC, state, and local health departments to collect electronic health data in real-time. So the findings in these studies are subject to several data-related limitations that are as follows: (1) diagnostic categories rely on the usage of certain codes which may be missing or utilized inconsistently across different institutions; (2) hospitals reporting to NSSP change over time when new facilities are established, and less frequently, when they close; and (3) NSSP data collection coverage is not uniform across all states. That is, in some states nearly all hospitals report their data, while in others, only the hospitals in certain counties report their data.

The decrease in ED volume in the United States during the pandemic could have been caused by the public fear of seeking medical care, causing the patients with time-sensitive critical conditions to delay their treatment. Kim et al. [7] compared the number of patients with serious diagnoses visiting seven EDs in greater Chicago, Illinois, during the pandemic period to that of the pre-pandemic period. This study demonstrated sharp reductions in ED visits for all major diagnosis classes (e.g., cardiac, surgical, orthopedic, neurologic, gastrointestinal, chronic respiratory) during the COVID-19 pandemic. In this study, the data are from a particular healthcare system Chicago, so the results may not be generalizable to other settings with different patient population characteristics and/or local government responses to the COVID-19 pandemic. Also, this study relies on ICD-10 coding data, which are based on the treating physician’s impression. To address this limitation, Kim et al. [7] excluded symptom-based diagnoses and included the diagnoses that often need objective findings obtained during ED evaluation. Although Kim et al. [7] used a valid and publicly available system to link ICD-10 codes to clinical diagnoses, it is possible that not all relevant ICD-10 codes for serious diseases are captured.

Jeffery et al. [1] examined ED visits and visits that led to hospital admissions in healthcare systems in five states, including Colorado, Connecticut, Massachusetts, New York, and North Carolina covering a four-month period before and during the COVID-19 pandemic. This cross-sectional study demonstrated that the ED visits in these five states significantly decreased from 41.5% to 63.5% during the pandemic. They also showed that the rates of the ED visits that led to hospital admissions were stable before the pandemic but increased from 22% to 149% during the pandemic. Since Jeffery et al.’s [1] study data are limited to ED visits to the healthcare systems of only five states, the results may not be generalizable to the other states in the United States. In addition, because their study data did not include diagnoses, they were unable to examine how ED patient case-mix have changed over time.

Westgard et al. [3] conducted a study of ED visits, demographics, characteristics, and diagnoses of the patients visiting an urban Level-1 trauma center in the United States 28 days before and 28 days after declaring a state emergency on March 13th, 2020. The results of their study show that ED visits significantly decreased after the state of emergency declaration. They also demonstrated that the decline in ED visits significantly changes by patient demographics (i.e., age, gender, and race) and visit characteristics (i.e., insurance status, arrival mode, and disposition). The data in this study are limited to only one center and a short study period, limiting the generalizability of the findings to other medical centers and the rest of the pandemic period.
Butt et al. [8] studied the volume and acuity of the patients visiting four EDs affiliated with general, cardiac, cancer, and obstetrics hospitals in Qatar during the pre-pandemic and pandemic periods. They demonstrated that the ED patient visits in both general and specialty hospitals substantially reduced during the pandemic. They also showed that the cardiac hospital and cancer hospital experienced the sharpest decline and the least decline in ED visits, respectively. Furthermore, the proportions of severely ill patients visiting EDs sharply dropped during the pandemic. The included EDs account for more than 80% of all ED visits in Qatar, making the results generalizable to all EDs in Qatar. The data in this study are limited to the first two months after the diagnosis of the first COVID-19 patient in Qatar, so the findings may change by increasing the length of the study time frame. In addition, the study data are limited to only the volume and acuity of the ED patients before and during the pandemic. Although the results show a significant decrease in ED volume due to the pandemic, the travel restrictions imposed by the state of Qatar due to the COVID-19 pandemic may have affected the volume and acuity of ED patients. However, the data studied by Butt et al. [8] did not include travel restrictions, so they could not examine the impact of travel restrictions on ED visits.

Compared to adults, children had a lower risk of COVID-19 infection, and therefore needed less emergency medical care [9]. Consequently, although many studies focused on the volume, epidemiological, and clinical characteristics of the ED visits related to the adult patients with COVID-19, data and studies on pediatric patients are limited. With this in mind, Lozzi et al. [10] studied the pediatric ED visits of five hospitals across Italy from March 1 to March 27, 2020 and showed that pediatric ED visits in March 2020 decreased by 73% in comparison to the same period in 2019. The data in this study are from only one pediatric ED in Italy, reducing the generalizability of the findings. Similar to Italy, pediatric ED visits in other countries changed during the pandemic. According to CDC, routine pediatric care in the United States decreased during the pandemic [11]. Additionally, an examination of Chinese outpatient pediatric care showed a drop in overall outpatient healthcare as well as a significant decrease in infectious complaints [12].

Social distancing, on the other hand, posed different risks to children. For example, data from a large pediatric hospital showed a threefold increase in dog bites, as well as a significant increase in national calls to poison control centers, including a high percentage of child exposures. Chaiyachati et al. [13] studied the effect of social distancing and a state-wide stay-at-home order on pediatric ED visits to a tertiary urban children’s hospital in the United States during the COVID-19 pandemic. This study compared the pediatric ED visits in 2020 after an official stay-at-home order with the ED visits in the last three years from 2017 through 2019 and showed reduced visits, increased acuity, and consistent chief complaints in 2020 in comparison with the last three years. Given that chief complaint scripts are not standardized across hospitals, the generalizability of this study is limited.

The review of literature shows that quite a few studies have been done to investigate the impact of the COVID-19 pandemic on the volume and acuity of ED patients. However, the impact of different public health mandates on ED visits; and the challenges and opportunities associated with ED visit data during the pandemic have not been extensively studied in the literature, which we seek to address in this study.

Methods

Data source

The dataset used in this study comes from a single medical center in Arizona and was collected from January 1, 2019 to August 31, 2020. The data elements were sourced from electronic medical records, quality dashboards that report the daily and monthly census, and additional specialty reports to track ESI and admission locations. Quality metrics were obtained from the hospital quality committees that track such data for state and national reporting. Diagnoses categories that are “suspected” in the ED and get validated later in the course of the admission are collected and collated by existing committees as mentioned above. We used quality reporting such as MIDAS, or other validated data sets to extract information regarding ST-Elevation Myocardial Infarction (STEMI). STEMs were obtained from the cardiovascular service line which reviews all arrivals and validates if the case was a STEMI or not for very specific reporting requirements. An overview of the informatics challenges and opportunities for improvement were obtained through direct in-person interviews with the clinical research team.

Common data elements

The initial study metrics abstracted from every ED arrival for 2019 influenza season (pre-pandemic) and 2020 (pandemic) included arrival time, arrival method, disposition type, disposition time, gender, age, ESI, chief complaint, lab results (e.g., flu A, flu B, respiratory syncytial virus, strep, respiratory pathogen polymerase chain reaction, and COVID-19) imaging results (e.g., chest X-ray (anteroposterior/lateral vs portable)). Also, the hospital metrics include daily hospital census, including total daily ED physician staffing hours, total daily trauma activations, total daily codes, transfers from an outside hospital, transfers out of the system, total daily admissions to each location (i.e., Intensive Care Unit (ICU)), acute, and Acute Palliative Care Unit), and status (i.e., total daily observations, and total daily admissions). We revised the dataset based on availability and the likelihood of obtaining data from various EDs in Arizona. The following are the current set of common data elements that we believe are needed to perform ED volume studies:
(1) Daily ED visit metrics: total adult ED visits and total pediatric ED visits;
(2) Monthly ED visits for each of the ESI categories (ESI is a measure of acuity, and each patient should be assigned a number from 1 (highest acuity) to 5 (lowest acuity) i.e., ESI 1, ESI 2, ESI 3, ESI 4, and ESI 5);
(3) Monthly ED admissions which include admissions for medical/surgical floor, step down/intermediate, and ICU;
(4) Monthly quality metrics that include ED stroke activations, ED ST-Elevation Myocardial Infarction (STEMI) activations, ED trauma activations, and ED sepsis activations. It should be noted that our study includes only adult patients, and pediatric patients were not considered in our study.

Data collection and coordination process

Coordination with other sites for obtaining data included reaching out to individuals who we thought would be interested and capable of obtaining data. This largely included previous or ongoing ED-based colleagues. We found that rapidly establishing was challenging and previous agreements did not include such uses of data for publication and would have required soliciting individual agreements with each institution to use the data. Consequently, the dataset used in this study is limited to only one medical center in Arizona, which reduced the generalizability of results. For example, we were unable to provide information regarding alternative institutions, such as urgent care, critical access, or suburban hospitals. Furthermore, given the issues and challenges that we had in obtaining data, we simplified the dataset to improve the likelihood of obtaining data. However, it is obvious that resolving data collection issues and obtaining more detailed information will result in more educated or specific findings and recommendations. For instance, simply knowing the raw volume of patient arrivals is a good starting point, but it is insufficient to know if either an increase or decrease in volume also has an increase or decrease in acuity. Are sicker patients staying home or unable to get care elsewhere? What was the impact of primary care offices closing? Did those patients requiring medication refills for diabetes or heart medications go to urgent care or EDs for refills or did they simply go without and subsequently suffer worse outcomes due to the forced non-compliance with their medications? Other challenges we faced include separating the pediatric population from the adult population since many EDs do not have a separate pediatric department that is open 24 hours per day, and they combine and merge the census. Consequently, the data on ED adult patients had to be manually extracted from the electronic health records.

Challenges and opportunities related to data sharing

Data protection regulations

The majority of data sharing challenges were largely related to privacy and security concerns of Protected Health Information. Local institutions must approve research projects involving human participants, and this process follows internal protocols. Even within the same county, institutional review board (IRB) protocol preparation and approval processes are generally different. The main variations are based on the structure and content of the documentation, the bureaucratic processes necessary for the documentation, the time it will take for the institution to process and approve it, and the number and kind of revisions requested by the IRB. As a result, such differences served as a barrier to multisite research and led to potential delays in starting the studies. These challenges were more pronounced for sites that do not have sufficient research administration capacity.

The use of de-identified data sets or population-level data removes some if not all the concerns regarding possible re-identification of patients, but it also removes some level of necessary detail. For instance, if we wanted to see which zip codes, ethnicities, ages, or genders were most impacted, it would have been more complicated to coordinate how best to protect patients via either a safe harbor or other methods of de-identification that would also allow aggregation amongst others.

Most institutional IRBs are established to review traditional research on drugs or devices and are less familiar with more of a population-based approach nor are they comfortable with sharing data across disparate institutions. Early approaches to obtaining IRB approval as well as data collection were delayed in part due to this misunderstanding. Using more relevant language regarding de-identified data, limited data sets, and quality improvement data may have served us better.

Data formats and report structures

Some healthcare organizations tend to have established departments for the submission of data to government and regulatory agencies in many different formats to comply with the specific needs for each request or requirement. Unfortunately, many of these established departments have become less flexible to modifications of or even sharing of their data collections for fear of manipulation or alteration of it. A report created for reporting to the Centers for Medicare & Medicaid Services is either overly cleaned or processed and often misses the details that physicians expect and need to ‘tune’ their internal diagnostic algorithms. Taken out of context, meaningful cases reported for disease entities such as heart attacks or strokes may seem either exaggerated or minimized, depending on the strict requirements for inclusion or exclusion. Instead of having a readily available source of heart attack, stroke, sepsis, or even ED visit data in an understandable format, we were often met with unclear or even confusing datasets created not to improve patient care but to comply with various uncoordinated agencies. Some data were necessarily delayed
until a diagnosis was assured, either from pathology, autopsy, or discharge diagnosis reports, making real-time reporting more challenging.

Instead of replacing existing departments and reporting structures, we recommend concurrent reporting of the same data in more clinically relevant formats that can better be used for monitoring population movements and clinical outcomes as well as improvement of processes. One example could be reporting of suspected severe sepsis or septic shock versus those diagnosed. By the time the definitive diagnosis is made, it could be hours after the patient has left the ED. It is important to provide feedback that a patient either was or was not septic to better recognize and diagnose the next patient, but often physicians are less concerned about the specific reporting requirements of sepsis versus severe sepsis in individual patients.

**Study design**

We conducted a descriptive, cross-sectional study of volume and acuity of adult patients visiting the ED of a medical center in Arizona in 2020 (the pandemic period) compared to those in 2019 (the pre-pandemic period). We stopped data collection in August 2020, which may limit generalizability through the remainder of the pandemic. We also examined how different public health-related mandates and statewide business openings/closings in Arizona, affected daily ED visits to the medical center. We created scatter plots for comparing the total daily ED visits, monthly ED visits for each ESI (i.e., ESI 1, ESI 2, ESI 3, ESI 4, and ESI 5), monthly admissions to each hospital unit (i.e., medical/surgical unit, step down/intermediate unit, and ICU), and monthly activations of each specialty team (i.e., trauma, STEMI, stroke, and sepsis) in the medical center before the COVID-19 pandemic with those during the pandemic. To compare mean differences from the pre-pandemic period with those of pandemic period, we performed paired Wilcoxon test (also known as Wilcoxon signed-rank test). We created a boxplot and reported summary statistics for four time periods affected by public health mandates and statewide business openings/closings during the pandemic. To compare mean differences from the pre-pandemic period with those of pandemic period, we performed a negative binomial regression to predict the daily ED visits in the following months based on different variables, including being in non-infectious or early infectious periods, potential public health mandates such as business/service closures, stay-at-home order, business/service reopening, and mask mandates. All analyses were performed using R (version 4.0.5) statistical computing software.

**Results**

**Trends in the daily ED visits before and during the COVID-19 pandemic**

Our analyses show that, except for January, daily ED visits during the pandemic period were substantially lower than those during the pre-pandemic period (see Figure 1). The mean (±SD) of daily ED visits during the pandemic was lower than that during the pre-pandemic period (106 ± 25 vs. 132 ± 15, p < 0.05). Indeed, it decreased by 20% during the pandemic. The lowest number of ED visits occurred during April (55 visits). Although the number of daily ED visits during the pandemic has increased since the noticeable decrease in April, it remained lower than the corresponding number of daily ED visits in the previous year.

**Figure 1.** Trends in the medical center’s daily ED visits before and during the COVID-19 pandemic

**Figure 2.** Daily ED visits in four specific periods during the pandemic, including period 1 (early infectious period, Jan 1 - March 29), period 2 (Stay-at-home order, March 30-May 15), period 3 (re-opening to secondary closure, May 16 - Jun 29), period 4 (second closure to current, June 30 – current)
Daily ED visits in four specific periods

As shown in Figure 2, the medical center had its highest daily ED visits (173 visits) during the early infectious period and experienced its lowest daily ED visits (55 visits) following the stay-at-home order. After reopening businesses in Arizona, the daily ED visits increased; then, it went into a small decline following the second closure. However, there is not a significant difference between the mean (±SD) of daily ED visits in the reopening period and that in the second closure period (101 ± 17 vs. 97 ± 12, p = 0.43).

Monthly ED visits for each ESI before and during the COVID-19 pandemic

Every included patient should fit in one of the ESI categories (i.e., ESI 1, ESI 2, ESI 3, ESI 4, and ESI 5). In this measure of acuity, ESI 1 is the highest acuity and ESI 5 is the lowest acuity. ED visits with ESI 1 and ESI 2 are considered high acuity ED visits. The results show that the mean (±SD) of monthly high acuity ED visits during the pandemic was higher than that in the pre-pandemic period (421 ± 46 vs. 363 ± 22, p < 0.05) (see Table 1). Likewise, the proportion of high acuity ED visits during the pandemic was higher than that of the pre-pandemic period (13% vs. 9%, p < 0.05). As evident in Figure 3, the mean (±SD) of monthly ED visits with ESI 3 in 2020 was lower than that in 2019 (2079 ± 394 vs. 2878 ± 246, p < 0.05). However, the mean (±SD) of monthly ED visits with ESI 4 during the pandemic was not significantly different from that during the pre-pandemic period (662 ± 207 vs. 682 ± 51, p = 0.74). The results also show that the mean (±SD) of monthly ED visits with ESI 5 during the pandemic period was lower than that in the pre-pandemic period (26 ± 5 vs. 39 ± 10, p < 0.05). Accordingly, ED visits with ESI 5 had the sharpest decline (33%) during the pandemic in comparison with the other ESI categories, showing the patients with the lowest acuity were most likely to avoid visiting EDs to get medical care during the pandemic.
Figure 3. Trends in the monthly ED visits for each ESI before and during the COVID-19 pandemic. Figure 3 shows that, during the pandemic, the medical center had the lowest number of ED visits for each ESI in April, except for the ED visits with ESI 5.

Monthly admissions to hospital care units before and during the COVID-19 pandemic

Patients presenting to emergency departments may get admitted to one of the hospital units (medical/surgical care unit, step down/intermediate care unit, intensive care unit), depending on the level of care needed. The analysis of monthly admissions to each unit shows that the center experienced a sharp decline in the number of admissions to all of its units in April after implementing a business closure order on March 19th and stay at home order on March 30th in the state of Arizona (see Figure 4). In addition, the admissions to each unit of the medical center increased in May following the reopening of businesses on May 16th. Since the declaration of public health emergency on March 11th, the medical center experienced the most admissions to each of its hospital units in June when the businesses were open and mandating wearing masks initiated on June 19th.

According to the results, there is not a significant difference between the mean (±SD) of monthly admissions to the medical center during the pandemic period and that during the pre-pandemic period (690 ± 87 vs. 725 ± 53, p = 0.383). Also, there is not a significant difference between the mean (±SD) of monthly admissions to the step down/intermediate unit during the pandemic period and that during the pre-pandemic period (191 ± 29 vs. 180 ± 21, p = 0.461). The mean (±SD) of monthly admissions to the medical/surgical unit did not significantly change during the pandemic compared with the pre-pandemic period (447 ± 52 vs. 445 ± 39, p = 1). On the other hand, the results show that the mean (±SD) of monthly admission to the ICU during the pandemic is not the same as that during the pre-pandemic period (52 ± 38 vs. 100 ± 10, p < 0.05). Indeed, there is a sharp decline (48%) in the mean of monthly admission to the ICU during the pandemic in comparison with the pre-pandemic period. There is not a significant difference between the proportion of ED visits that get admitted during the pandemic and that during the pre-pandemic period.
period (20.5% vs. 18.2%, p = 0.104). The proportion of the ED visits that become ICU admits during the pandemic is, however, lower than that during the pre-pandemic period (1.5% vs. 2.5%, p < 0.05) (see Table 2).

Monthly activations of each specialty team before and during the COVID-19 pandemic

The analysis of data on the number of activations of each specialty team in the medical center before and during the pandemic showed quite a few different trends. The mean of monthly trauma activations decreased by 15% during the pandemic (105 ± 18 vs. 135 ± 16, p < 0.05). Conversely, the mean of monthly sepsis activations increased by 15% during the pandemic compared to the pre-pandemic period (109 ± 14 vs. 95 ± 9, p < 0.05). There is not a significant difference between the mean (±SD) of monthly STEMI activations during and before the pandemic (2 ± 2 vs. 3 ± 1, p = 0.105). Likewise, there is not a significant difference between the mean (±SD) of monthly stroke activations during the pandemic period and that during the pre-pandemic period (4 ± 1 vs. 4 ± 3, p = 0.573).

Figure 4. Trends in monthly admissions to each unit of the medical center before and during the COVID-19 pandemic. As evident in Figure 4, during the pandemic, the ICU of the medical center had the sharpest decline in the number of admissions compared to the other hospital units.
in the community increased in May voluntary self observed an initial decrease in ED visits started just before these public health mandates, which may be because of of ED visits visiting EDs due to the fear of seeking care in hospitals the number of COVID pandemic period We observed that daily ED visits in comparison with the other public health mandates. On the other hand, accessibility to care is implemented. As public health mandates is considered as a binary variable. A binary variable associated with a specific period is equal to 1 during that period. Also, a binary variable associated with a public health mandate is equal to 1 when that mandate is implemented. As shown in Table 3, business closure, stay-at-home order, and business reopening have a reverse relationship with the daily ED visits and make a decline in it. Also, business closure makes the most decrease in the daily ED visits in comparison with the other public health mandates. On the other hand, according to the results, the mandatory wearing of masks increases the daily ED visits. In addition, the medical center has more ED visits during non-infectious or early infectious periods in comparison with the pandemic period. Furthermore, daily ED visits are more during the early infectious period in comparison with the non-infectious period.

**Negative binomial regression**

We performed a negative binomial regression to predict the daily ED visits in the next months based on different variables, including being in non-infectious or early infectious periods, potential public health mandates, including business/service closures, stay-at-home order, business/service reopening, and mandatory wearing masks. To do so, the number of ED visits is considered as the dependent variable. Also, each of the specific periods and each of the public health mandates is considered as a binary variable. A binary variable associated with a specific period is equal to 1 during that period. Also, a binary variable associated with a public health mandate is equal to 1 when that mandate is implemented. As shown in Table 3, business closure, stay-at-home order, and business reopening have a reverse relationship with the daily ED visits and make a decline in it. Also, business closure makes the most decrease in the daily ED visits in comparison with the other public health mandates. On the other hand, according to the results, the mandatory wearing of masks increases the daily ED visits. In addition, the medical center has more ED visits during non-infectious or early infectious periods in comparison with the pandemic period. Furthermore, daily ED visits are more during the early infectious period in comparison with the non-infectious period.

**Conclusion**

We observed that daily ED visits during the COVID-19 pandemic substantially decreased compared to the pre-pandemic period. However, it is not clear whether this reduction in the number of ED visits is because of a decline in the number of COVID-19 patients or because of a decline in the number of patients unrelated to COVID-19 who avoid visiting EDs due to the fear of seeking care in hospitals due to the pandemic. Also, the sharpest decline in the number of ED visits was in April 2020 after the implementation of state-wide business closure and stay-at-home orders. We observed an initial decrease in ED visits started just before these public health mandates, which may be because of voluntary self-isolation before the mandatory public health orders. The results show that the number of ED visits increased in May 2020. This could be because of reopening businesses and services, increasing the spread of the virus in the community, and increases in the number of patients who need to visit EDs.
ED visits with ESI 5 had the sharpest decline in comparison with the other ESI categories, suggesting that patients with the lowest acuity were most likely to avoid visiting EDs to get medical care during the pandemic. Although the proportion of ED visits resulting in ICU admission has not substantially changed in comparison with the prior year, the results show a significant decrease in the number of ICU admissions through the ED. This decline in ICU admissions raises concern that critically ill patients may not be getting timely care during the pandemic due to the fear of seeking care or travel restrictions. This ultimately delays interventions for serious health conditions and may also cause a surge in the number of ICU admissions after the pandemic subsides. It is yet to be determined whether there was an actual decrease in the number of patients who need intensive treatment during the pandemic and whether the decline in ICU admissions due to the pandemic increased the mortality rate. If confirmed, suitable strategies should be implemented to provide appropriate and prompt care to critically ill individuals. With this in mind, a more comprehensive dataset from multiple sites and for a longer time period is needed to be able to investigate the effectiveness of the public health mandates. Future extensions of this work include investigating the impact of public health mandates on the daily ED visits while adjusting for seasonality of daily ED visits.

Abstract

Age-related macular degeneration (AMD) is the leading cause of vision loss. Some patients experience vision loss over a delayed timeframe, others at a rapid pace. Physicians analyze time-of-visit fundus photographs to predict patient risk of developing late-AMD, the most severe form of AMD. Our study hypothesizes that 1) incorporating historical data improves predictive strength of developing late-AMD and 2) state-of-the-art deep-learning techniques extract more predictive image features than clinicians do. We incorporate longitudinal data from the Age-Related Eye Disease Studies and deep-learning extracted image features in survival settings to predict development of late-AMD. To extract image features, we used multi-task learning frameworks to train convolutional neural networks. Our findings show 1) incorporating longitudinal data improves prediction of late-AMD for clinical standard features, but only the current visit is informative when using complex features and 2) “deep-features” are more informative than clinician derived features. We make codes publicly available at https://github.com/bionlplab/AMD_prognosis_amia2021.

1 Introduction

Age-related macular degeneration (AMD) is the leading cause of vision loss, and is projected to affect approximately 288 million people by 2040\textsuperscript{1,2,3}. In the United States alone, the annual healthcare cost of treating this disease is $4.6 billion, creating an extreme burden on patients and the healthcare system\textsuperscript{4}. AMD is characterized by the destruction of a retinal pigment epithelial (RPE) cells, which directly interact with photoreceptors to allow for proper function of the eye\textsuperscript{5}. In AMD, drusens, or lipid deposits, form near the RPE cells, which can eventually lead to tissue atrophy in the eye. In addition, RPE cells normally contain melanosomes, which create a certain pigmentation in the eye.

The onset of the disease can be heterogeneous between individuals. The majority of patients have a form of the disease known as dry AMD, which has fairly slow progression, whereas some patients (10-15% of early-stage AMD) will develop choroidal neovascularization (CNV) which leads to the rapid loss of vision and faster onset of late-stage AMD\textsuperscript{5}. Therefore, to improve treatment plans for patients, it can be useful to understand the risk of developing CNV and in particular, the risk of developing late-stage AMD.

The current method to assess AMD severity requires the use of color fundus photographs (CFP), which are generated by a low-power microscope that captures general eye health and examines structures within the eye\textsuperscript{5}. These photographs are then sent to grading centers, where experts analyze specific characteristics, including presence, type, and extent of drusens, presence/extent of retinal depigmentation, serous sensory retinal detachments, subretinal hemorrhages, subretinal fibrosis, and geographic atrophy, which are used for characterizing AMD severity. A simplified AMD severity score and risk classification has been developed by the Age-Related Eye Disease Study (AREDS) Research Group\textsuperscript{2}. Based on characteristics from CFPs at the current time of visit, patients are binned into 5 categories (0-4), which estimate the likelihood the patient will progress to late-stage AMD. This five-step simplified severity

\textsuperscript{a}Equal contributions.

\textsuperscript{b}Equal contributions.
scale is the current clinical standard in assessing a patient’s risk of developing late-AMD. This risk is calculated using the size of drusens, presence of pigmentation abnormalities, age, and smoking status at the current time of visit.

Over the past decade, the use of deep learning has grown exponentially. Convolutional neural networks (CNNs) have been used to identify patterns within images to classify medical imaging data. Various models have been developed to characterize CFPs, based on several characteristics. Single task models have been used to classify characteristics such as geographic atrophy and drusen presence. In addition, multi-task models have been developed to characterize these eye characteristics simultaneously. Subsequently, researchers have used these image features derived from a CNN model in a survival setting to predict patients who are at risk of developing late-stage AMD. However, it is well known that the rate of progression for patients within the early-stage AMD category is heterogeneous. In this work we hope to utilize the time-varying information for these patients to improve upon risk-prediction for AMD patients.

We combine elements of multiple past works to improve upon AMD patient stratification, while introducing a novel time-varying component to improve model performance. A multi-task learning model was used to predict both drusen size and presence of pigmentation abnormalities in the right and left eyes of patients. Drusen size and presence of pigmentation abnormalities are the criteria used for the simplified AREDS severity scale. Image features are extracted from the multi-task learning model. Multi-task learning was incorporated to extract more generalizable image features than the clinician derived features, hoping to improve our ability to predict risk of developing late-AMD. Either the image features or clinical features are passed through either a multilayer-perceptron (MLP) or long short-term memory (LSTM) network, to predict patient risk of developing late-stage AMD. A survival loss function is utilized to train the risk prediction model to account for patients that end the study without developing late-stage AMD. We compare model performances of these image derived features with those of expert-derived features to compare our results to a baseline model. The end goal of this work is to (a) reduce the burden on grading centers by reducing the time needed to analyze simple cases and assisting in edge-case classification and (b) use the features derived from the images to improve upon the stratification of patients with early-stage AMD based on the risk of progressing to late-AMD.

2 Materials and Methods

2.1 Dataset

In this study, we use the AREDS cohort sponsored by the National Eye Institute (National Institutes of Health). It was a 12-year multi-center prospective cohort study of the clinical course, prognosis, and risk factors of AMD, as well as a phase III randomized clinical trial to assess the effects of nutritional supplements on AMD progression. In short, 4,757 participants aged 55 to 80 years were recruited between 1992 and 1998 at 11 retinal specialty clinics in the United States. The inclusion criteria were wide, from no AMD in either eye to late AMD in one eye. The AREDS dataset is publicly accessible to researchers by request at dbGAP. In the AREDS cohort, at baseline and at annual visits, comprehensive eye examinations were performed by certified study personnel using a standardized protocol, and CFP (field 2, i.e., 30° imaging field centered at the fovea) were captured by certified technicians using a standardized imaging protocol.

The longitudinal analysis of the AREDS cohort led to the development of the patient-based AREDS Simplified Severity Scale for AMD, based on the grading of CFP. This simplified scale provides convenient risk factors for assessing the risk of progression to late AMD that can be determined by clinical examination or by less demanding photographic procedures than used in the AREDS. The scale combines risk factors from both eyes to generate an overall score for the individual, based on the presence of one or more large drusen (diameter > 125 mm) and/or AMD pigmentary abnormalities at the macula of each eye. The Simplified Severity Scale is clinically useful in that it allows ophthalmologists to predict an individual’s 5-year risk of developing late AMD. This 5-step scale (from score 0 to 4) estimates the 5-year risk of the development of late AMD in at least one eye as 0.4%, 3.1%, 11.8%, 25.9%, and 47.3%, respectively.

In our study, the event of interest was the development of late AMD. The ground truth labels (AREDS Simplified Severity Scale and phenotype features such as drusen status and macular pigmentary abnormalities) used for both training and testing were the grades previously assigned to each CFP by expert human graders at the University of Wisconsin Fundus Photograph Reading Center. The reading center workflow has been described previously.

507
To train and test our models, we created a data subset that consisted of 3,747 patients from AREDS who had not reached late AMD through year 3. Of these patients, 2.7% reached late-AMD by year 5, 6.1% reached late-AMD by year 8, and 9.3% reached late AMD by the end of the study. This dataset consisted of the gradings from the certified study personnel, as well as inferred grades, such as presence of one or more large drusen and AMD pigmentary abnormalities at the macula of each eye.

2.2 Development of the algorithm

Figure 1 shows the overarching architecture used to A) develop the fine-tuned CNN drusen size and pigmentation abnormality classifiers trained on images from all patients and B) extract the "fine-tuned" and "pretrained" features on the images from years 0, 2, and 3 for the patients who had not reached late-AMD by year 3. Figure 1C demonstrates example model of how image features are used to predict risk of developing late-AMD at years 5, 8, and overall risk. We will describe each module in the subsequent sections.

2.2.1 Multi-task Learning

Multi-task learning is a field of machine learning where multiple tasks are learned in parallel while using a shared representation. It exploits the similarities (shared image features) and differences (task-specific image features) between the features present on different tasks, thus reduces the losses of various tasks simultaneously.

In this study, we created a multi-task deep learning model that trains the classification of drusen size and presence of pigmentation abnormalities simultaneously. Drusen size and pigmentation abnormalities are the features used to calculate the 5-step simplified severity scale. Of the 60,929 CFPs used in this study, 41,147 images from visits after year 3 were randomly sampled in a 90-10 split to train and test. Data augmentation was performed to improve model generalizability. Training images were randomly horizontally flipped, cropped, blurred, rotated, sheared, morphed, and the contrast was randomly strengthened or weakened using the ImgAug module in Python. These augmentations were set to plausible realistic ranges of CFPs. All images were resized to 256 × 256, then center cropped to 224×224. This aided in removing the unwanted areas as there is some blank space surrounding the eye image. Images were then normalized to a mean of 0 and standard deviation of 1 based on the mean and standard deviation of 10,000 randomly sampled images from the entire dataset.

Two different models were trained for this study to compare performance. ResNet152 and EfficientNetB3 were used to see how deep learning architecture affects model performance. Weights on both the ResNet152 and EfficientNetB3 models were both initialized to the pretrained ImageNet weights. The last-fully-connected layers of both models were replaced with two separate linear layers, one for predicting size of drusen (three-class) and one for predicting pigmentation abnormality (two-class) (Figure 1A).

---

https://github.com/rwightman/gen-efficientnet-pytorch
To account for the class imbalance, weighted cross entropy loss was used on each classifier. Weightings were set to $\frac{1-p_i}{n-1}$, where $p_i$ is the proportion of class $i$ in the training set, and $n$ is the number of classes. The model loss was set to the mean of the drusen classifier loss and the pigmentation classifier loss. The Adam algorithm was used as an optimizer with the learning rate set to 0.005. Up to 25 epochs, with a batch size of 16 images were run to train each model. Training ceased when the training loss dropped below 85% of the test loss. The weights from the epoch with the lowest test loss were saved and used to extract image features for deep survival analysis.

2.3 Image Feature Extraction

To extract image features, the fully-connected layers from the multi-task learning model were removed, and an n-dimensional vector was extracted from the last hidden layer for each image (2,048 for ResNet152 and 1,536 for EfficientNetB3). These features will be referred to as “fine-tuned” features. A comparison is also done with the ImageNet pretrained model to demonstrate improved feature extraction using the multi-task learning model. Those features will be referred to as “pretrained” features. Collectively, they are referred to as “deep” features.

2.4 Survival Analysis

Deep image features from CFPs at years 0, 2, and 3 and clinical data of 3,297 patients who had not reached late-AMD at year 3 were used to predict risk of developing late-AMD at years 5 and 8 and by the end of the study. Five-fold cross validation was used to evaluate the performance of all models. Of the 80% of the patients not in the test set, 80% were used to train the model and 20% were used as a validation set. One single batch was used during training to account for low numbers of uncensored data.

CoXPH Model Image features from each eye and each visit were concatenated to an $n \times 2 \times m$ vector, where $n$ is the size of the CNN output (2048 for ResNet152 and 1536 for EfficientNetB3) and $m$ is the number of years included. Using principal component analysis (PCA) from the scikit-learn library, a linear transformation to 10 dimensions was made on the training dataset. On average, these PCA decompositions explained 22.4%, 85.4%, 81.6%, and 73.6% of the variance for the ResNet152 pretrained, ResNet152 fine-tuned, EfficientNetB3 pretrained, and EfficientNetB3 fine-tuned feature vectors across the cross-validation training sets, respectively. Fewer than 10 principal components further reduced the explained variance, while more than 10 led to linearity convergence issues with the CoXPH model. The CoXPH Fitter model from the lifelines module was then fit with a step size of 0.1 and no penalizer, using the Breslow method for handling ties.

MLP Model For each patient, deep image features were extracted from images of the patient’s left eye and right eye at years 0, 2, and 3. Features were z-score normalized, fit to the training set, prior to training and evaluating the survival models. The models incorporated time-dependent information in two different ways, both utilizing the pytorch deep learning library. For the MLP model, the left and right eye image features were concatenated for the three different time points, generating a $(n \times 2 \times m)$ dimensional vector. The MLP model consisted of one hidden layer (32-dimension for 1 year and 96-dimension for 3 years) that then fed into a final linear layer with one node as the output for the survival loss calculation.

LSTM For the LSTM model (Figure 1C), the left and right eye data for each time point were concatenated separately for each visit, then passed through a single linear layer to decrease the dimensionality of the concatenated feature vector by a factor of 8, creating a tensor of size $(b \times 3 \times \frac{2 \times n}{8})$, where $b$ is the batch size and $n$ is the size of the feature vector from the CNN. Each of these time points were then used as a separate input into the LSTM to model the time-varying changes in eye features. The hidden state from the final time point was fed into a survival loss similar to what was done for the MLP model. The hidden state size for the model was 128. In addition, dropout ($p = 0.6$) was used prior to the linear layer to reduce overfitting. All models used the pycox loss, which is an approximation of the negative partial log likelihood. We adopted survival loss using Efron’s method to handle ties in the survival time using code from the Pysurvival package.

2.5 Evaluation Metrics

Survival Analysis To evaluate model performance, several different metrics were used. Concordance index was calculated using the pycox package. In addition, patients were categorized into late-stage or not late-stage AMD at

---

1https://github.com/CamDavidsonPilon/lifelines
2 years (year 5) and 5 years (year 8) after the year 3 time point. We then generated area under the receiver operating characteristic curve (ROC AUC) for predicting late-stage AMD at years 5 and 8 based on the risks generated from our model (represented as ROC AUC@5 and ROC AUC@8\textsuperscript{26}). In addition, using the R-based timeROC package with the rpy2 package, we evaluated the precision and recall of the models by generating AUC values indicating the extent of false positives and false negatives in the prediction\textsuperscript{g}. To visualize classification performance of the CNN model and to examine how they correlate with clinical features, we used t-SNE from the scikit-learn package in Python\textsuperscript{h}. Matplotlib\textsuperscript{i} was used for plotting all analyses.

**Multi-task Learning Analysis** We constructed contingency tables of the true and predicted values of drusen size and pigmentation abnormalities for both the fine-tuned ResNet152 and EfficientNetB3 models. Overall accuracy, sensitivity, specificity, and precision were calculated for each class. Drusen sensitivity, specificity, and precision were calculated in a one-vs-all method, where the identified value was considered positive and the other two values considered negative.

### 2.6 Analyzing Clinical Features

Two distinct datasets were used with both linear and non-linear models to predict the risk of patients developing late-AMD. The first set, labeled as clinical set A, contained age, smoking status, and for each eye, drusen size and presence of pigment abnormalities. These are the features used to calculate the 5-step simplified severity scale. Clinical set B contained age, smoking status, and for each eye: area of drusens within a central grid supplied to the grader, geographic atrophy (GA) within the central grid, subretinal GA atrophy, subretinal fibrosis, non-drusenoid pigment epithelial detachment, serous sensory retinal hemorrhaging, subretinal or subRPE hemorrhaging, RPE depigmentation, and increased pigmentation within the central grid. Drusen size and presence of pigmentation abnormalities in dataset A are calculated by binning features in dataset B to offer a more immediate and interpretable interpretation of the wellbeing of the patients’ eyes.

Features from either clinical set A or set B were extracted from the AREDS datasets. In a similar manner to the image features, the clinical features were either concatenated when analyzing multiple visits and the training sets were used to fit the same CoxPH model as described above. No PCA was used for clinical features. Survival analysis only included clinical features or "deep-features." No datasets contained both.

### 2.7 Hyper-parameter Tuning

Concordance index, ROC AUC at year 5, ROC AUC at year 8, precision-recall AUC at year 5, and precision-recall AUC at year 8 (as described in Evaluation Metrics) on the validation set were calculated for a wide range of learning rates on each combination of the model and dataset using 5-fold cross validation. The best learning rate for each combination was chosen as the learning rate which had the largest product of the mean of these five measures across the 5-fold cross validation in the validation set. All performance metrics shown are evaluated on the independent test sets during cross-validation.

### 3 Results and Discussion

#### 3.1 Longitudinal data improves risk prediction with clinical set A

With the limited features available in clinical set A, which are the features used in the 5-step simplifies severity scale, incorporating longitudinal data improves predictive performance (Table 1). Here, we see that the CoxPH with visits at years 0, 2, and 3 performs better than the CoxPH model using only data from year 3. We see a similar result with the MLP, where incorporating longitudinal data improved on the performance in comparison to using the single time point. Interestingly, the concatenated features performed better than the LSTM. As a whole, using longitudinal data with the clinical A dataset seems to be more informative than using just a single time point and the linear model performs equally as well as or better than the deep learning models.

\textsuperscript{g}https://cran.r-project.org/web/packages/timeROC/timeROC.pdf  
\textsuperscript{h}https://scikit-learn.org  
\textsuperscript{i}https://matplotlib.org/
### 3.2 Deep learning improves risk prediction with clinical set B

Clinical set B proves to be more informative than clinical set A in predicting a patient’s risk of developing late-AMD using all models (Table 2). In the more informative clinical set B, the deep learning models outperform the linear CoxPH model. Dataset B comprises many more features than dataset A, and these features are more “raw,” as in they are evaluated directly by the readers at the grading centers. It is possible that the deep learning models find more indicative interactions between the raw features than the transformation to dataset A does. The binning and dimensionality reduction for dataset A lost a large amount of useful information compared with the 22 features that are provided in dataset B. In this dataset, incorporating multiple timepoints only offers very slight improvements over using the single time point, indicating that the current time point is much more indicative of the patients’ risk of developing late-AMD than the previous time points.

### 3.3 Pretrained Features are not informative, but incorporating longitudinal data helps

ResNet152 and EfficientNetB3 pretrained features do not perform well (Table 3). The models that extract these features are tuned to classify dogs, birds, boats, and other types of natural image categories. The eye is a very delicate and intricate organ, where small sized abnormalities can cause a large difference. Therefore, the pretrained models are not capable of deciphering the sophisticated features that distinguish a healthy eye from a diseased eye. For both of these feature sets, the deep learning models outperform the CoxPH model. This is especially true in the case of the ResNet152 pretrained features because the PCA was only able to account for 22.4% of the variance in the feature set.

### 3.4 Fine-tuned features are more informative than the features they are trained on

The fine-tuned ResNet152 and EfficientNetB3 outperformed the clinical features and the pretrained features (Table 4). The models were trained on most of the features from dataset A yet outperformed dataset A in a survival setting. This
indicates that the deep learning models are able to extract more intricate features than drusen size and pigmentation, which can be more informative in predicting the risk of a patient developing late-AMD than drusen size and pigmentation. Figure 2 displays t-SNE plots of the feature vectors generated from the images used in the survival analysis (years 0, 2, and 3). Individual images are color coded by the amount of time between when that image was taken and when the patient reaches late-AMD. Dark red indicates that the patient is very soon to reach late-AMD, while white dots show that the patient has 8+ years until reaching late-AMD. The gray spots show the overall distribution of image features for both censored and uncensored patients. These t-SNE plots show that the deep feature extractors that are trained on drusen size and presence of pigmentation abnormalities are not only able to predict drusen size and presence of pigmentation abnormalities but are also able to extract features useful in predicting the risk of developing late-AMD without being explicitly trained to do so. These features are not only informative in predicting if a patient will develop late-AMD, but also in predicting if a patient will not develop late-AMD.

![Figure 2](image_url)

**Figure 2:** t-SNE plots of the fine-tuned deep features generated from the visits used in the survival analysis (years 0, 2, and 3). Colors indicate time to reach late-AMD. Dark red dots are soon to reach late-AMD. White dots will not reach for many years. Gray spots show the overall distribution of image features censored and uncensored patients.

### 3.5 LSTM improves short term predictions in fine-tuned features

Incorporating longitudinal data from the fine-tuned features does not aid in predicting all time risk of late-AMD. Only the most recent visit is necessary. However, incorporating longitudinal data and modeling the time dependencies of the data using the LSTM model improved on the more immediate prediction, shown by the large increase in PR AUC at year 5 for both the ResNet152 and EfficientNetB3 fine-tuned feature sets.

### 3.6 Multi-task Learning Performance

Both the EfficientNetB3 and ResNet152 were able to accurately classify drusen size and presence of pigmentation abnormalities. The EfficientNetB3 architecture more accurately predicted drusen size than the ResNet152 architecture. Both models had similar accuracies for predicting pigmentation abnormalities. As shown in Figure 3, both of the fine-tuned models are able to accurately cluster the different classifications. Additionally, in both models, we see a gradient from 0 to 2 in predicting drusen size. Class 2 drusen sizes are larger than class 1 and class 0 is the smallest. The models
are not explicitly told that this is the case, as each classification is treated as its own binary class. This shows that the fine-tuned CNN models are able to extract valid image features for evaluating fundus photographs.

**3.7 Discussion**

In this study, a multi-task learning framework was used to predict drusen size and pigmentation abnormalities. By visualizing these features using t-SNE and calculating accuracy, sensitivity, and specificity for the model, our results show similar performance to state-of-the-art methods for these classification tasks. Interestingly, our features also correlate with the time-to-event prediction, where there was a clear separation for patients that have already reached late stage AMD to those patients who have not. The benefit of using our fine-tuned model, as compared to a pretrained model using Imagenet is shown in the significant increase in model performance based on evaluation metrics in the survival models. In addition, we show that EfficientNetB3, a newer developed model with fewer parameters, as compared to the ResNet152 model, showed higher performance. This may be due to the fact that the EfficientNet models were shown to better capture fine image details within an image. Further, we improved upon the standard CoxPH model that is commonly used in previous literature using deep learning methods. Last, while incorporating longitudinal data we do see improvements in short-term prediction performance and in clinical feature performance as compared to using a single time point data, but do not see improved long-term performance. It is interesting to note that when year 3 features performed better than years 0-3 features, the data from year 0 showed a decline in model performance (data not shown). This may indicate that more recent time points, for both clinical and image features, are more predictive than earlier time points in predicting risk of developing late-stage AMD.

While the biological changes that occur during AMD are well understood, unfortunately, there is no cure. This model can be used to aid clinicians in predicting how at risk patients are of developing late-AMD. Patients with low risk can have a treatment plan that will decrease patient costs and decrease the burden of patient care on the healthcare system.
In contrast, patients with high risk can receive a more aggressive treatment plan, at an earlier point in the disease to prolong vision as long as possible.

This study remains limited. Primarily, of the cohort analyzed in the survival analysis, only 350 patients reached late-AMD and results were not validated on an external dataset. Additionally, measures can be taken to improve the interpretability of the model, such as analyzing saliency maps to see which features are deemed most indicative in the multi-task learning models. To expand the model, the multi-task learning classifier could be extended by increasing the number of tasks learned. Adding in confidence scores would allow this model to aid grading centers by both reducing the time needed to analyze simple cases and assist in edge-case classification. Finally, although we explored a wide range of hyper-parameters and architecture makeups, we plan to conduct a more exhaustive analysis of MLP architectures and other hyper-parameter tunings.

4 Conclusion

This study shows that multi-task learning can be used to extract image features that are highly predictive of developing late-AMD. These extracted features are more predictive than the expert grader acquired feature, which are labor intensive and expensive to generate. This model can be used to aid clinicians in the stratification of patients with early-stage AMD, based on the risk of progressing to late-stage AMD. This would ease the exhaustive burden on the experts in the grading centers and greatly reduce cost. Additional future directions include integrating clinical features, such as smoking and age, and image features into the same deep learning model to try to improve model performance.

This model architecture is applicable to many other eye related diseases, including longitudinal prognosis of glaucoma. Additionally, the model could be extended far beyond fundus photographs to aid in longitudinal evaluation of non-eye related diseases such as cancers, COVID-19 and other diseases and illnesses.

Abstract The Collaborative Open Outcomes tooL (COOL) is a novel, highly configurable application to simulate, evaluate and compare potential population-level screening schedules. Its first application is type 1 diabetes (T1D) screening, where known biomarkers for risk exist but clinical application lags behind. COOL was developed with the T1DI Study Group, in order to assess screening schedules for islet autoimmunity development based on existing datasets. This work shows clinical research utility, but the tool can be applied in other contexts. COOL helps the user define and evaluate a domain knowledge-driven screening schedule, which can be further refined with data-driven insights. COOL can also compare performance of alternative schedules using adjusted sensitivity, specificity, PPV and NPV metrics. Insights from COOL may support a variety of needs in disease screening and surveillance.

1 Introduction

The Collaborative Open Outcomes tooL (COOL) was designed to help researchers and clinicians evaluate different potential screening schedules simulating their impact on optimal case identification rates prior to symptom onset using retrospective datasets. The initial application has been in type 1 diabetes (T1D), however, the tool can be used for a variety of conditions in which changes in biomarkers may signal progression to disease.

T1D is a complex, heterogeneous, autoimmune disorder in which insulin-producing pancreatic beta cells are mistakenly destroyed by the body’s immune system. T1D has both genetic and familial components. Patients with T1D remain insulin dependent for life and are at high risk for serious long-term complications such as heart and kidney disease and diabetic retinopathy. For reasons that are not understood, T1D incidence rates have been rising dramatically. There is currently no cure or established prevention strategy for T1D and since newly diagnosed patients often present with diabetic ketoacidosis (DKA), a life-threatening condition with potentially long-term consequences, research on prevention and early detection is increasingly critical.

There are known biomarkers for T1D, however, progression to diabetes is heterogeneous, with generally a 1 to 5 year horizon from birth, which has complicated efforts to establish a practical screening paradigm. This pre-symptomatic period presents an opportunity for both improved prediction and prevention. The NIH-funded TEDDY study is currently investigating environmental determinants of T1D. Intervention trials of novel therapeutic agents focused on preventing or delaying (TrialNET and Innodia consortium), increase the importance of early identification of at-risk patients for trial recruitment. These efforts, combined with the known clinical risk of DKA at onset, means that early population-based screening could make important contributions to both research and practice.

The T1DI study group is a collaboration among IBM Research, JDRF and five of its academic partners: in the US (DAISY, DEW-IT, Sweden/DiPiS, Finland/DIPP) and Germany (BABYDIAB/BABYDIET). These studies have followed newborns and young children from the general population who are at genetic or familial risk for up to a period of 15 years for islet autoimmunity development or until diagnosis of clinical diabetes. The goal of the T1DI Study is to use advanced machine learning and statistical methods to derive novel insights into T1D disease processes and to develop risk stratification methods from the integrated T1DI cohort of over 24,000 subjects (with >2.5 million visits), approximately 3% of whom eventually received a T1D diagnosis. The T1DI cohort represents the largest data set for any natural history T1D study to date and the study aims to inform both research and clinical practice.
Figure 1: Screening for multiple biomarkers at age 5. COOL has 10 main panels - P1-P10. P1 defines the evaluation cohort. P2 defines the screening schedules. P3 allows the user to evaluate and explore the screening results. P4 shows the screening performance. P5-P7 show high level information about the cohort. P8 shows the number of subjects by category based on screening results. P9-P10 show further insights that could guide the user to refine the screening.

Cohorts, such as those included in this study, are expensive to maintain, and population-based screening also faces logistical obstacles in the case of a disease with heterogeneous onset patterns spanning many years. To complicate matters, geographical and socio-demographic factors also affect outcomes. The challenge for the practitioner and the researcher is to understand the nature of their own data enough to devise an effective screening paradigm.

Given the number and potential variety of variables involved, this poses a computational challenge for most clinicians and clinical researchers, and we knew of no tools available for this purpose. We developed COOL to help address this need, first applying it to our real-world case study of risk screening for T1D using the T1DI cohort. We have worked closely with our clinical collaborators to assure that the tool offers them the flexibility they need to iteratively ask “what-if” questions to determine how varying screening frequencies and ages can affect their ability to identify potential cases in a timely manner, and tuned to their specific population. This tool is currently being used actively in the T1DI Study in our efforts to define potential screening schedules for T1D.

2 Method

COOL is designed to allow users to simulate screening schedules for a given population to maximize identification of at risk patients based on known biomarkers. Four questions from clinical investigators in the T1DI collaboration will illustrate the utility of this highly configurable tool to gain new insights, and iteratively generate new hypotheses.

2.1 Research Question 1: When to screen subjects for biomarkers?

Clinical investigators start with a hypothesis such as: early detection of multiple biomarkers is likely to identify subjects with high risk of disease. Once validated, they must determine when screening should occur. COOL provides an intuitive interface, shown in Figure that helps users define, evaluate, and interactively explore the results of proposed screening schedules. Panels 1-3 allow the user to define a proposed schedule and panels 4-8 show the results for the available population. Panels 9-10 show additional insights that can guide the user to further refinements. These panels are described in more detail in the context of our results below.
COOL can also help evaluate and compare performance metrics for proposed screening schedules by providing functionality to address common challenges with retrospective cohorts. For example, a clinician may want to evaluate if screening for multiple biomarkers at the age of 5 years is sensitive enough to identify at-risk children. The question is domain knowledge driven, but the user may require special analytic techniques to utilize available data since not every subject may have been tested for known biomarkers at age 5. COOL can examine a subject’s data for a biomarker sample within a 6-month window before and after the target age. If found, biomarker test results classify the subject as positive or negative. If a subject has no biomarker sample in the given window, the test is deemed missing. Subjects’ biomarkers are thus categorized as: positive, negative, or no test. To evaluate screening performance given these categories, we compute cumulative sensitivity ($\text{sen}$), dynamic specificity ($\text{spc}$), positive predictive value ($\text{ppv}$), and negative predictive value ($\text{npv}$). These metrics are computed as:

$$\text{sen} = \frac{tp}{tp + fn + np}, \quad \text{spc} = \frac{tn}{tn + fp + nn}, \quad \text{ppv} = \frac{tp}{tp + fp}, \quad \text{npv} = \frac{tn}{tn + fn}$$

where $tp$ is the number of diagnosed subjects diagnosed who tested positive for the biomarker. $tn$ is the number of diagnosis-free subjects who tested negative. $fp$ and $fn$ are the numbers of false positives and false negatives, respectively. $np$ is the number of diagnosed subjects with no test and $nn$ is the number of diagnosis-free subjects with no test. Note that the denominator of sensitivity includes diagnosed subjects who had no test, i.e. $np$. This penalizes screening sensitivity if many subjects were diagnosed before the proposed screening age, but enables the metric to capture data on as many subjects as possible.

Right-censored data from subjects who are lost to follow up pose challenges in evaluating screening schedules because their outcomes are often unknown. However, excluding these subjects introduces bias in risk estimation for disease onset. To account for censoring, we use inverse probability weighting or IPCW mechanism, which assigns weights to subject data based on probability of censoring. It assigns larger weights to subjects with known diagnosis to offset those for whom it is unknown by the study end. For example, if the probability of censoring after 10 years of followup since birth is 0.2, it means that for any subject diagnosed by age 10, there are on average 4 subjects censored before age 10 and one subject followed through age 10. IPCW assigns a weight of 5 to the followed subject to offset the 4 censored subjects. Thus when computing $tp$, $tn$, $fp$, $fn$, $np$, and $nn$ metrics, each subject $i$ is assigned weight $w_i$. This built-in feature enables users to get unbiased results despite incomplete outcome data.

2.2 Research Question 2: How to improve screening performance?

The objective of screening is to improve early identification of at-risk subjects, but which screening strategy will be the most effective: a specific biomarker? any biomarker? multiple biomarkers? Can we modify the testing age? or add an additional testing age to obtain more sensitive (and specific) screening?

COOL allows the user to configure screening strategies by age and compare across different ages. In addition, the tool is flexible enough that a user can configure age-specific screening tests and chain them, such as: screening for any biomarkers at age 2 and for a specific biomarker at age 5. Figure 2 shows how COOL computes the results of a chained screening strategy. The result is positive if the subject tests positive at the first or second age or both. Subjects with no tests are categorized as missing. All other subjects (both negative or one negative and one missing) are categorized as negative. The advantage of this approach is that it can be applied recursively to chain any number of different screening tests at different ages.

2.3 Research Question 3: Should we confirm positive screening tests?

It is common practice to confirm positive (biomarker) test to reduce the impact of false positives although the confirmation strategy may vary by test. Subjects who test positive typically require subsequent tests. For example, when a subject tests positive for multiple biomarkers in the screening sample, should the confirmatory test focus on the initial positive biomarker(s) or all biomarkers? This question was raised to consider different confirmatory strategies to use in practice. COOL provides 5 strategies for confirmation, shown in Figure 3a. These policies are illustrated in Figure 3b for the screen for any biomarker strategy. The table shows sample status of four biomarkers in screening (blue columns) and confirmatory (green columns) samples. Subject S1 initially tested positive for two biomarkers,
Figure 2: Chain screening tests.

Figure 3: (a) COOL provides five confirmation options. *No confirmation*: no confirmation required for positive screens. *Confirm for any *IAb*: positive screen confirmed if any confirmatory sample biomarker is positive. *Confirm for at least one initial positive *IAb*: positive screen confirmed only if at least one positive screening biomarker is positive in confirmatory sample. *Confirm for at least two positive *IAb*: positive screen is confirmed only if at least two positive screening biomarkers are positive in confirmatory sample. *Confirm for all initial positive *IAb*: the positive screen is confirmed only if all positive screening biomarkers are positive in confirmatory sample. (b) Blue columns show the status of four biomarkers, B1-B4, for subjects S1-S6. Green columns show biomarker status in the confirmatory sample. 1=positive(+), 0=negative(-). Screening results (+/-) are shown for each subject and confirmation strategy.

B1 and B4. If *no confirmation* strategy is used, then screening results would be positive for S1. The *Confirm for any biomarker* strategy confirms positive screen if any biomarker is positive in the confirmatory sample regardless of the biomarker status in the initial sample. Under this policy, S4 confirmed positive although only B2 was positive in the first sample and only B1 was positive in the second (confirmatory) sample. The *Confirm for at least one initial positive biomarker* strategy confirms positive only if at least one of the positive biomarkers in the first sample is confirmed in the confirmatory sample. For example, S2 would screen positive under this strategy because it had two positive biomarkers B1 and B4 in the first sample, and one of them, B1, was confirmed positive. Similarly, the *Confirm for at least two initial positive biomarkers* strategy confirms positive screen only if at least two biomarkers are confirmed positive. Finally, the *Confirm for all initial positive biomarkers* policy confirms positive screen only if all positive biomarkers in the first sample are confirmed. The user can create more confirmation policies that suit the problem domain (it is beyond the scope of this paper to explain how the user can configure the tool).

2.4 Research Question 4: Is the screening universal or population-specific?

A fundamental attribute of screening guidelines is whether or not they can be applied universally. For example, Finland has the highest incidence of T1D, while The United States has the second highest incidence in North America. Is
the screening population-specific or universal? To answer this question, the same screening schedule can be applied to different cohorts with different characteristics, comparing performance in different populations. COOL provides a built-in cohort construction panel. The user can choose the evaluation cohorts in panel (1) in Figure 1 and compare screening performance on each chosen cohort. Whenever a screening schedule is evaluated, its results are appended to the table in panel (4) so users can compare performance across cohorts.

3 Results on Type 1 Diabetes

The following results are based on the T1DI cohort where islet autoantibodies were measured during 15-year follow-up or until T1D diagnosis.

3.1 Answer to Research Question 1: When to screen subjects for multiple biomarkers?

We use panel (1) to select the desired cohort and age, starting with age 5 years (Figure 4a), and to evaluate screening on the demo cohort for T1D risk by age 15. In panel (2) (Figure 4a) the user defines 3 screening parameters: target age, test and confirmation. Various screening strategies are implemented in COOL, such as multiple biomarkers, any biomarker, or specific combinations of biomarkers. These screening tests are shown in Figure 4b. For example, screening for any GADA tests the presence of Glutamic Acid Decarboxylase Autoantibodies in the blood sample. Screening for Only IAA+IA2 tests for the presence of Insulin Autoantibodies (IAA) and Insulinoma Antigen-2 Autoantibody (IA-2A) in the absence of other antibodies (GADA). The screening tests are not hard coded but are configurable by the tool making it easy to add additional tests. In the current use case, we screen for multiple biomarkers. Let us start with the hypothesis of no confirmation to reduce the number of tests and based on the results we can refine these parameters.

![Figure 4: (a) Panels 1-2: parameters to define a screening schedule. (b) Different screening strategies based on three biomarkers IAA, GADA, and IA2.](image)

After the user defines the screening schedule they can evaluate and explore the results. The tool immediately computes the performance of the screening schedule to assess how likely subjects are to develop disease by the designated age. The table in panel (4) shows the results of the chosen screening as in Figure 5a. Sensitivity, specificity, PPV, and NPV metrics are computed for evaluation of the schedule.

Showing the accuracy of the screening test is valuable to estimate how likely the screened-positive subjects are to develop the disease. If the results are not satisfactory the user can alter the proposed schedule to obtain improved results. The tool displays helpful insights about the results to guide the user about possible changes to the screening schedule or strategy. Panel (8) (Figure 5b) shows the number of subjects screened positive (red group, n=227), screened negative (green group, n=2779), and not tested (blue group, n=2994). The blue group did not have biomarker samples at the screening age. In each subgroup, the panel shows the number of cases and controls between parentheses. This information highlights the fact that there are many subjects with missing tests. So, if the user wants to capture these subjects they may want to screen at a different age, but what age needs to be determined?
3.2 Answer to Research Question 2: How to improve screening performance?

The previous section insights suggest that adding another test at an early age may improve screening performance. The user refines the screening schedule to two tests, at age 2 and 5 in panel (1), as shown in Figure 7a. The table in Figure 7b appends the results of the current screening strategy to the previous one for easy user comparison. From here, they can see that screening twice may be helpful - at ages 2 and 5 increases sensitivity from 0.35 to 0.51 and specificity from 0.51 to 0.56. The user can repeatedly chain different screening tests until improved results are obtained.

The results show that screening for multiple biomarkers twice at ages 2 and 5 is likely to identify subjects who will develop type 1 diabetes by age 15, but, can we improve performance further without an additional screening age, for example by exploring different testing strategies? COOL allows the user to explore different strategies as shown in Figure 4b. Figure 8 compares two screening policies at same ages but with different tests, screening for any biomarker versus screening for multiple biomarkers at ages 2 and 5. Screening for any biomarker has 13 points higher sensitivity than screening for multiple biomarkers, yet retaining similar positive predictive value. A user in a policy making capacity can perhaps use these results to begin to optimize the most effective screening schedule and tests for the intended population. In addition, the tool is flexible enough to allow the user to experiment. For example, screen for any biomarkers at age 2 and then screen for a specific biomarker at age 5 (Figure 9).
3.3 Answer to Research Question 3: Should we confirm positive screen?

As shown in Figure 10, various confirmation strategies are evaluated for screening for any IAb. The results indicate that confirming for any IAb has comparable sensitivity to no confirmation but a slightly higher PPV.

3.4 Answer to Research Question 4: Is the screening universal or population-specific?

The domain-knowledge driven screening schedule can be applied to each cohort, and results for each can be compared to assess whether the chosen screening schedule is applicable only to the selected cohort or universally, i.e. to all sub-cohorts in the available dataset. Furthermore, the user can evaluate them based on various domain attributes, e.g. male vs. female, high vs. low-risk HLA etc.

4 Discussion

We developed a pragmatic tool, (COOL), to evaluate efficacy of simulated screening strategies for chronic conditions. We applied COOL to screening for development of autoimmunity in progression to T1D onset. In this scenario, past research has provided important insights from discovery of immune biomarkers in the pre-symptomatic phase of the disease. These insights have yet to be translated into practice, specifically for screening children at risk for diabetes. However, the lack of screening in practice can be attributed to multiple factors, including unknowns of cost effectiveness and psychological readiness of those being screened, but the consequences are dire if not addressed expediently. This report also stresses that the natural history of the disease is still not fully understood, particularly varying ages and rates of progression, and the influence of ethnicity and environment. A tool such as COOL can help users explore the underlying data from large natural history studies to unlock potential explanations.

Using the example of T1D in 15 years of follow up and by leveraging existing data on autoimmunity development from the T1DI study group, we have shown how COOL can simulate population-level screening. We have shown four practical applications of this tool for evaluating screening strategies. A user can craft one or more competing “knowledge-driven” screening strategies. Then, the user can refine these strategies in a data-driven way by exploring the impact of underlying population distributions. These explorations can lead to further insights to improve risk screening performance, e.g. to maximize “at-risk catchment”. Screening strategies can be further improved by “chaining” different screening tests by screening age, testing sequence, or from what may be otherwise known in the domain.
Different strategies can be compared and a host of other alternative strategies devised for further exploration. Based on previously mentioned comparisons, a user can fine tune strategies for intended risk screening, e.g. universal or population specific. Within the framework of strategy development, a user can refine performance for varying time horizons (e.g T1D onset in 5, 10, or 15 years) as the tool accounts for right censored data in an unbiased way. Lastly, the built-in workbench capabilities of the tool retains alternatively evaluated strategies, which a user can recall later and further refine, for example when more data become available. The tool can also do a brute force search (evaluate all possible combinations configured) to find the optimal strategy.

In many ways the T1DI cohort is a unique dataset for understanding screening requirements, and for development of enabling tools. Its large sample size, variations in follow-up schedules among constituent studies and recruitment of newborns from both the general population and children and adolescents with family history have helped with experimentation on the domain problem as well as the tool design. The data lends itself to understanding variations in population-level screening policies to yield early results. This may be important because large scale screening studies in the US and EU are currently ongoing. The TEDDY study, which has rigorously followed at-risk children from young ages for development of autoimmunity and T1D is currently ongoing. There is no doubt TEDDY will shed more light on currently unknown disease processes and consequently inform screening policies but it will not reach the 15 year follow up mark until 2024. In the interim, as we have shown, evaluation of competing screening policies with existing T1D cohorts may help in the T1D domain. All stakeholders such as clinicians, policymakers, patient families may be able to pose pertinent questions, generate new hypothesis to test in-silico with COOL and get rapid answers. These advances will ultimately pave the way for faster adoption of screening in practice.

COOL differs from other tools in many respects. It is a general purpose and highly configurable evaluation tool, with built-in cohort selection and exploration capabilities that gives the user guidance based on underlying data and questions. Similar tools have generally focused on one question at a time, for example, risk prediction in a given time horizon, or evaluating drug design metrics or a web-based application for health-screening and have rarely sought to add functionality such as “chaining” alternate or competing strategies for risk evaluation and, to the best of our knowledge, none has sought to retain and compare all user-defined strategies in one tool.

However, as with all work, this tool also has some limitations. We do not address evaluation of repeated screening (or monitoring) strategies for a single patient (personalized), though we aim to investigate it in the future using state of

the art machine-learning (e.g. reinforcement learning) approaches and incorporate it into the tool. In this work, we also specifically aimed at risk screening policies in the pre-symptomatic period of a disease. As currently there is no readily available data on cost or yield, the cost effectiveness of screening (to prevent disease or cost of testing) was not evaluated. However, we believe that when these data become available, COOL can be enhanced to attach cost to the results of a screening test for evaluating cost-effectiveness.

5 Conclusion

In conclusion, the present analysis shows that Collaborative Open Outcomes tool (COOL) can unlock invaluable datasets, particularly from natural history studies of chronic conditions, to evaluate the efficacy and propel adoption of screening programs and potentially even inform current clinical practices. One example may be in a similar autoimmune condition - inflammatory bowel disease, where there are known biomarkers but no general population screening in practice. The tool’s capabilities can be applied to many forms of real world evidence such as data from electronic health records from hospitals, clinics and physician practices, as well as disease registries. A tool such as COOL can greatly facilitate exploration and evaluation of potential screening paradigms by clinical staff, using available data, which can have important implications for both research and clinical practice.

Abstract
We develop various AI models to predict hospitalization on a large (over 110k) cohort of COVID-19 positive-tested US patients, sourced from March 2020 to February 2021. Models range from Random Forest to Neural Network (NN) and Time Convolutional NN, where combination of the data modalities (tabular and time dependent) are performed at different stages (early vs. model fusion). Despite high data unbalance, the models reach average precision 0.96-0.98 (0.75-0.85), recall 0.96-0.98 (0.74-0.85), and $F_1$-score 0.97-0.98 (0.79-0.83) on the non-hospitalized (or hospitalized) class. Performances do not significantly drop even when selected lists of features are removed to study model adaptability to different scenarios. However, a systematic study of the SHAP feature importance values for the developed models in the different scenarios shows a large variability across models and use cases. This calls for even more complete studies on several explainability methods before their adoption in high-stakes scenarios.

Introduction
As recently published1 during the COVID-19 pandemic, several AI-based models have been developed, targeting a large variety of application areas, such as identification of disease clusters, monitoring of cases, prediction of the future outbreaks, mortality risk, diagnosis of COVID-19, disease management, or vaccine development2. A thorough review found that almost all prediction models were trained on small or low-quality datasets, poorly reported and at a very high risk of bias or overfitting3. Due to the sense of urgency and the lax regulatory landscape, some of these models were even used without clinical validation, raising legitimate concerns about patient safety and model clinical validity4.

A way to build more robust AI prediction models is to adhere to the PROBAST framework, which provides a structured approach to assess potential risk of bias and applicability to the intended population and setting5. Transparent reporting can be achieved by following the TRIPOD checklist6. While the validation of the model "as-is" on external datasets is perceived as a proof of the generalization power of the model by some, this may be very difficult due to intrinsic differences in available populations, collected data, protocols and guidelines. Instead, a definitive important step forward would be to validate the models in real clinical settings by SMEs while in parallel improving their interpretability and correcting their bias with the help of explainability methods.

In this paper, we develop hospitalization prediction models on a large cohort of COVID-19 case data collected in the US from March 2020 to February 2021 and comprising more than 110k positive-tested patients (113941 upon data extraction, 110996 after further preprocessing). Knowing which patients are at risk for hospitalization for COVID-19-related symptoms or complications can help physicians decide not only how to best manage a patient’s care from the time of testing (e.g. remote monitoring, more frequent encounters), but also how to allocate resources. All the models reach relatively high performance despite the high class unbalance and the noise, typical of large real world datasets. We find however that despite the similar performance, different models lead to very different explanation results. While some hospitalization prediction models have been published7–10, they are generally built on smaller cohorts and do not systematically explore explainability methods across different AI models and feature subsets.

†Equal contributions
Methods

In this section we describe in details the various components of our approach: (i) Cohort definition; (ii) Data extraction: sourcing and preparation of data with partition of patient history in time intervals to enable increased flexibility during feature extraction; (iii) Feature extraction: accurate preparation and selection of features with special attention to data leakage prevention, missing data imputation, and proper feature encoding for capturing the temporal dimension of the data; (iv) Model development, where we experiment with time dependent and independent models (early and model fusion of temporal and Boolean modalities), (v) Internal testing and adaptability of the model for the use in several settings, by reducing the number of features used to train the model or varying the time interval between predictor assessment and outcome determination, and (vi) Model explainability.

Cohort definition

Our analysis was performed on the IBM Explorys Electronic Health Record (EHR) Database[1], which contains real-world clinical, operational, and financial data, spanning various healthcare aspects, from ambulatory to inpatient to specialty care. Explorys data are sourced from integrated delivery networks (IDN), clinically integrated network providers (CIN), and care collaborative groups (CC) and are constantly updated with incoming records. Data are curated, standardized, and normalized by using medical international coding standards, classification systems, ontologies, and lab unit measures such as ICD-10, SNOMED, LOINC, and RxNorm. Furthermore, data are searchable through a de-identified database. Explorys data have been used by the medical community for several studies, such as recently for building a predictive model for chronic kidney disease[2].

We used data collected from March 2020 to February 2021. To draw evidence of COVID-19 infection we used diagnoses and observations. We defined two evidence classes for COVID-19 diagnoses, confirmed and suspected, and examined the diagnosis fields ICD-10 code, the SNOMED concept, and a short diagnosis description snippet available in our source EHR data. As confirmed we defined the diagnoses explicitly registered with the ICD-10 code “U07.1”, which was introduced by the WHO in April 2020 for use “when COVID-19 has been confirmed by laboratory testing irrespective of severity of clinical signs or symptoms”. Diagnoses with the ICD-10 code “U07.2” (for use “when COVID-19 is diagnosed clinically or epidemiological but laboratory testing is inconclusive or not available”) were classified as suspected. Where the above COVID-19-specific codes were absent, we searched for a set of specific COVID-19-associated text patterns in the diagnosis description as well as in SNOMED concept name (SNOMED search was performed in a hierarchy-aware manner, as described later. Pattern matches were classified as suspected, unless detected by a set of exclusion patterns we defined, in which case the diagnoses were altogether disregarded from further analysis. To extract observation-based COVID-19 evidence, we used LOINC “94500-6”, which is the recommended code when (i) the gene or region being tested is not specified and a qualitative result is being reported (e.g., Detected/Not detected); or (ii) a single qualitative overall result based on a combination of individual test results is being reported, and also by far the most frequently occurring COVID-19 diagnostic test LOINC code in the data. Observations registered with LOINC code “94500-6” and positive result were defined as positive-test[3].

As cohort of interest we defined the one consisting of patients who had both a COVID-19 diagnosis, whether suspected or confirmed, and a positive-test observation within a time frame from 4 weeks prior to their earliest COVID-19 diagnosis up to 4 weeks following it. This cohort finally comprised 113941 patients. A statistic summary can be seen on Table[1]. Restricting the cohort only to patients with confirmed COVID-19 diagnosis and positive-test observation in the same time frame as above did not lead to significantly different results. We excluded patients who had a COVID-19 diagnosis but no positive-test observation, in order to reduce noise and focus on cases documented more completely in our EHR data. The absence of an explicit positive-test, is indeed ambiguous and can be explained either by the patient having been diagnosed by other means, e.g. chest CT, or as missing information, e.g. case not properly documented, test done in other institutions or unavailable (selection bias was not studied in detail, but the demographic distribution when including such “diagnosis-only” patients was similar to that of our defined cohort). A schema of the cohort selection is given in Figure[1].

*Testing availability was very limited until March-April 2020.
Figure 1: Left: cohort selection process. Right: Time partitioning of patient’s history referenced to the COVID-19 diagnosis and collected features over time intervals (Blue). Selection of features over the period of interest for an exemplary patient hospitalized 6 days after the diagnosis (Colored regions).

Data extraction

For each patient belonging to the cohort, we extracted demographics (age, gender), medical conditions (chief complaints, symptoms, comorbidities), vital signs and laboratory measurements, based on literature findings and SME input. With the exception of the demographics, all pieces of information were extracted with their corresponding timestamp. To capture the temporal dimension of the data, but also to reduce complexity, each patient journey was partitioned into various time intervals using the patient’s earliest COVID-19 diagnosis as reference point. Each variable was then extracted in an aggregated manner for each interval. The partitioning is depicted in Figure 1 and was designed to allow a greater focus from the diagnosis time onward.

To maximize recall, the same approach based on SNOMED and text pattern matching used to extract the COVID-19 diagnosis was used to extract symptoms, comorbidities and other medical conditions. In the case of SNOMED search, we performed a hierarchical pattern matching including also matched ancestors and using exclusion patterns to reduce false positives. We assigned a Boolean values to each medical condition in each time interval. Measurements and test results were extracted from the observation data, using corresponding LOINC codes and were normalized into a single unit. For each observation we extracted one, in most cases continuous, numeric variable per time interval, representing the patient’s most recently observed value in that interval, as well as the minimum, maximum, average. The patterns and codes used for data extraction were compiled in cooperation with SMEs.

Figure 2: Number of COVID-19 cases by number of weeks since January 1, 2020.
In order to determine if a patient had been hospitalized in a given time interval, we examined the patient interactions with the healthcare providers, as captured in the patient’s encounter data. A patient was considered hospitalized in a time interval $T$, if they had an encounter with (i) encounter type inpatient, hospital emergency room visit or hospital encounter, (ii) admission date within $T$, AND (iii) duration above 24 hours. To exclude cases potentially hospitalized due to reasons other than COVID-19, patients with a hospitalization within the 4 weeks prior to the COVID-19 diagnoses were removed. After this cleanup step, patients with a hospitalization in the 4 weeks following the COVID-19 diagnosis were considered hospitalized due to COVID-19; we will refer to these patients simply as “hospitalized”. Interestingly, 79% of the hospitalized patients were admitted within 4 days following the COVID-19 diagnosis. The prediction target of our models was based on these COVID-19 hospitalization labels. It must be noted that some patients may be hospitalized in other institutions not part of the Explorys network, producing noise in form of false negatives. A possible reason could be bed unavailability due to sudden spikes in demand. The temporal distribution of hospitalized and non-hospitalized cases is illustrated in Figure 2.

Data preparation and feature extraction

Possible bias in the data was removed by discarding all features related to ethnicity, race, medical insurance type, location and any other available information not related to the medical conditions of the patient. Used feature types were demographics (age, gender), clinical presentation (symptoms, vitals, other medical conditions, comorbidities) and lab measurements. These categorical and continuous variables were associated to specific time intervals as previously described. We removed patients in case age information was unavailable or if all other features were empty. Missing values were replaced using data imputation methods, and features were encoded (e.g., one hot encoding for the age groups), after randomly splitting the data as 70% train set and 30% test set. More precisely, missing values for Boolean features were imputed with false, while continuous features were imputed with median substitutions learned on the train set. After feature imputation, we performed data normalization using average and standard deviation computed on the train set. For comorbidities and chronic conditions, mentions over all the available time intervals were aggregated using disjunction (“OR”) into a single Boolean feature (condition is present). For the other feature types, in order to avoid data leakage we selected only the time intervals from 14 days prior to the diagnosis up to the hospitalization (period of interest) with an upper limit of 28 days after COVID-19 diagnosis. Labs and vitals were kept with the corresponding time information, while all other Boolean medical conditions including symptoms were aggregated over the period of interest. We are aware that from a medical perspective the knowledge of whether a symptom was present for one or more consecutive days would be important to build the model, unfortunately our data did not consistently contain this type of information. Finally, for some conditions (i.e., stroke) we used the time intervals to distinguish between conditions belonging to the medical history of the patient (“past”) or to the period of interest. After the preprocessing steps described above the cohort comprised a total number of patients [110996], non-hospitalized [97082, %87] and hospitalized [13914, %13]. Since most patients were hospitalized within 4 days from the COVID-19 diagnosis date and given the sparsity of the features over time, we explored two approaches that combine the two data modalities (time series and tabular) at different stages in the model. In the first approach, the features from the two modalities were concatenated (early fusion) in an ordered feature vector $X = [X_1, X_2]$ where $X \in \mathbb{R}^{n \times k}$ with $n$ and $k$ the total numbers of patients and features, respectively. Data modality $X_1 \in \mathbb{R}^{n \times h}$ contains tabular data such as gender, age groups, comorbidities and other Boolean medical conditions, for a total of $h$ time-independent features. Data modality $X_2 \in \mathbb{R}^{n \times m \times t}$ contains $m$ features collected over $t$ time intervals, such as lab values and vitals. Concatenation of the modalities was performed after reshaping the second modality to a two dimensional matrix. In the second approach, the modalities $X_1$ and $X_2$ are fed into two different architectures, and their hidden representations are subsequently merged in the model (model fusion). Upon the described preprocessing, the total number of features $k = m \times t + h$ is $k = 1573$ with $h = 77$, $m = 88$ and $t = 17$.

Statistics

Statistical analysis was performed to compare the hospitalized ($H_1$) and non-hospitalized ($H_0$) populations and compute the significance on the rejection of the null hypothesis that there is no relationship between predictor and outcome. Demographic information, symptoms, comorbidities and other medical conditions are presented (as %) in Table 3, while median and IQR values for lab measurements and vitals are presented in Table 4. Comparison of the $H_1$ and
year old patients. A higher percentage of patients with symptoms were hospitalized (78.3%) of the 28.3% of the patients for which symptoms are actually known. Several of the conditions more commonly associated with older age: eighty year old patients are 4 times higher in nicotine dependence, chronic kidney disease). Our analysis shows increasing hospitalization admissions associated with progression (e.g. pneumonia, hypoxia, hypoxemia) or comorbidities and risk factors (e.g. hypertension, diabetes, nicotine dependence, chronic kidney disease). 

When comparing the percentages of symptoms and comorbidities reported in Table 2 to existing statistics, it should be noted that these numbers were calculated on the preprocessed dataset upon removal of all features collected after hospitalization. Large variability is generally observed across publications, likely due to differences in the cohorts, the way data were collected and the time the patient met the caregiver in their disease progression journey (e.g. at triage vs hospitalization). In the laboratory-confirmed US cohort described in Table 2, cough is reported in about 50% and fever in 43% of the 28.3% of the patients for which symptoms are actually known. Several of the conditions more commonly found in H1 in Table 2, are in agreement with literature findings, either as conditions correlated to severe disease progression (e.g. pneumonia, hypoxia, hypoxemia) or comorbidities and risk factors (e.g. hypertension, diabetes, nicotine dependence, chronic kidney disease). Our analysis shows increasing hospitalization admissions associated with older age: eighty year old patients are 4 times higher in H1 than H0, and 2 times higher for seventy and sixty year old patients.

Regarding the lab values reported in Table 3, it should be noted that these values are recorded before hospital admission.

Table 2: Demographic information, pre-existing comorbidities and acute conditions in % on COVID-19 positive patients. Comparison of non-hospitalized (H0) and hospitalized (H1) groups is performed with a \( \chi^2 \) contingency analysis with post-hoc correction (Benjamini–Hochberg procedure) is shown in the table with two asterisks when p-values < 0.001. Gender is one for males and zero for females.

H0 groups was performed with a \( \chi^2 \) contingency analysis for the Boolean feature and Mann–Whitney U test for the numerical ones. In our analysis we used post-hoc correction with the Benjamini–Hochberg procedure. Two asterisks were assigned when p-values are < 0.001.
where diagnoses of acute conditions are not available and the results of some very specific tests not accessible, we adaptability to different use cases, we removed selected lists of features. To emulate general practitioner settings (GP), we have defined a custom loss and weighted random sampling of the training data to take into account the high class unbalance.

To reduce overfitting. Comparing to the architecture trained by the Auto AI model with three dense layers followed by batch Stochastic Gradient Descend with momentum, learning rate was varied with a step scheduler and dropout used the number of epochs and let the library to find the best performing model. NN and T-CNN were optimized using mini iterations. The number of samples required to split an internal node, the minimum number of samples required to be at a leaf node parameters such as number of trees, number of features to consider for the best split, maximum tree depth, minimum split of the dataset into train, validation, and test sets was performed several times varying the seed.

During training we performed 3-fold cross validation and selected the best performing (best $F_1$-score) model on the validation set. Splitting of the dataset into train, validation, and test sets was performed several times varying the seed for the splitting. Precision, recall and $F_1$-score were collected by computing average and standard deviation over all iterations. RF and ET models were trained with a randomized parameter optimization to search for the optimal hyper-parameters such as number of trees, number of features to consider for the best split, maximum tree depth, minimum number of samples required to split an internal node, the minimum number of samples required to be at a leaf node either using the whole sample or bootstrapping. For the AutoKeras models we have varied the number of iterations and the number of epochs and let the library to find the best performing model. NN and T-CNN were optimized using mini batch Stochastic Gradient Descend with momentum, learning rate was varied with a step scheduler and dropout used to reduce overfitting. Comparing to the architecture trained by the Auto AI model with three dense layers followed by ReLu activation function and to emulate the same behavior of the NN (T-CNN) used in the training.

Prediction of hospitalization up to 28 days after COVID-19 diagnosis was modelled as a binary classification ($H_1$; hospitalized, $H_0$; not hospitalized). For early fusion approach we trained the following models: Random Forest classifier (RF), Extra Trees classifier (ET), fully connected neural network (NN) and Auto AI architectures (AutoKeras).

For the model fusion approach we trained an architecture combining NN for the time-independent modalities and temporal convolutional neural network (T-CNN) for the time-dependent one. The two models were combined together with additional NN layers. The T-CNN is a convolutional neural network consisting of 1-D temporal convolutions. During training we performed 3-fold cross validation and selected the best performing (best $F_1$-score) model on the validation set. Splitting of the dataset into train, validation, and test sets was performed several times varying the seed for the splitting. Precision, recall and $F_1$-score were collected by computing average and standard deviation over all iterations. RF and ET models were trained with a randomized parameter optimization to search for the optimal hyper-parameters such as number of trees, number of features to consider for the best split, maximum tree depth, minimum number of samples required to split an internal node, the minimum number of samples required to be at a leaf node either using the whole sample or bootstrapping. For the AutoKeras models we have varied the number of iterations and the number of epochs and let the library to find the best performing model. NN and T-CNN were optimized using mini batch Stochastic Gradient Descend with momentum, learning rate was varied with a step scheduler and dropout used to reduce overfitting. Comparing to the architecture trained by the Auto AI model with three dense layers followed by ReLu activation function and to emulate the same behavior of the NN (T-CNN) used in the training.

First, we built the models using all available features to have baselines (all features use case). Then, to test model adaptability to different use cases, we removed selected lists of features. To emulate general practitioner settings (GP), where diagnoses of acute conditions are not available and the results of some very specific tests not accessible, we

Table 3: Median and IQR of the time dependent features reported in the EHR close to the COVID-19 diagnosis. Comparison of non-hospitalized ($H_0$) and hospitalized ($H_1$) groups is performed with Mann–Whitney U test with post-hoc correction (Benjamini–Hochberg procedure) is shown in the table with two asterisks when $p$-values < 0.001.
removed the following: pneumonia, hypoxia, hypoxemia, myocarditis, all sepsis related conditions, acute respiratory distress syndrome, heart disease, pneumothorax, acute renal failure syndrome, thromboembolic disorder, acute hepatic failure, pulmonary embolism, renal failure syndrome, embolism, acute disease of cardiovascular system and lab tests such as D-dimer and hsTnT. This GP use case was designed under SMEs guidance. Finally, to test the model predictive power over time, we removed all available features in the day prior to the hospitalization for hospitalized patients (one day before use case). This drastically reduces the availability of lab values and vitals. Average precision, recall, $F_1$-score are given in Table 4 for the all feature use case, the GP use case and the one day before use case, as first, second and third values in the series, respectively. NN and T-CNN architectures were frozen across all use cases. In all described use cases, all analysed models achieved relatively high classification performance despite the unbalanced dataset. There is a minimal difference amongst the time dependent T-CNN model performance and the NN and the Auto Keras models for all features and the GP use cases. Drop of $F_1$-score when using a smaller number of features was limited to few percentages for all the models, at the exception of the T-CNN in one day before use case. The observed similar performances of the models may be due to the presence of several predictive features in the dataset, most likely, more than the dropped ones.

Table 4: Hospitalization prediction in terms of average precision (P), recall (R), $F_1$-score (F) within 28 days after the COVID-19 diagnosis by using (i) all available features prior to the hospitalization, (ii) carefully removing a selected list of features with guidance of SMEs, and (iii) removing all available features up to one day prior to the hospitalization.

To determine which features have the largest predictive power and assess model interpretability, we explored feature importance methods. Although several studies used MDI importance on datasets containing numerical features, we disregarded it, given its sensitivity to high-cardinality features. In addition, commonly used libraries compute MDI-based importance values on the training set and therefore the extracted important features are not useful to make predictions that generalize on the test set. Instead, we focused on the SHAP method and report feature importance values computed on the test set. Regarding the NN and T-CNN models, SHAP values computed with the gradient based approximation are very similar to the ones computed using different not-gradient-based approximations. Therefore we did not regularize the gradients during training as suggested by. The top 35 SHAP values computed on the RF and NN trained with all available features are given in Figure 3 (corresponding plots for ET and CNN have been omitted due to their similarity to the RF and the NN plots, respectively). Median of the absolute SHAP values and corresponding interquartile ranges (IQR) are reported with colored boxes, $1.5 \times$ IQR ranges with whiskers and mean of the absolute values with white circles. Although some features overlap (12/35, 34%), lab values and vitals are predominant in RF (60%) while a minority in the NN model (6%). This is even more accentuated after dropping the list of Boolean medical conditions in the GP use case (lab values 71% in RF vs 6% in NN, Figure 4). When removing all features up to one day prior to the hospitalization, the number of lab values available to the model drops consistently and in this case the overlap between important features for the two models increases up to 25/35 (71%).

For the Boolean conditions, a high level agreement is observed between the information of Table and the feature importance results shown in Figures. However, the statistical analysis is performed feature by feature and is fundamentally different from the feature importance model described. The latter is based on a predictive model which takes into account feature combination during the decision process and hence does not require features to be independent. In both cases, presence of relationship from the statistical analysis or importance from the SHAP method does not imply causality. Reason for hospitalization comes from combination of several factors.
Cerebrovascular disease (past)  Acute renal failure syndrome  Acute renal failure syndrome  Coronary heart disease

Figure 3: Median SHAP values for the RF (left panel) and NN (right panel) computed on the test sets (across all splits) and using all available features. Corresponding interquartile ranges (IQR) are reported with colored boxes, 1.5× IQR ranges with whiskers and mean values with white circles.

Figure 4: Same as Figure 3 but using a restricted number of available features. See text for further details.

Conclusions

We developed several AI models (RF, ET, NN, T-CNN) to predict hospitalization on a large cohort of COVID-19 patients (more than 110k) up to 28 days after the diagnosis, with competitive classification results on the test set. Despite the large data unbalance, using available features prior to the hospitalization, the models reach average 0.96-0.98 (0.75-0.85) precision, 0.96-0.98 (0.74-0.85) recall, and 0.97-0.98 (0.79-0.83) F1-score across all split iterations for H0 (H1). Similar results were obtained in more restrictive scenarios with lower number of available features, even when features ranked as top by importance models were removed from the baseline model (GP use case). We then systematically explored the SHAP feature importance method for all analysed models in all the use cases and observed an overall agreement with the results of the statistical analysis on the Boolean medical conditions. However, the observed
Figure 5: Same as Figure 3 but for RF and NN models after removing features.

large variability of the SHAP importance score across models calls for a careful usage of the importance results, their evaluation across different models and methods. When deriving feature importance, methods that can handle feature correlation like SHAP should be used or analysis of feature correlation carefully conducted. Undesired dependencies as the ones shown in this study need to be carefully evaluated before adoption in high-stakes decision.

Limitations

In this retrospective study we tried to adhere as much as possible to the PROBAST framework, in the constrained setting of this use case: hospitalization prediction requires a large dataset of hospitalized and non-hospitalized patients and therefore data sources of different provenience are needed (eg., GP office visits, emergency, hospital encounters). This means that if a patient left or suddenly came into the Explorys network for whatever reasons (e.g., hospitalized in other hospitals or regions), outcomes and data may be missing. This may lead also to large variability in laboratory values and measurements. Our models were not tested on external datasets or in clinical settings due time constraints.

Abstract

Analysing electrocardiograms (ECGs) is an inexpensive and non-invasive, yet powerful way to diagnose heart disease. ECG studies using Machine Learning to automatically detect abnormal heartbeats so far depend on large, manually annotated datasets. While collecting vast amounts of unlabeled data can be straightforward, the point-by-point annotation of abnormal heartbeats is tedious and expensive. We explore the use of multiple weak supervision sources to learn diagnostic models of abnormal heartbeats via human designed heuristics, without using ground truth labels on individual data points. Our work is among the first to define weak supervision sources directly on time series data. Results show that with as few as six intuitive time series heuristics, we are able to infer high quality probabilistic label estimates for over 100,000 heartbeats with little human effort, and use the estimated labels to train competitive classifiers evaluated on held out test data.

Introduction

Automatic analysis of electrocardiograms (ECGs) promises substantial improvements in critical care. ECGs offer an inexpensive and non-invasive way to diagnose irregularities in heart functioning. Arrhythmias are abnormal heartbeats which alter both the morphology and frequency of ECG waves, and can be detected in an ECG exam. However, identifying and classifying arrhythmias manually is not only error-prone but also cumbersome. Clinicians may have to analyze each heartbeat in an ECG record, and in critical care settings, carefully analysing each heartbeat is nearly impossible. As a consequence, the medical machine learning (ML) community has worked extensively on computational models to automatically detect and characterize arrhythmias1,2.

Rajpurkar et al.3 demonstrated that modern ML models trained on a large and diverse corpus of patients can exceed the performance of certified cardiologists in detecting abnormal heartbeats. But their Convolutional Neural Network model was trained on a manually annotated dataset of more than 64,000 ECG records from over 29,000 patients. Clearly, research on automated arrhythmia detection has moved the burden of monitoring ECG in critical care to annotating and curating large databases on which ML models can be trained and validated. This currently prevailing process involves laborious manual data labeling that is a major bottleneck of supervised medical ML applications in practice. Popular ML techniques, in particular deep learning, require a large supply of reliably annotated training data, containing records from a diverse cohort of patients. According to Moody et al.4 and our own experience, raw medical data is abundant, but its thorough characterization can be involved and expensive. This reliance on labeled data forces researchers to often use static and older datasets, despite evolving patient populations, systematic improvements in understanding of diseases, and advances in medical equipment.

Recent developments in e.g. web-based tools to visualize and annotate ECG signals have not reduced the annotation time and effort significantly. For example, it took 4 doctors, almost 3 months to annotate 15,000 short ECG records using the LabelECG tool5. In general, gold standard expert annotations can be costly. Conservative estimates place the hourly cost of highly qualified labor for the related task of EEG annotation between $50 and $200 per hour6.

In this work, we explore the use of multiple cheaper albeit perhaps noisier supervision sources to learn an arrhythmia detector, without access to ground truth labels of individual samples. We follow the recently proposed data programming (DP)7 framework in which a factor graph is used to model user-designed heuristics to obtain a probabilistic label for each heartbeat instance. DP has gained attention from the medical imaging and general ML community and has been used for various tasks such as automated detection of seizures from electroencephalography8, intracranial hemorrhage detection with computed tomography, or automated triage of Extremity Radiograph Series9.

Our experiments with ECG data from the MIT-BIH Arrhythmia Database indicate that with as few as 6 heuristics, we are able to train an arrhythmia detection model with only a small amount of human effort. The resulting model
Figure 1: Data programming with time series heuristics can affordably train competitive end models for automated ECG adjudication. Instead of labeling each data point by hand (fully supervised setting), experts encode their domain knowledge using noisy labeling functions (LFs). A label model then learns the unobserved empirical accuracy of LFs and uses them to produce probabilistic data label estimates using weighted majority vote.

is competitively accurate when compared to a model trained on the same data with full supply of pointillistic ground truth annotations. It can also outperform another alternative model trained using active learning, a popular technique used to reduce data labeling efforts when they are expensive. We also show that domain heuristics can be automatically tuned to account for inter-patient variability and further boost reliability of the resulting models.

While many different types of arrhythmias exist, for illustration purposes we focus on identifying heartbeats showing Premature Ventricular Contractions (PVCs). Whereas isolated infrequent PVCs are usually benign, frequent PVCs with exceptionally wide QRS complexes† may be indicative of heart disease and eventually lead to sudden cardiac death\textsuperscript{10}. However, our approach is general and applicable to all classes of abnormal heartbeats.

Related Work

Automated Arrhythmia Detection Automatically detecting abnormal heartbeats is a widely studied problem. Most researchers in the past relied on manually labeled corpora such as the MIT-BIH Arrhythmia Database, the AHA Database for Evaluation of Ventricular Detectors, etc., to train and validate their models\textsuperscript{1, 2}. Rajpurkar et al.\textsuperscript{3} recently demonstrated that a deep Convolutional Neural Network (CNN) can even exceed the performance of experienced cardiologists. However, their model was trained on as many as 64,121 thirty-second ECG records from 29,163 patients, manually-labeled by a group of certified cardiographic technicians. Hence, to fuel advances in automated arrhythmia detection and, more generally, in ML-aided healthcare, there is a clear need to affordably label vast amounts of data.

Some recent studies have attempted to address the annotation bottleneck, albeit at a different context and scale. These studies have used semi-supervised or active learning to incrementally improve the accuracy of models without significant expert intervention. For instance, to overcome inter-patient variability without additional manual labeling of patient specific data, Zhai et al.\textsuperscript{11} iteratively updated the preliminary predictions of their trained CNN using a semi-supervised approach. Correspondingly, Wang et al.\textsuperscript{12} used active learning on newly acquired data to choose the most informative unlabeled data points and incorporate them in the training set. Sayantan et al.\textsuperscript{13} used active learning to improve their model’s classification results with the help of an expert. So far, the work which comes closest to addressing the problem of intelligently labeling vast quantities of ECG data is that of Pasolli et al.\textsuperscript{14}. Starting from a small sub-optimal training set, the authors proposed three active learning strategies to choose additional heartbeat instances to further train an Support Vector Machine (SVM) model. Their work demonstrated that models trained using active learning can achieve impressive performance while using few labeled samples. In this work, we also compare the performance of our weakly supervised method with active learning. As against Pasolli et al.\textsuperscript{14} who used a manually

†QRS complexes are generally the most prominent spike seen on a typical ECG. They are a combination of the Q wave, R wave and S wave, which occur in rapid succession, and represent an electrical impulse.
curated set of ECG features and trained an SVM using margin sampling, we train a Convolutional Neural Network (CNN) which can automatically learn rich feature representations using uncertainty sampling, another popular active learning strategy.

**Weak Supervision** Of late, some studies have explored the use of multiple noisy heuristics to programatically label data at scale. The recently proposed Data Programming framework\(^7\), where experts express their domain knowledge in terms of intuitive yet perhaps noisy labeling functions (LFs), is a prominent example. Recent studies have used DP for a wide range of clinical applications, ranging from detecting aortic valve malformations using cardiac MRI sequences\(^8\), seizures using EEG\(^9\) and brain hemorrhage using 3D head CT scans\(^9\). With the exception of Khattar et al.\(^10\), most prior work on DP has been on image\(^8,15\) or natural language\(^17\) modalities. Moreover, prior DP research either used weak annotations from lab technicians, students\(^8\), or heuristics built on auxiliary modalities (e.g., clinician notes, text reports\(^9\), patient videos\(^8\)), some of which only allow for coarse annotation of the entire time series rather than of the individual segments. On the contrary, we define heuristics directly on time series. This enables seamless labeling of entire time series or their segments using the same framework.

**Methodology**

In this section, we will describe how we use domain knowledge to define heuristics to detect PVC in ECG time series. These heuristics will noisily label subsets of data. We will model these noisy labels to obtain an estimate of the unknown true class label for each data point. We then use the estimated labels to train the final classifier, which will be evaluated on held out test data and compared to alternative models trained using ground-truth labels directly. Fig. 1 describes the full workflow we follow to train the end model \(f\).

**Domain Knowledge to Identify PVC** A Premature Ventricular Contraction is a fairly common event when the heartbeat is initiated by an impulse from an ectopic focus which may be located anywhere in the ventricles rather than the sinoatrial node. On the ECG, a PVC beat appears earlier than usual with an abnormally tall and wide QRS-complex, with its ST-T vector directed opposite to the QRS vector, Fig. 2(ii). These generic characteristics allowed one non-domain-expert user to define 6 heuristics in less than 30 minutes. The user was initially unfamiliar with clinical ECG interpretation and referred to an online textbook\(^18\) to develop heuristics. Expert clinicians are likely able to define heuristics more rapidly and thoroughly. The heuristics listed below are defined directly on time series. This is in contrast to prior work which uses weak annotations or heuristics defined on an auxiliary modality such as text or images.

**Heuristics:** i. R-wave appears earlier than usual, ii. R-wave is taller than usual, iii. R-wave is wider than usual, iv. QRS-vector is directed opposite to the ST-vector, v. QRS-complex is inverted, vi. Inverted R-wave is taller than usual.

**Modeling Labeling Functions over Patient Time Series** We will now describe our formal assumptions about the dataset and heuristics, and introduce the modeling procedure. Given an ECG dataset of \(p\) patients \(X = \{x^j\}_{j=1}^p\), where \(x^j \in \mathbb{R}^T\) are raw ECG vectors of length \(T\), we can segment each ECG \(x^j\) into \(B < T\) beats such that \(x^j = \{x^j_1, \ldots, x^j_B\}\). Each segment \(b \in \{1, \ldots, B\}\) has an unknown class label \(y_b \in \{-1, 1\}\), where \(y_b = 1\) represents a premature ventricular contraction (PVC). Our goal is to use domain knowledge to model the unknown \(y_b\), without having to annotate the instances individually, to then train an end classifier \(f(x^j_B) = y_b^j\) for automatic detection of PVC. We define \(m\) labeling functions (LFs) \(\{\lambda_h(x^j_i)\}_{h=1}^m\) directly on the time series. These LFs noisily label subsets of beats with \(\lambda_h(x^j_i) = \{-1, 0, 1\}\) corresponding to votes for negative, abstain, or positive. These LFs do not have to be perfect and may conflict on some samples, but must have accuracy better than random\(^9\). DP uses this voting behavior to infer true labels by learning the empirical accuracies, propensities and, optionally, dependencies of the LFs via a factor graph. We use a factor graph as introduced in Ratner et al.\(^7\) to model the \(m\) user defined labeling functions. For simplicity, we assume that the LFs are independent conditioned on the unobserved class label. Let \(Y^j = (y^j_1, \ldots, y^j_B) \in \{-1, 1\}^B\) be the concatenated vector of the unobserved class variable for the \(B\) beat segments of patient \(j\) and \(\Lambda^j = \{-1, 0, 1\}^{B \times m}\) be the LF output matrix where \(\Lambda^j_{ik} = \lambda_k(x^j_i)\) is the output of LF \(k\) on beat \(i\) of
patient \( j \). We define a factor for LF accuracy as

\[
\phi^{Acc}_{i,k}(\Lambda, Y) \triangleq 1\{\Lambda_{ik} = y_i\}
\]

We also define a factor of LF propensity as

\[
\phi^{Lab}_{i,k}(\Lambda, Y) \triangleq 1\{\Lambda_{ik} \neq 0\}
\]

Then, the label model for a patient \( j \) is defined as

\[
p_{\theta}(Y^j, \Lambda^j) \triangleq Z_{\theta}^{-1} \exp\left( \sum_{i=1}^{B} \sum_{k=1}^{m} \theta_k \phi^{Acc}_{i,k} (\Lambda^j_i, y^j_i) + \sum_{i=1}^{B} \sum_{k=1}^{m} \theta_k \phi^{Lab}_{i,k} (\Lambda^j_i, y^j_i) \right)
\]

where \( Z_{\theta} \) is a normalizing constant. We use Snorkel\(^{17}\) to learn \( \theta \) by minimizing the negative log marginal likelihood given the observed \( \Lambda^j \). Finally, as introduced in Ratner et al.\(^{7}\), the end classifier \( f \) is trained with a noise aware loss function that uses probabilistic labels \( \hat{Y}^j = p_{\theta}(Y^j|\Lambda^j) \).

**Figure 2:** Examples of a normal (i) and PVC (ii) heartbeat. Dotted green horizontal lines represent the ECG baselines detected during pre-processing, blue and red vertical lines mark the QRS-complexes and T-waves.

**From Domain Knowledge to an Automated Arrhythmia Detector** First, we minimally pre-processed the raw ECG signals by removing baseline wandering using a forward/backward, fourth-order high-pass Butterworth filter\(^{20}\).

To segment ECG \( (x^j) \) into individual beats \( (x^j_b) \), we followed a simple segmentation procedure, where we considered the time segment between two alternate QRS-complexes to be a heartbeat.

We had to determine the precise locations of the QRS-complexes and T-waves. As in most prior work, we used the approximate locations of the R-wave available for each ECG record in the database, along with Scipy’s peak finding algorithm\(^{21}\) to find the exact locations of the R and T waves. Further, we used the RANSAC algorithm\(^{22}\) to fit a robust linear regression line to each ECG record, to determine its baseline (horizontal green lines in Fig. 2). The baselines were used to accurately characterize the height and depth of the R and T-waves\(^{‡}\) (blue and red vertical lines in Fig. 2).

Next, we defined 6 simple LFs based on the domain knowledge to assign probabilistic labels (PVC, OTHER or ABSTAIN) to each beat. Fig. 4 provides example pseudocodes for two of the LFs that were defined. To express the loosely-defined domain knowledge we described previously as LFs, we have to automatically assign thresholds to them. For instance, one heuristic to identify a PVC beat is to check whether its “R-wave appears earlier than usual”. To turn this heuristic into a LF (LF\(_{Early \text{ R-wave}}\)), one has to determine the “usual” position of the R-wave. For this, we used the Minimum Covariance Determinant algorithm\(^{23}\) to find the covariance of the most-normal subset of the frequency histogram. We then set the threshold to the value 2 standard deviations away from the estimated mean in the direction of interest. For example, for a particular subject (Fig. 3) LF\(_{Early \text{ R-wave}}\) returns PVC for any beat with the R-wave appearing earlier than \( T_{Early \text{ R-wave}} = 238 \text{ ms} \) (vertical green line). To account for inter-patient variability, we automatically compute these subjective thresholds for each heuristic and every patient separately. Note that some of our heuristics did not require estimating any subject-specific parameters.

\(^{‡}\)The topological prominence measure returned by Scipy’s peak finding algorithm was imprecise.
To turn a loosely defined heuristic such as “R-wave appears earlier than usual” into an LF, we must characterize the “usual” location of the R-wave. To accomplish this, we we fit a robust Gaussian distribution to model the variance of R-wave locations, and assume any beat located two standard deviations earlier (solid green line at $T_{\text{Early R-wave}} = 292$ ms), than the estimated mean, to be a PVC beat. Since these attributes vary widely from patient-to-patient, we automatically compute these thresholds separately for each patient and heuristic.

The End-Model Classifier
With these heuristics, we use the label model in Eq. (1) to obtain probabilistic labels for heartbeats of all training patients in the MIT-BIH Arrhythmia Database. We use these probabilistic labels and the segmented beats to train a noise-aware ResNet classifier, in which we weigh each sample according to the maximum probability that it belongs to either class. Recent studies have shown that ResNet not only performs on par with most of the state-of-the-art time series classification models\(^{24}\), but also works well for automatic arrhythmia detection\(^1\).

Experiments and Results

Data
The Massachusetts Institute of Technology – Beth Israel Hospital (MIT-BIH) Arrhythmia Database\(^4\) is one of the most commonly used datasets to evaluate automated Arrhythmia detection models. It contains 48 half-hour excerpts of two-lead ECG recordings from 47 subjects. In most records, the first channel is the Modified Limb lead II (MLII), obtained by placing electrodes on the chest. We only used the first channel to detect PVC events, since the QRS-complex is more prominent in MLII. The second channel is usually lead V1, but may also be V2, V4 or V5 depending on the subject. We refer the interested reader to Moody et al.\(^4\) for more details on how the database was curated and originally annotated.

Experimental Setup
Our experimental setup follows the evaluation protocol of arrhythmia classification models stipulated by the American Association of Medical Instrumentation (AAMI) as described in\(^{25}\). The AAMI standard, however, does not specify which heartbeats or patients should be used for training classification models, and which for evaluating them\(^2\). Hence, we used the inter-patient heartbeat division protocol proposed by De Chazal et al.\(^{26}\) to partition the MIT-BIH Arrhythmia Database into subsets DS1 and DS2 to make model evaluation realistic. Furthermore, in the MIT-BIH Database, PVCs only account for $8\%$ of the 100,000 beats, thus to prevent issues stemming from high class imbalance, we randomly oversampled PVC beats in DS1 before using it to train the ResNet classifier. The
architecture of our ResNet models is the same as in Fawaz et al.\textsuperscript{24}. To tune the learning rate, batch size, and number of feature maps hyper-parameters, we split the training data into train and validation subsets in the 70/30 proportion. All the models were trained for 25 epochs. In the next subsection, we report the results of the ResNet models which had the best true positive rate (TPR) at low false positive rate (FPR) on the validation data.

We also compare the performance of our weakly supervised model with an active learning (AL) alternative. For AL, we used ResNet to iteratively identify data points for manual labeling using uncertainty sampling\textsuperscript{27}. The model initially had access to a randomly sampled balanced seed set of 100 labeled data points. In each AL iteration, we retrained ResNet using the training data extended with 100 newly labeled data points. We continued this process until the training set consisted of 4,000 points. AL hyper-parameters (the query size and size of the seed set) are similar to Pasolli and Melgani’s setup\textsuperscript{14}. Table 1 reports the performance of the final ResNet model trained on 4000 data points incrementally labeled using AL, averaged over 10 random initializations of the seed set.

Table 1: Results on held-out test set. Weakly supervised ResNet performs on par with the fully supervised model and outperforms ResNet trained using active learning. FPR\textsubscript{50% TPR} and FNR\textsubscript{50% TNR} represent the FPR and FNR at 50% TPR and TNR, respectively. Similarly, TPR\textsubscript{1% FPR} and TNR\textsubscript{1% FNR} represent the TPR and TNR at 1% FPR and FNR, respectively. The reported AL results are averaged over 10 independent initializations of the random seed set. All measures are computed with PVC as the positive class.

**Results** We trained ResNet models on DS1 as a training set, using either probabilistic labels or the full ground truth, and evaluated them on the held-out set DS2. The results, summarized in Tab. 1, reveal that the end classifier trained using weak supervision is competitive with the model trained on the full ground truth data. Moreover, our weakly supervised model also outperformed the ResNet trained using 4,000 data points obtained via active learning.

**Figure 5:** Active learning results. Our weakly supervised model either exceeds or matches the performance of its AL counterpart. The shaded red regions correspond to the 95% Wilson’s score intervals.

Let us review the key insights stemming from these results. First, the thresholds for the labeling functions that were automatically determined by our proposed auto-thresholding algorithm varied quite drastically across subjects. For instance, the threshold on the position of the R-wave, T\textsubscript{Early R-wave} had a mean of 230 ms and a standard deviation of 77.14 ms. This simple personalization of the LF parameters turned out to be the key to good generalization properties of the end-model; it failed to perform well when these parameters were fixed to reasonable global settings. The auto-thresholding algorithm is a practically important contribution of our work, as it allows our methods to scale across diverse cohorts of subjects while mitigating potentially excessive manual effort in tuning LFs to specific patients. However, unsurprisingly, even with auto-tuning, our LFs and the estimated probabilistic labels (denoted “Pr. labels” in Tab. 1) were not perfect. In fact, we observed high variability in the performance of Pr. labels across different subjects, when compared to ground truth. For example, while they had almost perfect sensitivity for Subject 228 (TPR = 0.994),
they performed extremely poorly for Subject 214 (TPR = 0). Overall, Pr. labels had low TPR and high TNR on their own on the training set and held-out test set, which is understandable given the prior class imbalance.

![Graphs](i) (ii) (iii)

Figure 6: Class Activation Maps for weakly [(i) - (iii)] and fully supervised [(iv) - (vi)] ResNet reveal that the models discriminate between PVC and OTHER beats primarily based on the morphology of the QRS-complex. The models appear to have learned to focus on similar regularities. Graphs (i) and (iv) represent an example OTHER beat, while the others show two examples of PVC beats.

Tab. 1 summarizes performance metrics on the held-out test set (True Positive Rate (TPR), True Negative Rate (TNR), Positive Predictive Value (PPV), False Positive Rate (FPR), and Accuracy (Acc)) measured at the 50-50 class likelihood threshold, chosen for consistency with prior literature on the PVC prediction task. The weakly supervised ResNet (Weak sup.) significantly improves sensitivity to the PVC class compared to just using the LF labels directly (Pr. labels) to directly predict the test data. This illustrates that WS ResNet is able to generalize effectively beyond the hypothesis learned by the noisy weak LFs. Our end model performs on par with the fully supervised ResNet (Fully sup.) trained on the same data but using all the available pointillistic labels in the MIT-BIH Database.

Tab. 1 also compares performance of the four models under consideration at operational settings of pragmatic interest in clinical practice, that is at very low error rates. We report the ability to confidently identify positive cases at FPR of 1%, and the ability to confidently identify negatives at FNR of 1%. We complement these results with the error rates observed at 50% probability of detection of both negative and positive cases. The results show very little operational utility potential from applying the inferred probabilistic labels directly. However, our weakly supervised ResNet model trained on those inferred labels is highly competitive to the equivalently structured ResNet trained on the abundant supply of manually annotated data. Weakly supervised ResNet appears particularly strong at identifying negative cases, while its positive recall performance is close to the ground-truth based equivalent.

Next, we compare performance of the weakly supervised ResNet versus ResNet trained using active learning (“Active learn.” in Tab. 1), and it looks better on all performance metrics barring TNR, PPV and FPR. Graphs in Fig. 5 show that in the range of up to 4,000 pointillistically labeled training data points, weakly supervised models either outperform or matches its active learning counterpart, but at a drastically lower requirement of human effort.

To closely examine what the weakly and fully supervised ResNet models are learning, we plotted Class Activation Maps\(^2^8\) of a normal and PVC beats in Fig. 6. It is evident that to discriminate between PVCs and other beats, our models are primarily paying attention to the QRS complexes in these examples. Moreover, it also appears from these plots that both models not only perform on par, but they also tend to focus on similar signatures of the ECG signals. This observation suggests at least some equivalence between the model trained on ground-truth annotation and the one trained on labels inferred from a small number of simple heuristics. These results reassure us that the more expensive process can be effectively replaced by the proposed framework of weak supervision that uses a few labeling functions.
based on high-level aspects of domain knowledge derived directly from the time series characteristics.

Discussion and Conclusion

We demonstrated that weak supervision with domain heuristics defined directly on time series provides a promising avenue for training medical ML models without the need for large, manually annotated datasets. To support this claim, we developed an arrhythmia detection model which performs on par with its fully-supervised counterpart, and does not need point-by-point data annotation. This weakly supervised model has been developed in a fraction of time that would be required to provide a fully labeled training set.

We only needed a handful of heuristics to infer probabilistic labels sufficient to yield a reliable end model. These simple heuristics reflected basic clinical intuition that can be gleaned from ECG diagnostics tutorials. We expect that engaging expert clinicians to harvest additional heuristics would allow further improvements. We stipulate that the proposed approach does not only save effort and time, but it also aligns the process of knowledge acquisition from domain experts better with human nature, than its tedious pointillistic data annotation alternative. Further, we show that domain heuristics can be automatically tuned to patient specific characteristics by defining parameter tuning rules. In our example, auto-tuning of ECG waveform interpretations accounts for inter-patient variability, while keeping manual labor at its minimum.

The ML community has devised several techniques to overcome the limitations of expensive pointillistic labeling such as intelligently choosing the most informative training samples to label, combining both labeled and unlabeled data and harnessing the power of crowds. While semi-supervised learning has been successfully applied to improve arrhythmia detection models without patient-specific data, these methods still rely on a significant proportion of labeled training data to start with. On the other hand, crowdsourcing has shown promise in generating ground truth for e.g. medical imaging, but prior research found several limitations such as the lack of trustworthiness, inability of non-expert workers to annotate fine-grained categories and ethical concerns around patient privacy. Active learning, however, has by far been the most commonly utilized technique in settings where annotating large quantities of data en-masse is prohibitively expensive.

Multiple avenues of future work include modelling dependencies between LFs to improve both the efficiency and accuracy of label models, and developing a library of time series primitives to streamline development of LFs for such data. We would also like to build interfaces to support interactive discovery of LFs and to rigorously validate resulting end models. Further, we intend to investigate hybrid approaches that will opportunistically combine weak supervision with pointillistic active learning, and conduct user studies with clinicians to better understand the challenges and opportunities for interactive harvesting of domain knowledge. We also aim to enable detection of other types of abnormalities that can be seen in ECG data, and apply our approach to other types of hemodynamic monitoring waveforms.

Time series data is prevalent in healthcare. However the costs of preparing such data for training and validation of new models, as well as for the maintenance of already developed models, prohibit the otherwise realizable benefits from widespread adoption of machine learning in clinical decision support. We believe that approaches similar to the one presented in this paper could help making a decisive push towards proliferating beneficial uses of machine learning in this important field of its application.

Abstract

Chest X-ray becomes one of the most common medical diagnoses due to its noninvasiveness. The number of chest X-ray images has skyrocketed, but reading chest X-rays still have been manually performed by radiologists, which creates huge burnouts and delays. Traditionally, radiomics, as a subfield of radiology that can extract a large number of quantitative features from medical images, demonstrates its potential to facilitate medical imaging diagnosis before the deep learning era. In this paper, we develop an end-to-end framework, ChexRadiNet, that can utilize the radiomics features to improve the abnormality classification performance. Specifically, ChexRadiNet first applies a light-weight but efficient triplet-attention mechanism to classify the chest X-rays and highlight the abnormal regions. Then it uses the generated class activation map to extract radiomic features, which further guides our model to learn more robust image features. After a number of iterations and with the help of radiomic features, our framework can converge to more accurate image regions. We evaluate the ChexRadiNet framework using three public datasets: NIH ChestX-ray, CheXpert, and MIMIC-CXR. We find that ChexRadiNet outperforms the state-of-the-art on both disease detection (0.843 in AUC) and localization (0.679 in T(IoU) = 0.1). We make the code publicly available at https://github.com/bionpllab/lung_disease_detection_amia2021, with the hope that this method can facilitate the development of automatic systems with a higher-level understanding of the radiological world.

1 Introduction

The chest X-ray is one of the most common medical procedures for diagnosis, but the interpretation of chest x-ray images is subject to significant diagnosis variability for important clinical decisions. A radiologist reads about 20,000 images a year, roughly 50-100 per day, and the number is increasing. Each year, the US produces 600 billion images, and 31% of American radiologists have experienced at least one malpractice claim, often missed diagnoses¹. The shortage of radiologists and burnout of physicians creates an urgent demand for immediate solutions. Building automatic or semi-automatic approaches to medical imaging diagnosis becomes an unavoidable next step.

The recent development of artificial intelligence, especially deep learning, offers great potential to improve medical imaging diagnosis². It also sneaks into the radiology reading rooms to build a new paradigm for precision diagnosis³–⁵. Pioneering work on chest X-rays mainly focused on two problems: disease classification and localization. The recent release of large-scale datasets, such as NIH Chest X-ray⁴, CheXpert⁶, and MIMIC-CXR⁷, have enabled many studies using deep learning for automated chest X-ray diagnosis, such as thorax disease classification³,⁸–¹⁰ and localization⁸,¹¹,¹².

In practice, radiologists use pattern recognition on medical images to make a diagnostic decision¹³. The knowledge of radiologists can be captured by Radiomics, which has demonstrated the effectiveness of image-based biomarkers for cancer staging and prognostication. Formally, radiomics extracts quantitative data from medical images to represent tumor phenotypes, such as spatial heterogeneity of a tumor and spatial response variations. It plays an important role in precision medicine to support evidence-based clinical decision-making. For example, radiomics can generate the detailed quantification of tumor phenotype¹⁴ and acts as a radiographic imaging phenotype which is associated with tumor stage, metabolism, and gene or protein expression profiles¹⁵,¹⁶.

While radiomics offer the potential for more precise and accurate clinical predictions, it is surprising that radiomics has not been implemented in the layers of the neural networks, nor to the best of our knowledge in the deep learning

*Equal contributions.
Figure 1: Model overview. The model contains three major parts. Blue arrows represent the feedforward multi-label classification part. The below black arrows represents the mask generation and radiomic features extraction part. Red arrows means the radiomic features regularization and backward part.

workflow for X-ray analysis\textsuperscript{17,18}. To bridge this gap, in this paper, we propose ChexRadiNet, a new framework that incorporates domain-specific knowledge (radiomics) into deep learning algorithms as soft constraints, and then learns end-to-end to automatically detect thorax diseases and generate bounding boxes on chest X-rays. Compared with previous studies, our proposed model does not need pre-annotated bounding boxes for training and can achieve state-of-the-art performance for thorax disease localization. Therefore, it provides a way to introduce prior information about anticipated explanations, a technique that is widely used in the “Rationale model”\textsuperscript{19} (Section 2). For ensuring ChexRadiNet is robust and generalizable, three public benchmarking datasets were used for this purpose: NIH Chest X-ray\textsuperscript{4}, CheXpert\textsuperscript{6}, and MIMIC-CXR\textsuperscript{7}. We demonstrate that our model outperforms baseline methods for both thorax disease classification and localization (Section 3).

2 Method

Figure 1 shows our proposed ChexRadiNet, which consists of two branches. The first branch predicts whether the pathology is present or not in the image. The second branch localizes its regions using the radiomic features extracted from the first branch. ChexRadiNet utilizes a multi-task, closed-loop strategy to learn and use radiomic features as soft constraints. Formally, we are learning a two-part latent-variable model of the form \( E_{z \sim p(z|x)} p(y|x, z) \), where the latent \( z \) is a radiomic-based mask over the image \( x \) with the probability \( p(z|x) \). \( p(y|x, z) \) is a masked version of the classification framework. Therefore, we consider the training process as a weakly-supervised learning. In this section, we first illustrate the architecture of ChexRadiNet and then present the training process.

2.1 Model architecture

2.1.1 Branch I: Multi-label classification

In this branch, we label each image with a 14-dim vector \( y = [y_1, \ldots, y_k, \ldots, y_K] \), \( y_k \in \{0, 1\} \), \( K = 14 \) for each image. \( y_k \) indicates the presence with respect to the according pathology in the image while a zero vector represents the status of “Normal” (no pathology is found in the scope of any of 14 disease categories as listed).

We use the residual neural network (ResNet) architecture\textsuperscript{20}, given its dominant performance in ILSVRC competitions and the triplet attention mechanism (see Section 2.1.3). However, our framework can be applied to other CNNs. ResNet-18 and ResNet-50 are used in this paper. After removing the final classification layer and global pooling layer, an input image with shape \( h \times w \times c \) produces a feature tensor with shape \( h' \times w' \times c' \) where \( h, w, \) and \( c \) are the height, width, and number of channels of the input image, respectively while \( h' = h/32, w' = w/32, c' = 2048 \). The output of this network encodes the images into a set of abstracted feature maps. Then through an application of two convolutional layers (each followed by batch normalization and ReLU activation), the number of channels is modified
to $K$, where $K$ is the number of possible disease types. A perchannel probability for each disease class is then derived by a fully-connected layer with a sigmoid activation function; this is denoted $p(k|I)$, where the probability is that whether the image belongs to class $k$ and $I$ denotes the image. Since we intend to build $K$ binary classifiers, we will exemplify just one class $k$. Note that $k$th binary classifiers will use the $k$th-channel features to do prediction. Since all images have their labels, the loss function for class $k$ can be expressed as minimizing the binary-cross entropy as $L_k = -y_k \log p(k|I) - (1-y_k) \log(1-p(k|I))$, where $y_k$ is the ground truth label of the $k$ class. To enable end-to-end training across all classes, we sum up the class-wise losses to define the total loss as $L_I = \sum_k L_k$.

2.1.2 Branch II: Mask generation

In this branch, we generate bounding boxes (B-Box, or masks) based on the classification result of Branch I to get the most indicative areas using the class activation mappings (CAMs). The heatmap produced from the model indicates the approximate spatial location of one particular thoracic disease class each time. Due to the simplicity of intensity distributions in these resulting heatmaps, applying an ad-hoc thresholding-based B-Box generation method for this task is found to be sufficient. Followed by the work of Wang et al., the intensities in heatmaps are first normalized to $[0, 255]$ and then thresholded by $\{60, 180\}$ individually. Finally, B-Boxes are generated to cover the isolated regions in the resulting binary maps.

**Radiomic features extraction.** With the generated B-Boxes and original images, we extracted radiomic features to regularize the model. Quantitative radiomics can be categorized into the following subgroups:

- **First-order statistics features** describe the distribution of individual pixel values without concerns for spatial relationships. They are histogram-based properties using mean, median, maximum, and minimum values of the pixel intensities on the image, as well as their asymmetry, flatness, uniformity, and entropy.

- **Shape features** describe the shape of the region of interest (ROI) and its geometric properties (e.g., volume, maximum diameter along with different orthogonal directions, maximum surface, tumor compactness, and sphericity).

- **A Gray Level Co-occurrence Matrix (GLCM) features** describe the second-order joint probability function of an image region constrained by the mask. The matrix $P(i, j|\delta, \theta)$ represents the number of times the combination of levels $i$ and $j$ occurs in two pixels in the image, that are separated by a distance of $\delta$ pixels along angle $\theta$.

- **A Gray Level Size Zone (GLSZM) features** quantify gray level zones in an image. A gray level zone is defined as the number of connected pixels that share the same gray level intensity.

- **A Gray Level Run Length Matrix (GLRLM) features** quantify gray level runs, which are defined as the length in number of pixels, of consecutive pixels that have the same gray level value.

- **A Neighboring Gray Tone Difference Matrix (NGTDM) features** quantify the difference between a gray value and the average gray value of its neighbors within distance $\delta$. The sum of absolute differences for gray level $i$ is stored in the matrix.

- **A Gray Level Dependence Matrix (GLDM) features** quantify gray level dependencies in an image. A gray level dependency is defined as the number of connected pixels within distance $\delta$ that are dependent on the center pixel.

All above features can be extracted either directly from the images or after applying different filters or transforms (e.g., wavelet transform). In our design, we utilize the Pyradiomics tool to extract radiomic features (https://pyradiomics.readthedocs.io/).

Finally, we use the pairwise distance between radiomic features and image features as regularization. Therefore, the adjustable loss function is $L_{II} = L_I + \|I_F - R_F\|_p$, where $I_F$ and $R_F$ are the image features and radiomic features, respectively, and $\| \cdot \|_p$ denotes the norm and $p$ represents the norm degree, e.g., $p = 1$ and $p = 2$ represent the Taxicab norm and Euclidean norm, respectively. In this paper, we set $p$ to 2. Please note that although the original shapes of $I_F$ and $R_F$ are not equal, we easily adapted one-layer MLP to project them into the same dimension space.
2.1.3 Triplet Attention

To boost the quality of masks, we integrate the triplet-attention mechanism\(^ {22}\). Triplet Attention mechanism requires few learnable parameters and could capture important features by taking cross-dimension interaction into account\(^ {22}\). In other words, it includes three sub-branches to respectively capture the dependency between spatial dimensions Height (\(H\)), Width (\(W\)), and the Channel (\(C\)) dimension. For the first branch, in measuring the interactions between dimension \(H\) and dimension \(C\), it first performs a Z-pool operation by concatenating the result of average pooling and max pooling across dimension \(W\). This operation can be summarized as \(\chi_1 = z\text{-pool}(\chi') = [\text{MaxPool}_w(\chi'); \text{AvgPool}_w(\chi')]\) where \(\chi' \in \mathbb{R}^{W \times H \times C}\) is a 90 degree anti-clockwise rotation along the \(H\) axis from the output of the previous convolutional layer \(\chi \in \mathbb{R}^{C \times H \times W}\) and \(\chi_1 \in \mathbb{R}^{2 \times H \times C}\) is the output of a Z-Pool operation. \(\chi_1\) then passed through a standard 2D convolutional layer followed by sigmoid activation \(\sigma\) to get attention weights for \(\chi_1\). It would finally rotate back to match the original shape of \(\chi\) after applying the attention weights. These steps can be represented by the following: \(y_1 = r(\sigma(\text{CNN}_1(\chi_1)))\) where \(r\) is the rotation operation to retain the original shape of input. Similarly, \(y_2, y_3\) are obtained from the last two branches by measuring the interactions between dimensions \(W\) and \(C\) and between dimensions \(W\) and \(H\), respectively. Note that the last branch is similar to the spatial attention in CBAM\(^ {23}\), and it requires no rotation. The refined input \(y\) is represented by averaging outputs from three branches: \(y = \frac{1}{3}(y_1 + y_2 + y_3)\).

2.2 Training Strategy of ChexRadiNet

ChexRadiNet adopts an end-to-end multi-task training scheme. Each epoch consists of two tasks. In the first task (Branch I), we use the whole image to fine-tune the ResNet + Triplet Attention network pre-trained on ImageNet. During this process, we feed the generated masks into the radiomics extraction block to get radiomic features. In the second task (Branch II), we use radiomic features as regularization to further fine-tune the whole model. In each epoch, we use the model with the highest AUC on the validation set for testing.

3 Experiments

3.1 Datasets

For the abnormality classification task, we evaluated the ChexRadiNet framework using the NIH Chest X-ray\(^ {4}\), CheXpert\(^ {6}\), and MIMIC-CXR\(^ {7}\) datasets (Table 1). The Chest X-ray dataset contains 112,120 X-ray images collected from 30,805 patients. The disease labels were extracted from radiological reports with Natural Language Processing tools\(^ {24}\). There are 15 classes, one for “No findings” and 14 diseases: Atelectasis, Cardiomegaly, Consolidation, Edema, Effusion, Emphysema, Fibrosis, Hernia, Infiltration, Mass, Nodule, Pleural thickening, Pneumonia, and Pneumothorax. The disease labels are expected to have above 90% accuracy. In addition, the Chest X-ray dataset includes 984 bounding boxes for 8 types of chest diseases annotated for 880 images by radiologists.

CheXpert dataset is another large-scale public chest X-ray dataset currently available, which contains 224,316 X-ray scans of 65,240 patients. This dataset was labeled for the presence of 14 observations, including 12 common thoracic pathologies. Each observation can be assigned to either positive (1), negative (0), or uncertain (-1). To simplify the task, we choose to ignore all the uncertain samples. In addition, to compare with previous literature, we follow the same evaluation protocol over 5 observations: Atelectasis, Cardiomegaly, Consolidation, Edema, and Pleural Effusion.

MIMIC-CXR is also a large-scale CXR dataset, which contains 377,110 chest X-rays associated with 227,827 imaging studies. Images are provided with 13 labels. Similar to CheXpert, each label can be assigned to either positive (1), negative (0), or uncertain (-1).

| Table 1: Descriptions of the datasets. |
|-------------------------------|-----|-------|
| Datasets          | Patients | Chest X-rays |
| NIH Chest X-ray   | 30,805   | 112,120 |
| CheXpert          | 65,240   | 224,316 |
| MIMIC-CXR         | 227,827  | 377,110 |
3.2 Evaluation metrics and experimental settings

For the abnormality detection task, we randomly split each dataset into training (70%), validation (10%), and test (20%) sets. Note that there is no patient overlap between the sets. We use AUC scores, the area under the ROC curve, to measure the disease identification accuracy. A higher AUC score indicates better performance.

For the abnormality localization task, following the work of Li et al\(^1\), we only consider 8 diseases for the evaluation of mask generation because only eight types of diseases are provided with bounding boxes in the NIH Chest X-ray dataset. We use intersection over union (IoU) to evaluate the predicted disease regions against the ground truth bounding boxes.

We use ResNet-50 as the backbone model. We set the batch size as 256 and train the model for 20 epochs. The model is optimized using the stochastic gradient descent (SGD) optimizer with a learning rate of 0.1 and decay the learning rate by 0.1 every 5 epochs of training. We trained our model on AWS with 16 Nvidia K80 GPUs. The model is implemented in PyTorch.

3.3 Results

3.3.1 Disease classification

Table 2 shows the AUC of each class and a mean AUC across the 14 chest diseases. We used ResNet-50 pre-trained on ImageNet as the backbone. Our ChexRadiNet outperforms other models in terms of mean AUC. For every single class, our proposed framework is better than all other models except with DensNet-121 for Fibrosis, Hernia, Mass, Nodule, Pneumonia, and Pneumothorax. Possible reasons can be that Rajpurkar et al’s backbone is much deeper than our ResNet-50\(^3\), which enables it to capture more discriminative features than our ResNet-50. In addition, “Mass” and “Nodule” parts are small and hard to detect. For “Fibrosis” and “Hernia,” they are not annotated with bounding boxes and diffuse, and thus we cannot apply the weakly-supervised learning with radiomic features.

Table 3: Disease localization under varying IoU on the NIH Chest X-ray dataset. Please note that since our model doesn’t use any ground truth bounding box information, to fairly evaluate the performance of our model, we only consider the previous methods’ results under the same setting, therefore, for the case T(IoU)=0.1, we have two baselines, but for the rest cases, we only have one baseline.

3.3.2 Disease localization

We compare our disease localization accuracy under varying IoU to other state-of-the-art models, shown in Table 3. Our model predicts well not only for easy tasks but also for hard tasks like localizing “Mass” and “Nodule”, where the disease localization is within a small area. When the IoU is set to 0.1, our model outperforms other models in terms of Atelectasis, Cardiomegaly, Effusion, and Pneumothorax. As the IoU threshold increases, our framework is superior to other models in terms of better accuracy and maintains great performance. For instance, when IoU is set to 0.3, our result for “Cardiomegaly” is 0.73 while the reference model is only 0.46. We get more than 0.15 accuracy improvement for Effusion, Infiltration, Mass, Pneumonia, and Pneumothorax. When IoU is set to 0.5, our result for “Cardiomegaly” is still as high as 0.59 while the reference model drops to barely 0.18.

Following Li et al.¹¹, we prefer a higher IoU threshold, i.e., IoU = 0.7, for disease localization because we expect high-accuracy disease localization application in clinical use. To this end, the method we proposed is superior to the baseline by a large margin.

Please note that for some diseases, e.g., Pneumonia and Infiltration, the localization of disease can appear in multiple places while only one bounding box is provided for each image. Thus, it is reasonable that our model doesn’t align well with the ground truth when the threshold is as small as 0.1, especially for Pneumonia and infiltration. Overall, our model outperforms the reference models for all IoU thresholds except for T(IoU)=0.1 (probably because ground truth has missing annotation while ours does not).

4 Discussion

4.1 Ablation study

We conducted an ablation study to demonstrate the performance of radiomics on NIH Chest X-ray (Table 4), CheXpert (Table 5), and MIMIC-CXR (Table 6). We tried ResNet50+Triplet Attention without radiomic features. Table 4 shows that AUC will drop significantly when not using radiomic features. We observe the same trend in the other two datasets. This demonstrates that it is beneficial to include radiomic features.

We also report results of ChexxRadiNet using ResNet-18, a relevant small network, as a backbone. Table 7 shows the results with and without using the radiomic features in three datasets. We observe the AUCs drop significantly when
not using radiomic features in all cases. This suggests that the generalizability of our proposed method in smaller networks. In addition, the ResNet-18 version still performs better than other models in Table 2 except Rajpurkar et al. It indicates the superior of our proposed method for using radiomic features.

4.2 Qualitative analysis

Figure 2 shows the attention map of our model against the ground truth bounding boxes. The visualization provides better explainability of our model. In Figure 2 we visualized our results for Cardiomegaly, Mass, and Pneumonia. Cardiomegaly is considered to be present if the cardiothoracic rate is larger than 50% (cardiothoracic Ratio equals “Maximum horizontal cardiac width” over “Maximum horizontal thoracic width”), which means an enlarged heart. The 2nd image in the 1st row as well as the 2nd image in the 2nd row in Figure 2 shows that our model successfully detects cardiomegaly, an enlarged heart, perfectly, and aligned with the yellow bounding box well.

A lung mass is an abnormal spot in the lungs that is more than 3 centimeters. Our results (4th images in the 1st and 2nd rows), although focusing on larger areas, can capture some clues of lung mass.
Figure 2: Visualization of the disease localization on the test images with ChexRadiNet and ground truth bounding boxes. The attention maps are generated from the final output tensor and overlapped on the original radiology images. The left image in each pair is the chest X-ray image and the right one is the generated attention map and the ground truth (in the yellow box).

Note that in the chest X-ray 14 dataset, only one bounding box is annotated for one disease image. Though some patients are diagnosed with several diseases, only the most important disease is annotated on the radiology image. This means that ground truth has missing annotations (shown by Pneumonia). Pneumonia inflames the air sacs in one or both lungs. For Pneumonia detection, radiologists will look for white spots in the lungs. For the 6th image in the 2nd row, both lungs are infected and white spots are shown in both lungs. However, the bounding box of the 6th image only annotates the right lung while our model successfully localizes Pneumonia for both lungs.

Overall, our results show that the predicted disease localizations have a great alignment with the ground truth and can even serve as a supplement to the ground truth.

5 Conclusion

We propose a framework that jointly learns radiomic features and predicts 14 thoracic diseases. We evaluated our model on three publicly available corpora. We showed that both our disease identification and localization outperform state-of-the-art models in the quantitative and qualitative analysis.

Our proposed framework has two main limitations. First, chest X-rays are very different from natural images, but we rely on deep learning models (ResNet) that work better on natural images. Second, the robustness of radiomic features relies on the accuracy of bounding boxes, in our work, the bounding boxes are generated by heatmaps. It is not guaranteed that the generated heatmaps are always good and accurate. Our future work will continue to solve these two limitations.

Automatically generating correct bounding boxes can be a milestone to push the agenda for AI-driven medical imaging diagnosis. It can abruptly increase the annotated medical images at a much lower cost so that better CNN models can be trained, therefore better diagnosis models can be obtained. Bounding boxes can increase the interpretability of AI solutions by locating the abnormalities as the visual evidence in medical images, which can build trust between doctors and patients.

Abstract

Chronic diabetes can lead to microvascular complications, including diabetic eye disease, diabetic kidney disease, and diabetic neuropathy. However, the long-term complications often remain undetected at the early stages of diagnosis. Developing a machine learning model to identify the patients at high risk of developing diabetes-related complications can help design better treatment interventions. Building robust machine learning models require large datasets which further requires sharing data among different healthcare systems, hence, involving privacy and confidentiality concerns. The main objective of this study is to design a decentralized privacy-protected federated learning architecture that can deliver comparable performance to centralized learning. We demonstrate the potential of adopting federated learning to address the challenges such as class-imbalance in using real-world clinical data. In all our experiments, federated learning showed comparable performance to the gold-standard of centralized learning, and applying class balancing techniques improved performance across all cohorts.

Introduction

Diseases such as chronic diabetes have evidence of engendering other fatal long-term comorbid complications. For instance, prolonged uncontrolled diabetes can lead to microvascular complications, including diabetic eye disease, diabetic kidney disease, and diabetic neuropathy1-3. Diabetes-related complications resulted in 16 million emergency department visits and 7.8 million hospitalizations, as estimated in 2016, contributing to an increasing burden on the US healthcare system. Diabetes is also the leading cause of end-stage kidney disease, with a crude prevalence of 38% and new cases of vision disability with a crude rate of 11.7%3,4.

However, the long-term complications often remain undetected at the early stages of diagnosis, and most of the treatment plans for addressing the complications are reactive rather than proactive. Developing a state-of-the-art prediction model that can learn from the patient-related factors to identify the patients at high risk of developing diabetes-related complications can help design better treatment interventions. Hence, it can play an essential role in minimizing costs related to hospitalizations, medications, and treatment procedures ensuing from those complications.

Digitizing healthcare data in electronic health records (EHR) evolved into a rich source of patient health history, thus generating more opportunities to innovate data-driven tools and techniques to improve the availability and accuracy of medical services5. Potential utilization of machine learning in predicting health outcomes can involve incorporating large amounts of data generated by independent health systems6,7. However, developing centralized algorithms for centralized data repositories raises privacy, confidentiality, and regulatory concerns such as the HIPAA and HITECH Acts8. For instance, incidences of diabetes-related complications are rare events among the diabetes population. Thus, it is imperative to accumulate data from different healthcare systems to build reliable and robust predictive models using a large representation of the population for such rare complications. To address the persistent concerns related to data-sharing among the healthcare systems, we present a federated learning-based framework that can consolidate predictive models without using central repositories of the actual data itself.

In recent times, the concepts of federated learning have been seamlessly adapted in the healthcare domain to address the privacy concerns on sharing potential patient information among the healthcare systems. A decentralized prediction engine can potentially use data stored from independent health systems without ethical or legal circumstances. This study is the first implementation of federated learning in predicting diabetes-related complications using real-world clinical data to the best of our knowledge. Moreover, predictions of diabetes-related complications using federated learning encounter significant challenges from the inherent class-imbalance characteristics of real-world clinical data. The main objective of this study is to design a decentralized privacy-protected federated learning
architecture that can deliver comparable performance to centralized learning. We demonstrate the potential of adopting federated learning to address the challenges in using real-world clinical data.

The key contributions of our study include (i) identifying a diabetes population and three cohorts related to diabetic eye disease, diabetic kidney disease, and diabetic retinopathy from Health Facts EMR data using a structured framework, (ii) implementing a decentralized privacy-controlled federated learning architecture that can utilize the federated datasets from different healthcare systems to predict the complication in each cohort without sharing data among themselves, (iii) performing sampling techniques to address the class-imbalance characteristic of the datasets in the federated learning architecture, and (iv) comparing the performance of federated learning to centralized learning in different sampling conditions.

Background
Federated learning involves iteratively analyzing separate databases and sharing only mathematical parameters (metadata), but not the actual data itself that might reveal potential patient identifiers. Federated learning mechanisms were initially more popular in image classification and enhancing wireless communication systems. The recent adaptation of federated learning models in the healthcare domain includes predictions on healthcare outcomes such as mortality, hospital stay-time for ICU patients, hospitalization for cardiac events, dyspnea, adverse drug reactions. However, most of the implementation of federated learning in predicting healthcare outcomes utilized small datasets and partitioned the data hypothetically (randomly) to mimic the inherent characteristics of real-world data. In this study, we utilize the natural partitions of the Health Facts data using the information of the healthcare systems for each patient data to demonstrate our framework.

In most federated learning applications in the healthcare domain, classification algorithms such as logistic regression, artificial neural network, multi-layer perceptron, support vector machines, random forest were used to build federated predictive models. Existing literature in predicting diabetic retinopathy (eye disease), neuropathy (peripheral nerve disorder), and nephropathy (kidney disease) involve centralized machine learning algorithms using small-size datasets from the US population with limited cases of complications and limited patient information. For our study, we implemented three machine learning models, including logistic regression, 2-layer multiple perceptrons, and 3-layer multi-perceptron in federated learning architecture for binary classification of the incidence of three diabetes-related complications affecting eyes, kidneys, and peripheral nerves, respectively.

Methods
Data Source
We have used Cerner’s “Health Facts EMR Data” as our data source in this study. Health Facts is a de-identified electronic health records relational database consolidated from over 90 healthcare systems in the US between 2000 and 2016 in which Cerner has a data use agreement. Health Facts database contains patient-level attributes, such as demographics, encounters, diagnoses, lab results, procedures, prescription orders, and other clinical observations on 69 million unique patients. We identified the diabetes population, defined three cohorts for diabetes-related complications, and extracted patient-level comorbid features for our cohorts using a detailed pipeline on this dataset.

Diabetes Population Selection
We identified the diabetes population in our study using the SUPREME-DM (Surveillance, PREvention, and ManagEment of Diabetes Mellitus algorithm) based on eight criteria (Table 1). Six criteria were based on lab results, while two criteria were based on International Classification of Disease (ICD-9 and ICD-10) diagnosis codes related to inpatient and outpatient encounters. Patients satisfying at least one criterion or more were selected as the diabetes population. Only patients aged 18 or above at the first encounter were included.

Selection of Cohorts with Diabetes-Related Complications
The diabetes-related complications among the selected diabetes population were identified using International Classification of Disease (ICD-9 and ICD-10) diagnosis codes. We selected three cohorts, including diabetic eye disease (EDD), diabetic kidney disease (KDD), and diabetic neuropathy (ND), from the selected diabetes population. Figure 1 shows the flow diagram of the selection of cohorts with ICD codes for each of the diabetes-related complications.
Table 1: We used the following eight criteria to select the diabetes population from Health Facts. The first six criteria were based on lab results, while the last two were based on ICD-9 and ICD-10 diagnosis codes. The thresholds for the lab tests are chosen based on the SUPREME-DM. Patients satisfying at least one criterion were selected as the diabetes population.

Many studies have shown that patients diagnosed with diabetes show higher chances of developing these complications after five years of chronic exposure\textsuperscript{20–22}. Patients diagnosed with any of the above complications who had at least five years of chronic diabetes with total encounters between 25 and 500 were selected as “cases”. For the “non-cases”, patients with at least seven years of chronic diabetes with no diagnosis of any of the complications and total encounters between 25-500 were selected. The patient-related comorbid features were extracted using the diagnosis table.

Table 2: The summary statistics for each of the three cohorts among the diabetes population are shown below. We excluded the healthcare systems with less than 100 cases from the dataset, which reduced the number of cases in each cohort, as shown in the following table.

The diagnosis ICD codes were mapped into the Clinical Classification Software (CCS) tool developed by Healthcare Cost and Utilization Project (HCUP). We used 283 CCS coded features consolidated from the individual ICD-9 and ICD-10 codes by grouping the ICD codes into clinically similar entities, which are used as predictors for the experiments. Table 2 shows the summary statistics for the selected three cohorts of diabetes-related complications.

Decentralized Data Architecture
To demonstrate the method of privacy-preserved federated learning using the three selected cohorts, we utilized the hospital system identifiers for each patient in each cohort. The variable “ALT_HEALTH_SYSTEM_ID” was used to extract the hospital identifiers from the “hs_d_hospital” data table for each “PATIENT_ID”. The patient IDs were mapped to “PATIENT_SK”, which were linked to the CCS table of patient features for each cohort. Table 2 shows the number of hospital systems in each of the cohorts. We distributed the data for each cohort into small datasets for each hospital system to facilitate our federated learning architecture, as discussed below. The healthcare systems with less than 100 cases were discarded from the analysis.

Figure 1: Flow diagram showing the cohort selection for diabetic eye disease, diabetic kidney disease, and diabetic neuropathy from the diabetes population using the shown diagnosis codes.
Centralized Predictive Model

A centralized predictive model approach was implemented to represent the characteristics of a centralized data warehouse gathering data from multiple sites. We considered a general binary classification of the diabetes-related complications in this study. Each primary response variable, including diabetic eye disease, diabetic kidney disease, and diabetic neuropathy, is categorized into binary responses, such as cases vs. non-cases. The CCS comorbid features of each patient in each cohort are used to predict the complication as binary responses. For this purpose, we considered logistic regression, 2-layer multiple layer perceptron, and 3-layer multiple layer perceptron models. The machine learning models were trained using 70% of the complete dataset, while 30% were used for testing and validation. The algorithms were implemented using the sci-kit learn module from Python 3.6. The centralized approach to predict each complication from each cohort will act as a benchmark to compare with the federated learning approach.

Federated Predictive Model

The federated learning approach utilized the partitioned data from each cohort to predict the binary cases and non-cases for each complication. We used sci-kit learn, NumPy, pandas for the machine learning tasks, and TensorFlow to create the federated mining pipeline. To demonstrate this approach, separate training and testing datasets were created for each disjointed partitioned dataset, i.e., each healthcare system in each cohort. The labels from training data for each cohort were 1-hot-encoded using the LabelBinarizer() object from sk-learn. The features were then transformed into TensorFlow data objects. We used binary cross-entropy as loss function and stochastic gradient descent as the optimizer to compile three models: logistic regression, a 2-layer multi-perceptron, and a 3-layer multi-perceptron. Since the data in our study are horizontally partitioned, local model parameters will contribute to the global model weighted by the proportion of data points from each participating healthcare system.

We developed the training module for federated learning using the federated averaging algorithm from McMahan (2017)\(^8\). Algorithm 1 shows the two main functions used to train the federated models. At first, the global model weights are initialized, which serve as the initial weights for all local models. Using these initial weights, the local models for each healthcare system \(k = 1, ..., K\) are trained to obtain the updated weights. The updated weights are then scaled by a factor \(\frac{N_k}{N}\), which is the proportion of data for \(k^{th}\) Healthcare system and summed to obtain a new set of weights. These averaged weights (as shown in line 9 from Algorithm 1) are then used to update the global model. The process continues until \(T\) rounds of aggregating local model weights to update the global model. Thus, a federated learning mechanism only relies on sharing the weights of the local models without sharing any raw data from the individual healthcare systems. We repeat these steps to predict the three complications in the three cohorts separately. Figure 3 shows the system design of federated learning deployed in our study.

---

Algorithm 1: Federated Learning Model for Predicting Diabetes-Related Complications. The \(K\) healthcare systems are indexed by \(k\); \(E\) is the number of epochs, \(b\) is the mini-batch size, \(\eta\) is the learning rate, and \(l(\omega; b)\) is the loss function.

14: return \((\omega)\)

---

**Class-Imbalance Learning**

As shown in Figure 2, an imbalance between the cases and non-cases of the three diabetes-related complications among the diabetes population exists. Moreover, the federated datasets for the three cohorts are also subjected to unequal distribution of cases and non-cases. This is consistent with our expectations since the complications are rare for most patients diagnosed with diabetes. Classification algorithms applied in datasets with non-cases as the minority class is more likely to predict new observations in the majority class since they fail to characterize their imbalanced nature. Also, federated averaging would not account for the varying distribution of cases across the different healthcare systems. Thus, it is imperative to consider this inherent characteristic of class distribution in our model training. We applied sampling techniques, such as oversampling and undersampling, to address the class-imbalance attribute of the cohort datasets. Oversampling supplement the minority class, whereas undersampling randomly removes the majority class. For centralized learning, oversampling, undersampling, and no-sampling were performed on the training datasets for each cohort before model compilation. In the federated learning approach, similar sampling strategies were applied on the federated datasets for each cohort before the local model compilations. The module “resample” from sk-learn was used for executing the oversampling and undersampling techniques with “n_samples” parameter set to the class size for both over- and under-sampling.

**Experimentation and Evaluation Metrics**

The three machine learning models were run for each of the cohorts for the three sampling techniques including, no balancing, oversampling, and undersampling. In total, there were 27 experiments for the federated learning.
Architecture and 27 experiments for centralized learning. We combined the testing data from all sites within each cohort to evaluate the performance of the federated model. When the datasets are subjected to class-imbalance, F-1 scores are a more reliable measure compared to accuracy. Performance metrics, such as F-1 score, recall, and precision, were used to compare the performance of the federated learning to centralized learning.

R version 3.4.4 (R Foundation for Statistical Computing, Vienna, Austria) and Python 3.6 were used for data management and all computations were performed on a Mac Book Pro running macOS Catalina version 10.15.2 with 16GB of RAM.

Comparative Analysis
The performance measures across all the classifiers and datasets showed federated learning to exhibit comparable predictive performance with respect to centralized learning. As shown in Table 3, multilayer perceptron consistently performed well compared to logistic regression in predicting diabetic eye disease patients. For logistic regression, applying the undersampling improved the recall by 12% for both federated and centralized learning. The F-1 scores for both multi-layer perceptron models were improved by about 4% for federated learning and 13% for centralized learning. However, precision measures decreased by 20% for both oversampling and undersampling experiments for both the learning mechanisms. The difference between the precision scores between federated and centralized learning varied by 6-7%.

Table 3: Performance metrics (F-1 score, Precision, and Recall) for centralized learning and federated learning, obtained from three machine learning models: logistic regression, 2-layer multi-perceptron, 3-layer multi-perceptron for the diabetic eye disease cohort.

All the classifiers from the two setups performed better in the diabetic kidney disease cohort, as shown in Table 4. Both oversampling and undersampling improved recall for logistic regression and multi-payer perceptron models. For both centralized and federated learning, recall improved by 20%. The maximum difference in recall between federated and centralized learning was within 3% for both the oversampling and undersampling cases. Maximum F-1 scores were obtained by the multi-layer perceptron models and were comparable for both federated and centralized learning. The maximum difference in F-1 scores between federated and centralized learning were about 4% when the balancing techniques were applied. When no balancing technique was implemented, the maximum difference in the performance metrics between the two learning setups is about 10%.

As shown in Table 5, for logistic regression applying sampling techniques improved the F-1 score by 6-7% for federated learning and about 1% for centralized learning. Recall improved by 34-35% in federated logistic regression, while a 26% increase is observed in centralized logistic regression. The maximum difference in F-1 score and recall between federated and centralized logistic regression is about 2%. In the 2-layer multi-perceptron model, sampling techniques improved F-1 score by 4-5% in federated learning, while an improvement of 6-7% was observed in centralized learning. Recall improved by 24% in federated and 31% in centralized learning setups upon implementing sampling techniques. The maximum difference between F-1 scores is about 3%, while only a 1% difference in the recall. The 3-layer multi-perceptron model is the best performing model in the diabetic neuropathy cohort. Oversampling improved recall by 10% for federated learning vs. centralized learning, while equivalent recall values were obtained for both. F-1 measure improved by 2% and equivalent precision measures were also obtained for
federated learning in this scenario. Among the three cohorts, federated learning with sampling performed consistently well in the diabetic neuropathy cohort.

**Table 4:** Performance metrics (F-1 score, Precision, and Recall) for centralized learning and federated learning, obtained from three machine learning models: logistic regression, 2-layer multi-perceptron, 3-layer multi-perceptron for the diabetic kidney disease cohort.

**Discussion**

The use of federated learning can bring numerous opportunities to investigate rare clinical events by building decentralized models without exchanging direct raw data. In this paper, we developed a decentralized privacy-protected predictive classifier that can successfully predict diabetes-related complications such as retinopathy, neuropathy, and nephropathy. The federated architecture shares a common global model with the healthcare systems, which utilize their electronic health records to train locally. Updates from the local models are aggregated later to update the global model. In this process, no personal patient identifiers are shared. We used the Health Facts database to demonstrate the process, which is an information-enriched database for patient records. We used the unique identifiers for healthcare systems to partition the data into real federated data sets. We applied class balancing sampling techniques to address the challenge of low class-ratios of cases to non-cases. In all our experiments, federated learning showed comparable performance to the gold-standard of centralized learning.

Moreover, federated learning with 3-layer multi-perceptron model performed consistently better than its centralized counterparts in the diabetic neuropathy cohort. Interestingly, this cohort had fewer class-imbalance issues, hence greater number of cases of neuropathy in the dataset, which accounts for the consistent performance of federated learning in this case. Also, it is evident that applying the class balancing techniques reduced the gap between the measures of federated and centralized learning across all the cohorts. Thus, federated learning models are useful for the healthcare systems where data sharing is a major barrier for building machine-learning based clinical decision support systems.

**Table 5:** Performance metrics (F-1 score, Precision, and Recall) for centralized learning and federated learning, obtained from three machine learning models: logistic regression, 2-layer multi-perceptron, 3-layer multi-perceptron for the diabetic neuropathy cohort.

Conclusion and Future Scope
In conclusion, our results are consistent with the prior and current implementation of federated learning in healthcare domain\(^{2,3,4}\). Currently, our model architecture is limited to multilayer perceptron, whereas logistic regression is also a special case for that. We plan to extend our federated learning architecture to include more classifier algorithms such as support vector machines, decision trees, and random forest for future work. The major limitation of the analysis is the use of a relational database, which leads to under-representation of the challenges in the federated learning process in a real setting. Another key challenge is data inconsistencies, incompleteness, and lack of standardization. As future goals, we plan to use health systems that are already partitioned for better demonstration. Furthermore, we will explore other averaging techniques, optimal methods to address class-imbalance issues, better approaches for hyperparameter tuning of the global model, and extract other important patient-related factors from other data tables to continue our efforts building a more reliable and robust federated predictive model for diabetes-related complications. Our future work will also involve exploring and comparing other privacy-protected learning methods with federated learning.

A Proposed Patient-Inclusive Methodology for Developing and Validating Telehealth Surveys that Include Social Determinants of Health

Izower, Mitchell, MD1,2, Liao, Zoe, B.S. Pharmacy1,3, Kim, Jeongeun, B.A.1,2, Quintana, Yuri, PhD1,2

Abstract

This paper discusses a method to develop and validate telehealth surveys that include social determinants of health domains. We performed a scoping review of literature on measuring social determinants of health and extracted 50 social determinants of health domains. We evaluated 14 validated telehealth surveys for questions associated with social determinants of health. We categorized the questions from the validated telehealth surveys using our extracted social determinants of health. We found that current validated telehealth-specific surveys only cover 16 (32%) of social determinants of health domains, with the most commonly evaluated domains being “Medical Needs” and “Social Connections/Isolation”. Telehealth services are a valuable modality to provide care to patients. Surveying patients is integral to performing quality improvement and improving patient outcomes. Social determinants of health are important factors in determining patient outcomes. We propose an approach to validating the missing domains and evaluating survey validity.

Introduction

The COVID-19 pandemic has greatly increased the use of telehealth services1. Telehealth services have several benefits over in-person healthcare delivery, such as reducing resource use at health centers, improving access to care, and minimizing the risk of disease transmission from person to person2. If the appropriate measures are taken in the realms of workforce development and support, consumer empowerment, healthcare funding reform, improvements to the digital health ecosystem, and telehealth integration into routine care, then the expanded use of telehealth will persist beyond the COVID-19 pandemic3.

We must regularly and comprehensively assess telehealth services to ensure that telehealth services continue to deliver high-quality care. Surveys can be used to measure patient satisfaction, experience, preference, and attitudes, and to assess the technical quality of the telehealth visit4. The major strengths of surveying include confidentiality, independent assessment of clinicians and patients, pre-existing scales which allow cross-study comparison, low cost relative to sample size, result generalizability, and the ability to validate surveys, thus ensuring accurate measurements of desired constructs5.

While surveys can identify valuable information for improving telehealth services, they also have limitations. Inappropriately constructed surveys may exhibit a lack of response variability5, poor reliability6, inapplicable response scale design5, lack of construct validity5, poor selection of constructs5, question ambiguity5, biased questions5, significant “halo” effect5, and other technical issues. Therefore, it is recommended that validated surveys be used to assess telehealth services5.

Validated surveys have been assessed and modified to ensure that their questions achieve face validity, usefulness, construct validity, convergent and discriminant validity, and content validity, and that the overall survey instrument achieves reliability and internal consistency5. Validated surveys have been developed to ensure that survey measurement of constructs is accurate, dependable, and reliable6,7. A recent systematic review identified 12 validated telehealth surveys8. Another review of telehealth research identified an additional 4 telehealth-specific surveys8. Examples of validated surveys include the “Patient Assessment of Communication during Telemedicine” (PACT)9 and “Telemedicine Satisfaction and Usefulness Questionnaire” (TSUQ)4.

However, while these validated telehealth-specific surveys provide valuable confidence in survey meaningfulness, they, too, still have shortcomings. Namely, while these surveys may evaluate patient experience and satisfaction, they may fail to identify underlying factors that contribute to those scores. One such group of underlying factors are social determinants of health.

The World Health Organization defines social determinants of health (SDoH) as “the conditions in which people are born, grow, live, work and age”. SDoH can contribute to health inequalities if they are not adequately addressed9.
is vitally important that telehealth services seek to evaluate the social determinants of health of patients using them. For this reason, it is important to consider if current validated telehealth-specific surveys can evaluate social determinants of health domains.

This paper evaluates current telehealth-specific validated surveys for coverage of social determinants of health. It seeks to provide recommendations for improving the evaluation of social determinants of health using validated telehealth-specific surveys. We propose a method for researchers to develop validated telehealth-specific surveys which include social determinants of health domains.

Methods

Our objective is to understand how current telemedicine surveys covered social determinants of health domains. To identify SDOH domains, we conducted a scoping literature search in PubMed with the search terms “social determinants of health,” and “screening,” “documentation,” “electronic health records,” or “data collection.” We reviewed papers where data was collected on at least one social determinant of health domain in a clinical setting as part of the care delivery process, and data were recorded in the electronic health record (EHR). Twelve studies covering 18 health organizations were included for analysis, and from these studies, 50 SDoH domains were identified.

We then searched the literature for validated telehealth-specific surveys. From this search, we identified 16 validated telehealth-specific surveys. One of the recommended surveys was about attitudes towards the Internet, and one was about the efficacy of email, so we excluded these two. The surveys were divided amongst each group member (4 people), and questions from each survey were correlated with a social determinant of health using a methodology derived from clinical and professional judgment. The final association between question and social determinant of health was reviewed by a physician, pharmacist, and Ph.D. with experience in medical informatics. Data analysis was then performed on the 14x50 matrix to see how the survey questions covered the SDoH previously identified. We subsequently developed a method to develop validated new survey questions for some of the missing domains.

Results

In reviewing the 14 validated telehealth surveys, we found that the questions only covered 16 (32%) of the 50 social determinants of health domains that we identified in Table 1. Of the covered domains, “Medical Needs” was covered by the most surveys (12, 86%), followed by Social Connections/Isolation (10, 71%), and Literacy/Learning Style (8, 57%).

Discussion

Social determinants of health have been shown to contribute up to 40% towards determining health outcomes. Currently, no SDoH screening tool has been shown to be validated for all dimensions of validity. As telehealth becomes a common modality of health care delivery post-COVID-19, social determinants of health that influence patient experience and satisfaction should be evaluated to reduce existing health disparities and to improve telehealth services. In our review of validated telehealth-specific surveys, only 32% of surveys had questions related to the 50 social determinants of health domains, which is not enough for a comprehensive evaluation.

Since current validated telehealth-specific surveys do not adequately evaluate social determinants of health domains, we recommend creating new validated telehealth-specific questions which could be added to extant validated telehealth surveys that include social determinants of health. During development, survey developers should consider the social determinants of health domains that they desire to assess. Determining which SDoH domains should be included requires engagement with both providers and patients. Over 4 decades ago, Dr. Warner Slack once said, “The basis for our use of the computer in medicine is the thesis that the largest and least utilized provider of healthcare is the patient,” emphasizing that patient experience should be assessed through the lens of the patient in a respectful and meaningful way. Decades later, we are still trying to find meaningful ways to involve patients in their healthcare. Meaningfully engaged patients, providers, and relevant stakeholders must be part of the process from the very beginning. The success of telehealth depends not only on the technology, but the alignment and inclusion of all stakeholders. SDoH domains may be conceptualized by working with patients, as doing so can produce effective telehealth innovations.

Some pertinent SDoH domains that affect telehealth services include inadequate material resources, utilities, health literacy, language preference, and financial resource strain. Optimizing utility access, such as broadband internet, to participate in telehealth services can encourage the participation of underrepresented populations. Providing technical support to improve the health literacy of patients with difficulty understanding how telehealth works can lower the barrier to use telehealth. Another approach for increased inclusivity is to expand the service to non-English speakers, as language barriers and the availability of interpreter services prevent the utilization of telehealth.
by non-English speakers in low-income communities. However, such expansion in the service comes with costs: cost of the equipment, cost of hiring interpreters, cost of including more physicians in the service.

Once SDoH domains are chosen, questions may be selected from non-telehealth-specific surveys (validated if possible) or by modifying existing validated telehealth-survey questions. A recent systematic review found 21 screening tools that evaluated at least 2 social risk factors and were administered in a clinical setting. Reliability or validity testing was available for 8 of those survey instruments, with two of the instruments (Partners in Health Survey and Women's Health Questionnaire) reporting results from validity or reliability pilot testing. If no previously prepared questions are acceptable, new questions may be constructed. During this process, speaking to patients within the study population, for example by focus groups, can help identify candidate questions. Questions selected for inclusion in the survey should be evaluated for their relevance to the desired SDoH domain, bias, readability, responsiveness to change, clarity, consistency, and sensitivity to difficult topics. It is recommended that some questions be phrased positively and others negatively to diminish the “halo” effect. Also, recall questions should be avoided, as respondents may have limited ability to recall the past. The questions should offer logically distinct response options, including an option for non-response. Often, survey questions use a five-point Likert scale for scoring, when doing so, the scales should be scored in the same direction to make sense when summed. Once selected, modified, and new survey questions are prepared, they may be added to an extant survey, or combined into a new survey instrument. The modified or new survey instrument should then be validated.

The validation process should include two pilot studies and a final validation study. The first pilot study should aim to assess face and content validity, the usefulness of survey items, remove items that perform poorly, and ensure the survey assesses all relevant constructs. The second pilot study reevaluates the survey for the above qualities after editing, and refines wording and layout. Finally, the validation study should establish the construct, convergent, discriminant, and criterion-related validity of questions. The validation study also assesses the survey instrument for parallel forms reliability, test-retest reliability, internal consistency reliability, including calculating Cronbach’s alpha, and psychometric properties. Preferably, the validation study should be performed on a large population which is similar to the population planned to be evaluated by the validated survey.

Planning must be done for how to best administer the survey. Surveys may be administered as either a self-completion questionnaire or interview. During the pilot and validation studies, consideration should be given to sampling frame and strategy, sample size, administration methods, means to improve response rate, data management and analysis decision, and disclosures to participants. To understand the feasibility of survey implementation, consideration should be given to the number of times the survey needs to be administered, and maintaining respondent anonymity. In addition, a comprehensive method of data entry should be specified prior to data collection. Double data-entry is recommended to reduce error. Data storage should be secure and adhere to regulations, including patient privacy regulations.

One particular limitation of studies making use of and validating telehealth survey instruments is their frequently small sample size. Unfortunately, small sample sizes may be due to a significant amount of pilot and feasibility studies, and results in issues when performing meta-analysis and with study generalizability. Small sample size is one of the major obstacles in conducting randomized controlled trials and sample surveys to evaluate the impact of telemedicine programs. Small sample size may also limit generalizability and create bias in study results. Future studies should strive to reach an adequate sample size to ensure the power of the analysis and generalizability of results.

Our study did have some limitations. We limited our review to the SDoH domains that were collected by screening tools for documentation in electronic health records. More research is needed to draw evidence-based conclusions on which social determinants can affect telehealth uptake and subsequently health outcomes. However, these domains may not be fully comprehensive. For example, our 50 SDoH domains did not include broadband internet access, which was recently proposed as a critical SDoH in the age of telehealth. As our social determinants of health domains were not fully comprehensive, some questions may not have been able to be categorized, while others may have benefitted from an alternative categorization.

**Conclusion**

Social determinants of health (SDoH) have been shown to contribute up to 40% towards determining health outcomes. Despite this, no SDoH screening tool has been evaluated for all types of validity. Of the 14 validated telehealth surveys evaluated, the questions only covered 16 (32%) of the 50 social determinants of health domains that we identified. Telehealth services are a valuable modality to provide care to patients, but to improve them we
will need more comprehensive, validated telehealth surveys which include SDoH questions. In addition to being validated, these surveys should also include patients in their development. We have proposed a patient-inclusive method for developing and validating telehealth surveys that include social determinants of health. Future work includes involving patients in the co-design process to determine SDoH, and to develop validated telehealth surveys which include comprehensive social determinants of health domains.

Semantic Expansion of Clinician Generated Data Preferences for Automatic Patient Data Summarization

Ashutosh Jadhav, Ph.D, Tyler Baldwin, Ph.D, Joy Wu, MD MPH, Vandana Mukherjee, Ph.D, Tanveer Syeda-Mahmood, Ph.D
IBM Almaden Research Center, San Jose, CA

Abstract

Patient Electronic Health Records (EHRs) typically contain a substantial amount of data, which can lead to information overload for clinicians, especially in high-throughput fields like radiology. Thus, it would be beneficial to have a mechanism for summarizing the most clinically relevant patient information pertinent to the needs of clinicians. This study presents a novel approach for the curation of clinician EHR data preference information towards the ultimate goal of providing robust EHR summarization. Clinicians first provide a list of data items of interest across multiple EHR categories. Since this data is manually dictated, it has limited coverage and may not cover all the important terms relevant to a concept. To address this problem, we have developed a knowledge-driven semantic concept expansion approach by leveraging rich biomedical knowledge from the UMLS. The approach expands 1094 seed concepts to 22,325 concepts with 92.69% of the expanded concepts identified as relevant by clinicians.

1 Introduction

Patient Electronic Health Records (EHRs) usually contain very detailed information and are a source of a large amount of clinical data for a patient. EHRs document various aspects of the patients’ clinical information such as the reason for visit, problem list, labs and test results, allergies, medications, etc. They include information over multiple patient encounters and care provided by different healthcare professionals. Although the information is valuable, an abundance of patient information can lead to an information overload condition for clinicians. In order to find information pertinent to the current case, clinicians may go over several notes, labs, and reports spread across multiple visits and years. In such cases, identifying the most relevant information for clinical decision making can be difficult and time-consuming. Moreover, current EHR systems often do not present this tremendous amount of patient data in a way that supports the clinical workflow or cognitive reasoning, and immensely large records can negatively affect clinical work due to error of omission or delay. Thus, it would be beneficial to have a mechanism for summarizing the most clinically relevant patient information. Previous studies have shown that EHR summaries can have a positive impact on overall patient care.

Selecting the relevant information from a patient record is a difficult problem. In this work, we propose a method for the curation and expansion of EHR data preferences, towards summarization based on clinician identified concepts. In the first step, clinicians manually generate a summarization blueprint, or a “summary template”, by specifying which information they would like to see in a holistic summary of a patient’s EHR. This patient information is captured by identifying important clinical concepts and their categories that are useful for generating summary documents. Since the summary template is generated manually, it has limited coverage and may not cover all the important terms relevant to a concept. For example, for the “diabetes” concept, there are multiple relevant concepts such as diabetes mellitus, high blood sugar, diabetes mellitus infantile, insulin pump, diabetes mellitus insulin dependent, insulin resistance, pregnancy induced diabetes, etc. Moreover, for a given seed concept, the related concepts may span across multiple categories such as medication, labs, and allergy.

The objective of this work is to semantically expand the clinician-generated initial summarization template in order to have broader coverage of clinically relevant concepts and categorize these concepts in the selected 11 clinical categories. Although powerful tools such as the Universal Medical Language System (UMLS) Metathesaurus are able to aid in the expansion of medical concepts, there is no universally agreed upon method for performing this expansion. The most straightforward expansion methods all have notable limitations. Keyword-based search on the UMLS Metathesaurus does not consider the semantics of the query and returns all the concepts containing the keyword; it does not rank concepts by considering the relevance of the expanded concepts to the seed concepts. And
while UMLS has relationships between nodes, these relationships are often vague and inconsistent in their granularity, making simple graph traversal perilous. Using UMLS semantic types and relationships provides a large number of possible related concepts that has to be filtered-out vigilantly to select relevant expansions. Thus, most naïve methods of semantic expansion would require a large amount of manual correction by clinician experts.

In order to address this problem, we propose the following multi-step summary template generation approach. First, clinician experts provide a list of important concepts of interest across multiple summarization categories. As these experts may not have knowledge of the UMLS structure, these concepts are initially provided in plain-text format rather than mapped to UMLS identifiers. In the second step, we use a clinical concept extractor to map these plain text terms to UMLS concept identifiers automatically. This automated mapping is then validated and corrected as necessary by the original clinical experts. These validated seed concepts are then automatically expanded by leveraging rich information from a UMLS-backed biomedical knowledge graph. The seed concepts are expanded by identifying their clinical variants and related concepts based on the hierarchy and relationships from the biomedical knowledge graph. Further, the expanded concepts are filtered by removing duplicate concepts and semantically irrelevant concepts. In the fourth step, the filtered concepts are categorized into selected clinical categories.

This work aims to utilize semi-automated clinician-in-the-loop systems in order to efficiently understand data preferences. By doing so, we are able to keep the burden on the clinical experts low while greatly expanding upon their seed concepts and ensuring that their initial intent is understood and met. Further, linking every term to one or more concepts in the knowledge base ensures that they can be mapped to EHR data from disparate sources. The proposed method is able to expand 1,094 seed concepts from 11 clinical categories to 22,325 expanded concepts. Also, this is done while keeping the relevancy rate at 92.69% and with 84.52% concepts categorized into correct clinical categories, which helps to reduce the validation burden. By streamlining data preference gathering and interpretation, summarization systems may more easily be tailored towards the needs of specific specialists. To the best of our knowledge, this is the first EHR data prioritization approach, which keeps the clinicians’ inputs as the focal point while leveraging the rich knowledge from a biomedical knowledge base. The data prioritization and expansion techniques described herein should be applicable across disciplines.

1.1 Related work

1.1.1 Patient summarization report generation

Summarization methods can be broadly categorized as extractive or abstractive. Extractive summaries are created by borrowing phrases or sentences from the original input text. In the domain of clinical summarization, an extractive approach can identify pieces of the patient’s record and display them without providing additional layers of abstraction. Abstractive summaries generate new text that synthesizes the original text. In the domain of clinical summarization, abstractive summaries may provide additional higher-level context to explain the data, such as computed quantities (e.g., trends) or automatically generated text. Much of the current research on summarization in the biomedical domain has focused on text summarization, in which one or more texts are reduced to a single condensed reference text. Text summarization strategies have been developed for automated summarization of scientific literature, generation of literature abstracts, and summarization and translation.

Another dichotomy in summary generation techniques is between methods based on knowledge and those based on data. The data-driven approaches require less context-specific knowledge to create the summary while “knowledge rich” methods necessitate larger and more advanced knowledge bases. A review by Mishra et al. indicated that there is a growing interest in knowledge-rich approaches in the biomedical domain, coinciding with the increased availability of comprehensive lexical resources, such as WordNet and the Unified Medical Language System (UMLS). Common techniques of extraction-based summarization include topic-based sentence extraction, where the relevance of a sentence is computed with respect to one or more topics of interest; Van Vleck et al. performed structured interviews to identify and classify phrases that clinicians considered relevant to explaining a patient's history.
1.1.2 Automatic expansion of medical terms:

In this paper, we present an approach to data expansion reliant on automatic semantic expansion of seed terms. This is similar to existing methods in information retrieval (IR) that falls broadly into the category of automatic query expansion (AQE)\(^6\). The majority of AQE techniques are tailored towards Web search and rely on relevancy feedback\(^7\), click-through data\(^8,9\) or similar queries\(^6\). Until recently most techniques used in AQE were “knowledge-poor”, but with recent advancements in knowledge graphs\(^20,21\) some AQE techniques have been developed to leverage this knowledge\(^22\).

In the medical domain, researchers have developed AQE techniques based on domain-specific ontologies and using the UMLS Metathesaurus. Most of the recent medical IR research has focused on developing knowledge-based (or concept-based) retrieval models dependent on medical resources such as the UMLS. Aronson and Rindflesch\(^23\) use the MetaMap program for associating UMLS Metathesaurus concepts with the original query. They conclude that the optimal strategy would be to combine query expansion with retrieval feedback. Many studies have also utilized the Medical Subject Headings (MeSH) thesaurus in query expansion\(^24\). Zhou et al.\(^25\) expanded query terms utilizing several vocabulary sources, including MeSH. Sondhi et al.\(^26\) used both the MeSH medical thesaurus and manual physician feedback in query expansion, comparing different combinations of methodology.

2 Methods

This section gives an overview of the proposed data preference gathering method based on summary template generation and expansion. Broadly, the major steps are as follows: 1) Generation of the seed summarization template, 2) Semantic expansion of the summarization template, and 3) Patient summary generation based on the expanded template.

Table 1. Clinical categories selected for the summarization template

2.1 Generation of seed summarization template

The seed summarization template is a minimal version of one or more clinical experts’ data preferences seeded by manual curation. To arrive at this initial template, one must first identify the clinical categories of interest and the terms within those categories that are most relevant to the clinical experts. The following are the major components to the generation of the seed summarization template:

- Identification of Clinical categories: The clinical categories of interest may vary between specialties. In each iteration of the data preference gathering technique described herein, the clinical experts provide feedback to help select the appropriate categories. In any examination of electronic health records, the clinical variables of interest can be described in terms of a set of known clinical categories denoted as \(\{C_1, C_2, \ldots, C_n\}\). The clinical categories used in this work are shown in Table 1. These categories were first seeded by those commonly used in the history
and physical examination and were then modified based on input from radiologists who participated in the seed summary template generation.

- Term identification: During the term identification stage, 10 practicing radiologists worked collaboratively to identify data items in each category that they felt were important to see as part of a clinical summary, focusing specifically on what data was of interest in their discipline. These terms were provided as plain text explanations with varying levels of specificity. For instance, categories such as Physical Exam Findings could contain both terms specific to a particular finding such as murmurs, or a much more general statement of interest such as enlarged solid organs.

- Term to clinical concept (CUI) mapping: Terms identified by clinicians are free text English terms and in order to understand their semantics we need to map these terms to their respective clinical concepts in a biomedical knowledge base. Using a medical concept extractor, we mapped the clinician identified terms to UMLS concepts.

- Concept mapping review: With automatic term to CUI mapping, each term can be mapped to multiple concepts or may fail to be mapped as at all. Therefore, to confirm that the terms are mapped to the correct concepts, the mapping is reviewed by the clinicians who first generated the seed terms. A summarization template \( T \) is then defined as collection of clinical concepts linked seed concepts corresponding to their clinical category \( C_i \).

2.2 Semantic expansion of the summarization template

A multi-fold, automated semantic term expansion methodology is employed in order to improve the coverage of the seed summarization template. The following are the major components of the semantic template expansion approach: 1) Biomedical knowledge graph, 2) Clinical variant generation, 3) Hierarchical expansion, 4) Concept filtration, 5) Concept categorization, and 6) Review and validation of expanded template concepts

2.2.1 Biomedical knowledge graph.

The core of our biomedical knowledge graph is the UMLS\(^6\). The National Library of Medicine (NLM) produces the UMLS to facilitate computer understanding of biomedical text. The UMLS is a repository of more than 100 biomedical vocabularies. The UMLS consists of the following three subcomponents: the metathesaurus, the semantic network, and the SPECIALIST lexicon. The Metathesaurus forms the base of the UMLS and comprises of over 4 million biomedical concepts and 16 million concept names, all of which stem from the over 130 incorporated controlled vocabularies and classification systems. The Semantic Network consists of semantic types and semantic relationships. Semantic types are broad subject categories like “Disease or Syndrome” and “Clinical Drug”. Semantic relationships are useful relationships that exist between Semantic Types. Each concept in the Metathesaurus is assigned one or more semantic types (categories), which are linked with one another through semantic relationships. The SPECIALIST lexicon is an English-language lexicon that contains biomedical terms. The lexicon entry for each word or term records the syntactic, morphological, and orthographic information of the respective lemma. It also contains spelling variants, acronyms, and abbreviations.

The biomedical knowledge base used in this work contains a subset of the UMLS, generated as follows: all vocabularies with license type 0 as defined by UMLS are selected along with SNOMED CT. All vocabularies in this set that are not in English are then removed. Our biomedical knowledge base also includes Radlex\(^7\), a radiology-specific vocabulary not typically contained within UMLS. To link terms from this vocabulary to the UMLS-based concepts in the rest of the knowledge base, we utilize the linking provided by the National Cancer Institute Metathesaurus (NCIm)\(^8\).

2.2.2 Clinical variant generation

In the initial summarization template generation step, all the terms identified by clinicians are mapped to clinical concepts in the knowledge base. In the variant generation process, clinical variants of each seed concept are generated by identifying synonymous concepts. In the UMLS, each concept is associated with a single unique identification string referred as its Concept Unique Identifier (CUI). This CUI may be linked to multiple concepts from the source vocabularies that feed into UMLS, which may be described by different term variants. For instance, UMLS CUI
C0020538 “Hypertensive disease” is linked to multiple term variants such as “high BP”, “high blood pressure”, and “hypertension”. The clinical variant generation collects all of these synonymous concepts.

In the second phase of clinical variant generation, related concepts are identified. The candidate-related concepts are assembled by a keyword-based search performed on the knowledge-base using the lexical variants of the seed concepts and their clinical concept variants as inputs. The keyword-based search on the clinical knowledge-base returns numerous concepts. In order to maintain the relevancy of the concepts, from the search results, we select all the concepts that encompass either the seed terms or their clinical variants (e.g., for “diabetes”, get all the concepts that contains “diabetes”) and select only top 20 concepts from the partial match results. While this particular step helps us to improve our recall for the concept expansion to identify relevant concepts, it also identifies a lot of irrelevant concepts. For example, for “diabetes”, this step identifies concepts like “diabetes insipidus” and “vasopressin resistant diabetes insipidus” which are clinically not relevant to “diabetes”. Therefore, the candidate-related concepts are filtered out based on the semantic and textual features as described in the “Template concept filtration” section.

2.2.3 Hierarchical expansion

Hierarchical expansion involves identification of parent, sibling and children concepts for the clinical variants. Concepts in the UMLS are connected to each other using semantic relationships in the semantic network. For each concept, we can retrieve the concept’s parent and children concepts by traversing the concept hierarchy of a source vocabulary (such as SNOMED CT). Using the seed’s parent concept, we further identify the siblings of the seed term. The concept hierarchy traversal is done for two hops and parent/children concepts are retained only if their semantic type matches with the starting concept. This helps to keep the scope narrow and to get relevant concepts. For all the concepts retained in the concept hierarchy traversal, we further identify their clinical variants as described previously. Figure 1 illustrates an extract of the relevancy graph generated for the seed term “diabetes” that maps to the concept ‘diabetes mellitus’ in the knowledge graph. As shown, the sphere of influence for a semantic expansion includes synonyms and many similar terms that may have been intended to be captured by the original clinician-provided phrase.

![Figure 1. Illustration of semantic expansion of a seed term (“diabetes”).](image-url)
2.2.4 Concept filtration

During the clinical variant generation and hierarchical expansion steps multiple synonymous and related concepts are identified as relevant for the seed concepts. In this step, duplicate and semantically irrelevant concepts are filtered out to reduce noise. First, all concepts are converted to singular form (e.g., medications to medication). Duplicate concepts are filtered out based on the syntactic and morphological information of the concepts. If multiple concepts contain the same set of words in a different order (e.g., “high blood pressure”, “blood pressure, high”), all but one of these concepts is filtered out.

Semantically irrelevant concepts are identified by examining the semantic information associated with each concept in the knowledge base as well as some empirically discovered textual features. The semantic features employed include the semantic type of the concept, the distance in hops from the concept to the original seed concept, and the UMLS relationship types between the concepts. We have selected a list of semantic types from UMLS that are relevant to EHR summarization such as “Clinical Drug”, “Laboratory or Test Result”, “Diagnostic Procedure”, “Disease or Syndrome”, and “Medical Device”. We retain only those concepts that have semantic types from our selected list of semantic types. Second, we compute the distance from the expanded concept to the seed clinical concept in the knowledge graph and we retain only those concepts that are less than or equal to 3 hops. This step helps us to filter out “diabetes insipidus” as a related concept for “diabetes” since the distance between these concepts in the knowledge-graph is not less than or equal to 3 hops. Finally, we perform filtration based on selected UMLS relationship types.

For textual features, several stop words indicative of semantic drift were identified by experimentation. Examples of identified stop words include “institute”, “doctor”, “nurse”, “admission”, “hospital”, “education”, and “facility”. The semantic and textual features were selected and tuned based on iterative empirical analysis of relevant and non-relevant concepts.

2.2.5 Concept categorization

In the concept categorization step, the concepts are categorized into the selected 12 clinical categories. This work is inspired by previous approach that uses UMLS semantic types for the concept categorization\(^2^9\). As mentioned earlier, we have curated a list of semantic types that relevant for EHR summarization. We mapped these selected semantic types to one or more clinical categories from (Table 1). We found direct mapping to one or more of from the selected list of semantic types for most of the health categories e.g., for the “Medication” clinical category, we have mapped “Pharmacologic Substance”, and “Clinical Drug” semantic types. For some of the categories, we have used a combination of semantic types and concepts for the categorization, e.g., for “Social history” category, we have used semantic types like “Occupational Activity” and concepts/keywords like “smoking”, “substance abuse”, and “illicit drug”.

2.2.5 Review and validation of expanded template concepts.

Once potentially relevant concepts have been identified via the above expansion process, they are given to clinician annotators for review. Two clinicians were involved in the review process. To reduce the probability of human errors and subjectivity, the two clinicians worked together to set-up an annotation scheme and annotated the first 250 concepts collaboratively. First, the clinicians labeled each term as relevant or not relevant for the template. Second, for each relevant concept, the clinicians checked the assigned clinical category of the concept based the category description and label it correct/incorrect. The clinicians then worked independently to annotate the rest of the expanded concepts from the dataset. Each concept was annotated by two clinicians. After all the annotations were completed, the annotators discussed and resolved conflicts on the concepts that had mismatching labels. This step is further elaborated on in the Results section.

2.3 Use-case - Patient summarization report generation

Once the expanded template is complete, it can be used in conjunction with EHR extraction tools to generate a patient summarization report. If a piece of information in the patient record is linked to a UMLS CUI, the expanded summarization template can be used as a guide to understand its relevancy. All the assembled concepts from the patient’s electronic health record can be matched against the concepts from the expanded template, with only matched
concepts retained in the summary. Alternatively, the extracted information could be ranked based on template-guided factors, such as whether the patient information matches concepts specified by the clinician in the initial template or the expanded concepts or the depth of the knowledge graph to which the concept matches. Since much of the clinical information is buried in free text such as in surgical notes or discharge summaries, having a list of important concepts would be very valuable. Furthermore, since the concepts are organized by the clinical categories, one approach would be to extract relevant sections of EHR documents and use concepts from related clinical categories for the summarization purpose.

3 Results

The seed template generated based on methodology described in section 2.1 had 1094 concepts. The distribution of these seed concepts across the selected clinical categories is listed in the 2nd column of the (Table 2). After all the steps in the template expansion process were completed, the 1,094 concepts in the seed template were expanded to a total of 22,325 concepts. The (Table 2), provides a summary results of our template expansion work. The “number of relevant concepts” is computed based on the concept annotations (section 2.2.5) while the “percentage of relevant concepts” is computed as \( \frac{\text{number of relevant concepts} \times 100}{\text{number of concepts after expansion}} \). The “number of relevant and correctly categorized concepts” indicates the number of concepts that clinician found 1) relevant for the summarization template and 2) categorized into correct clinical categories. The “percentage of relevant and correctly categorized concepts” is computed as \( \frac{\text{number of relevant and correctly categorized concepts} \times 100}{\text{number of concepts after expansion}} \). Finally, the “average number of relevant and correctly categorized concepts per seed” is computed as \( \frac{\text{number of relevant and correctly categorized concepts}}{\text{number of seed concepts}} \).

Table 2. Summary result for template concept expansion by clinical categories

As shown in (Table 2), the number concepts, their expansion, relevancy percentage, and categorization performance differ with the clinical categories. The “Problem list” and “Patient Management” categories had most number of seed concepts while “Allergy”, “Family Member”, “Social history”, and “Vitals” categories had least number of seed concepts. The “percentage of relevant concepts” is over 90% for most the categories, while “Family history”, and “Family member” had lowest “percentage of relevant concepts”. The outcome of “percentage of relevant and correctly categorized concepts” is over 90% for most the categories.
categorized concepts” is dependent on the performance of each of the previous modules (clinical variant generation, hierarchical expansion and concept filtration) as well as our categorization approach. We found that 84.52% of the expanded concepts are relevant for the summarization template and categorized into correct clinical categories. The “average number of relevant and correctly categorized concepts per seed” shows the average concept expansion rate for relevant and correctly categorized concepts by clinical categories. The “Problem list” and “Vital” categories had most average concept expansion rate (more than 26 concepts per seed concepts) while “Family history” and “Family member” categories had least average concept expansion rate (less than 5 concepts per seed concepts). During the validation step, clinicians manually corrected the categories of misclassified concepts and removed incorrect concepts resulting in a final template of 20,694 validated concepts.

Although the validation of the expanded concepts gives some indication of the overall precision of the method, it is unable to assess its recall. A full understanding of recall would need ground truth information about all concepts that are relevant to each seed concept, which would be a taxing and likely unreliable thing to produce via manual clinician input. However, in order to get a rough understanding of recall, we performed a manual analysis on a small scale. We randomly selected twenty seed terms from the original summarization template, and two clinicians manually expanded these selected terms. Since manual expansion between two clinicians for the selected few terms did not match (varied by multiple terms), we could not calculate the recall statistics. However, we discovered that our automated approach covered, on average, 94% of the terms mentioned by the clinicians and many relevant terms that clinicians missed. The 6% terms that were missed in the automated expansion were related to the seed terms but were separated by multiple hops in the knowledge graph.

4 Discussion and Conclusion

Patient Electronic Health Records (EHRs) usually contain very detailed information. Although the information is valuable, an abundance of patient information can lead to an information overload condition for clinicians. Thus, it would be beneficial to have a mechanism for summarizing the most clinically relevant patient information pertinent to the needs of the clinicians. For example, let us consider a real-world use-case with radiologists. Radiologists today rely mostly on their visual interpretation of imaging studies for their diagnostic decisions. There is considerable information about the patient in the electronic health record that could positively impact their decisions. However, this data is often physically distributed across many enterprise hospital systems including electronic medical record (EMR) systems, radiology informatics systems (RIS), picture archiving and communication systems (PACS), laboratory systems, pharmacy systems, etc. Due to the volume of imagery to examine, radiologists have little time themselves to assimilate all pertinent clinical information from these distributed records. As a result, overlooking of diagnosis and misinterpretation is a common problem contributing to diagnosis error rates. This problem is further exacerbated by the differing needs among clinicians. Much of the information of note to a primary care physician would not impact a radiologist’s diagnosis, but certain domain-specific pieces of knowledge, such as an allergy to imaging contrast, could be critically important. If a radiologist’s visual examination could be augmented by providing a compact summary of the patient’s clinical history that focused on their specific data needs, it could lead to improvement in overall clinical decision making.

To this end, this work presents a hybrid approach that leverages biomedical knowledge and expert (clinician) knowledge for efficiently gathering clinical data preferences for use in the production of a EHR data summary. To do so, we introduce the notion of a “summarization template”, a catalogue of data preferences linked to a knowledge base. Summarization template is crafted semi-automatically with clinician assistance. An initial summarization template is manually generated by clinicians and is a high-level specification of patient information that the clinician would like to see in a holistic summary of the patient’s EHR. In its initial state, the template is incomplete and specifies the expected information in free text without linking to a knowledge base. If used as such, it would have limited coverage within an actual patient record. To alleviate this, seed concepts from the initial template are automatically linked to the knowledge base, validated by clinicians, and further expanded with related concepts. The expanded template is then reviewed and validated by clinical experts before it is considered to be ready for use in EHR summarization.

Limitations and outlook: In this work, we have not presented evaluation of the summaries generated using the summarization template due to scope of this work. In section 2.3 we have discussed an approach for EHR summarization using the summarization template. In future, we are planning to report evaluation of the summaries
generated using the summarization template and investigate if specialty templates (e.g., cardiology, neurology) are more helpful in summarization than a generic summarization template.

This study provides a novel approach to EHR data preference selection, keeping the clinicians at the center. It presents a knowledge-driven semantic expansion approach that leverages a rich biomedical knowledge base to expand upon manually identified seed terms. The approach expands 1,094 seed concepts to 20,694 clinically relevant concepts. Results of a validation study indicate that the expansion technique is able to identify relevant concepts with a relevancy rate of 92.69% and able to correctly categorize these concepts in 84.52% of cases, keeping the burden of the clinical validators fairly low. By iteratively relying on clinical expertise and automatic semantic expansion, the proposed method is able to generate and validate specialty-specific data preferences, which can then be used to tailor the output of EHR summarization systems to the needs of each specialist. The approach presented in this work can be used to curate custom vocabularies for different specialties of medicine like cardiology vocabulary, neurology vocabulary. Another possible application of this work would be in improving EHR document annotation and understanding. The approach presented in work is transferable to (and replicable) to address different problems in healthcare field that may benefit from domain/problem-specific custom vocabularies.

Learning Predictive and Interpretable Timeseries Summaries from ICU Data

School of Engineering and Applied Sciences, Harvard University, Cambridge, MA

Abstract

Machine learning models that utilize patient data across time (rather than just the most recent measurements) have increased performance for many risk stratification tasks in the intensive care unit. However, many of these models and their learned representations are complex and therefore difficult for clinicians to interpret, creating challenges for validation. Our work proposes a new procedure to learn summaries of clinical timeseries that are both predictive and easily understood by humans. Specifically, our summaries consist of simple and intuitive functions of clinical data (e.g., “falling mean arterial pressure”). Our learned summaries outperform traditional interpretable model classes and achieve performance comparable to state-of-the-art deep learning models on an in-hospital mortality classification task.

1 Introduction

Accurate predictions of patient risk in critical care units can aid clinicians in making more effective decisions. Specifically, early identification of patients at high risk for in-hospital mortality is critical to assess patient disease acuity and inform life-saving interventions [1, 2]. To predict in-hospital mortality risk, researchers have developed algorithms ranging from simple score-cards [1, 3] to statistical machine learning (ML) models. Recent advances in ML have led to the development of models with vast improvements in predictive accuracy for patient in-hospital mortality risk [4–7].

Despite these improvements, however, ML models are still prone to critical errors, often failing to generalize across different care settings or institutions [8]. An emerging line of research in interpretability, defined by [9] as “the ability to explain or to present in understandable terms to a human,” provides an alternative way to ensure systems preserve properties such as safety or nondiscrimination. If a model is interpretable to stakeholders, then clinical experts can inspect the model and verify that its reasoning is sound. This ability to audit and validate is especially important when the models are used to inform critical decisions affecting patient health.

In this work, we present a novel ML method to learn clinical timeseries summaries that are interpretable and predictive. We introduce functions to compute summaries that align with simple and intuitive concepts, such as whether the timeseries is decreasing or spikes above a critical threshold. In contrast to prior work, our method learns how much of the timeseries should be used to calculate these summaries, discarding earlier timesteps that may be irrelevant for a specific prediction task. Importantly, we introduce relaxations of our summary definitions to enable differentiable optimization, allowing summary parameters to be learned jointly with those of a downstream model. We show that with our method, we can achieve accuracies comparable with state-of-the-art baselines without sacrificing interpretability.

2 Related Work

Prior work on explaining clinical timeseries models fall into two categories: learning simple models that are inherently interpretable, and generating explanations of complex black box models. We summarize a few key examples below.

Interpreting Deep Models. One popular strategy for explaining ML models is learning a second post-hoc explanation model to explain the first black box model [10]. Many post-hoc explanation techniques for clinical timeseries models train explanation models that quantify the relative importance of each clinical variable [11, 12]. However, several works argue against the use of post-hoc explanation techniques, as explanation models are not always faithful or representative of the true underlying black boxes [13, 14]. Our method avoids these problems by design, instead explicitly optimizing for interpretability so that a second explanation model is not needed.

Another line of research proposes attention mechanism models specifically designed for timeseries. [15, 16] present neural attention architectures for clinical timeseries and argue that attention scores measure feature importance. However, attention methods are often highly complex and nonlinear. Furthermore, [17] shows attention scores do not always reflect true importance. Instead of approximating importance, our study uses linear models over richer fea-
tures, where importance does not need to be approximated but can be directly read off model coefficients.

**Expert Systems and Expert Features.** Our work extends a long tradition of clinical experts hand-crafting features to create interpretable clinical decision-support algorithms. Two expert systems widely used in ICUs are SAPS-II [1] and APACHE [3], which use simple score-card algorithms to evaluate patient acuity. These systems use input features such as the patient’s average or worst lab or vital values over time to compute mortality risk. While SAPS-II and APACHE are simple and simulable to clinicians, their predictiveness is limited, as they cannot capture how labs or vitals change across a patient’s stay.

A similar line of research proposes manual construction of expert features from clinical data, which are then used as input to ML models [18, 19]. One limitation of this approach is that expert feature derivation is expensive and requires clinical expertise. Rather than relying on expert knowledge to identify which summary features will be the most predictive for a given task, our work instead uses optimization with a sparsity constraint to automatically learn which summary features are the most predictive.

**Summarizing Clinical Timeseries.** A number of works have proposed a wide range of summary statistics for patient timeseries data. Many works such as [4, 20] train clinical models using the minimum value, maximum value, first measured value, or skew of clinical timeseries data. [21] proposes a more comprehensive set of 14 summary statistics to characterize the central tendency, dispersion tendency, and distribution shape of clinical timeseries data. Our work extends this research, and is the first to our knowledge to use the slope of the timeseries or proportion of time above or below critical thresholds. Our work is also novel in that we explicitly model and optimize for the duration over which we compute each summary feature.

### 3 Cohort and Problem Set-Up

Our goal is to learn summaries of patient timeseries data that are both human-interpretable and predictive for a downstream classification task. Our approach will define how to calculate these human-interpretable summaries, and describe how both summary and classification model parameters are learned through optimization. In what follows, we detail each of these processes.

**Prediction Task.** Our work examines early prediction of in-hospital mortality. We use the patient’s first 24 hours of data to predict if they would later expire over the course of the remainder of their admission. Patients who expired in the first 24 hours of their stay were excluded from our cohort.

**Cohort Selection.** We use data from the MIMIC-III critical care database [22], which contains deidentified health data from patients in critical care units of the Beth Israel Deaconess Medical Center between 2001 and 2012. All data was extracted from MIMIC-III PhysioNet version 1.4, which contains 30,232 patients. We exclude patients under 18 years of age and patients whose weight is not measured. We include data from each patient’s first hospitalization only, and only patients with stays between 24-72 hours [4]. After applying these criteria, our final cohort contained 11,035 patients, 15.23% of whom died in-hospital. Cohort characteristics and demographics are summarized in Table 1.

### 3.1 Extracting Inputs and Outputs

For each patient \( n \) in our \( N \) patient cohort, we extracted static observations and physiological data including labs and vital signs sampled hourly. All clinical variables were separately normalized to have zero mean and unit variance. Figure 1 shows how features are extracted for patients that are positive versus negative for in-hospital mortality.
Figure 1: Example positive and negative time-series to illustrate feature extraction. The two trajectories have input data extracted from time 0 to time of prediction $T = 24$. Figure inspired by Sherman et al [23].

**Static observations $S$.** Matrix $S : (N \times 8)$ contains 8 demographic variables for each patient $n$: their age at admission, gender, and other information about their ICU stay (their first ICU service type, and whether their admission was urgent, emergency, or elective).

**Per-timestep clinical observations $X$.** The clinical variable tensor $X : (N \times D \times T)$ contains $D = 28$ measurements of clinical variables for each of the $N$ patients at time $t$, discretized by hour. These 28 measurements consist of vital signs and labs: diastolic blood pressure, fio2, GCS score, heart rate, mean arterial blood pressure, systolic blood pressure, SRR, oxygen saturation, body temperature, urine output, blood urea nitrogen, magnesium, platelets, sodium, ALT and AST, hematocrit, po2, white blood cell count, bicarbonate, creatinine, lactate, pco2, glucose, INR, hemaglobin, and bilirubin. Missing values at timestep $t$ were imputed using either the most recent measurement of the variable, or the population median if the variable had not yet been measured during the patient’s stay. We use the patient’s first $T = 24$ hours of data to predict in-hospital mortality. We use subscripts to index into the tensor: for example, $X_t$ indicates the $(N \times D)$ matrix of measurements taken at time $t$.

**Per-timestep measurement indicators $M$.** The measurement indicator tensor $M : (N \times D \times T)$ contains indicator elements $M_{n,d,t}$ which are 1 if their corresponding clinical variable in $X_{n,d,t}$ was measured at time $t$, 0 otherwise.

**Outcome labels $y$.** Label vector $y$ contains indicators $y_n$ which are 1 if patient $n$ expired in-hospital, 0 otherwise.

### 4 Methods

Given a cohort of $N$ training examples $\{X, M, S, y\}$, we propose a novel procedure for learning predictive human-interpretable timeseries summaries. Concretely, we first compute summaries $H$ from clinical timeseries data $(X, M)$. We then use the summaries $H$ in addition to static data $S$ and clinical variables $X$ as input to a Logistic Regression model to predict labels $y$. This process of using human-interpretable summaries for prediction is shown in Figure 2.

In Section 4.1 we motivate and introduce our novel summary features. In Section 4.2 we give continuous relaxations of summary feature definitions to enable efficient inference of summary parameters. In Section 4.3 we discuss how predictive summary features can be jointly learned with downstream classification model parameters.

#### 4.1 Model: Defining human-interpretable summaries

Measures of central tendency and dispersion have commonly been used to summarize timeseries (see survey in [21]). Our key modelling innovations include adding additional features that correspond to how clinicians themselves describe timeseries. Our novel contributions include explicitly modelling the overall trend of a lab/vital and the number of hours that a lab/vital dips above or below a threshold, as well as allowing different features to be computed over different periods of time (e.g. the most recent 6 hours vs. the most recent 24 hours).
Figure 2: Illustrates summary extraction for prediction from timeseries data. First, non-static clinical variables \( \{X, M\} \) are used to compute interpretable summary features \( H \). Then, summary features \( H \), static features \( S \), and the non-static variables \( \{X, M\} \) at the time of prediction are given as input to a Logistic Regression model \( g \), which predicts output labels \( \hat{y} \). Figure inspired by Ghassemi, Szolovits et al \[24\].

The \( I = 13 \) summary statistics used in this study are listed in Table 2. Each of the summary statistics takes into account measurement indicators \( M \) so that clinical variable summaries are computed only using timesteps where the variable is measured. Each summary statistic is applied to each of the \( D \) clinical variables to create the summary feature tensor \( H : (N \times D \times I) \).

Below, we expand on the parameterization of our summary features. Next, we describe how we enable efficient, automated search over summary feature parameters. Importantly, our approach automates many processes associated with summary design, enabling optimization over summary parameters.

**Incorporating Duration.** Many prior works in clinical timeseries modelling do not use all timesteps for the patient, but instead only the most recent available data, such as the six or twelve hours before the time of prediction. In contrast to prior works, we explicitly model how much of each timeseries should be used to compute each of the \( I \) summaries in \( H \). For example, we may wish to exclude earlier measurements of a particular clinical variable if only the variable’s recent measurements before time of prediction \( T \) are significant for a prediction task. Specifically, for each variable \( d \) and for each summary function \( i \), we define a duration time \( C_{d,i} \). Only the variable’s timeseries data that occurred in the immediately previous \( C_{d,i} \) hours before the time of prediction is used to calculate summary \( i \). We organize all the duration time parameters \( C_{d,i} \) into a \((D \times I)\) matrix \( C \).

To exclude data that occurs before time \((T - C_{d,i})\) when computing summary features, we multiply each of the original timeseries variables by indicator variables for whether the measurements occurred within \( C_{d,i} \) hours before time of prediction \( T \). For example, a mean summary statistic would be computed using indicator variables \( 1(\cdot) \) as:

\[
H_{i=\text{mean}} : (N \times D) = \left( \sum_{t=1}^{T} 1(t > T - C_{i=\text{mean}}) \odot X_t \odot M_t \right) / \left( \sum_{t=1}^{T} M_t \odot 1(t > T - C_{i=\text{mean}}) \right)
\]

(1)

where \( \odot \) is the element-wise multiplication operator and division is performed element-wise. Our objective is to learn duration parameters \( C \) that maximize the predictiveness of their corresponding summary features \( H \).

**Threshold Parameters.** Some of the summary functions \( f_i \) in Table 2 have additional parameters such as thresholds. For example, one of the summaries is the proportion of the patient’s measured timeseries where their measured clinical variables are above some \( D \)-dimensional critical threshold parameter vector \( \phi^+ \) for each variable:

\[
\left( \sum_{t=1}^{T} M_t \odot 1(X_t > \phi^+) \right) / \left( \sum_{t=1}^{T} M_t \right)
\]

(2)

These summaries correspond to clinically-intuitive ideas, such as whether the patient been mostly well or sick. As with durations, we learn threshold parameters automatically to avoid burdening experts and to assist in prediction.
4.2 Continuous Relaxations for Efficient Inference

Learning Duration Parameters. In Equation\textsuperscript{1} we showed how summary functions \( f_i \) that only use the most recent \( C \) hours of data can be calculated using indicator variables \( 1(t > T - C_{d,i}) \). These indicator variables, however, do not have informative gradients and are not differentiable. To enable differentiable optimization for duration time parameters \( C \), we introduce weight parameters \( W \) by relaxing the indicator random variables using the sigmoid function \( \sigma(x) = \frac{1}{1 + e^{-x}} \). Using the duration parameter matrix \( C \), we define \( D \)-dimensional vectors \( w_{t,i} \) that compose weight tensor \( W : (T \times I \times D) \):

\[
w_{t,i} = \sigma((t - T + C_i)/\tau)
\]

For each feature \( d \) and summary \( i \), clinical observations \( X_{d,i} \) where \( t > T - C_{d,i} \) will have corresponding weights \( w_{t,i,d} \) near 1. Timesteps \( t \) where \( t < T - C_{d,i} \) will have corresponding weights \( w_{t,i,d} \) near 0. Temperature parameter \( \tau \) controls the harshness of the weight matrix: small temperatures push the sigmoid function towards its edges, learning weights that are closer to exactly 0 for timesteps before \( T - C_{d,i} \) and 1 for timesteps after \( T - C_{d,i} \), effectively functioning as the indicator variables in Equation\textsuperscript{1}.

Weighted summary functions \( f_i \) used to derive human-interpretable summaries \( \mathbf{H} \) can be found in Table\textsuperscript{2}. Duration parameters \( C \) that determine weight tensor \( W \) are included in \( \beta_H \), the set of all parameters necessary to compute the summaries.

</tbody>
</table>

Table 2: Table of functions \( f_i \) used to calculate human-interpretable summaries \( \mathbf{H} \). For each of the \( D \) clinical variables, all \( I \) of the above functions are applied to each of the \( N \) patients. Each of the \( I \) summary features \( i \) is defined with respect to \( D \)-dimensional weight vectors \( w_{t,i} \) defined in Section\textsuperscript{2}. Parameter \( \tau \) is a temperature parameter for the sigmoid function. \( 1(\cdot) \) denotes indicator variables for events inside the parentheses, \( \odot \) indicates element-wise matrix multiplication and division is done element-wise. Additionally, \( X = \sum_{t}^{T} M_t \odot X_t / \sum_{t}^{T} M_t \), \( \bar{M} = \frac{1}{T} \sum_{t}^{T} M_t \).

Learning Threshold Parameters. Our work relaxes summary definitions to enable differentiable optimization to learn summary parameters. The indicator variables used to define the proportion of hours that a patient’s timeseries is above thresholds \( \phi^+ \) in Equation\textsuperscript{2} are non-differentiable with respect to \( \phi^+ \). To enable differentiable optimization,
our work defines our threshold summary features using the sigmoid function $\sigma$ with temperature parameter $\tau$:

$$ f_{\text{threshold}}(X, M, W) = \left( \sum_{t=1}^{T} w_{t,i=\text{threshold}} \odot M_t \odot \sigma \left( \frac{X_t - \phi^+}{\tau} \right) \right) / \left( \sum_{t=1}^{T} M_t \cdot w_{t,i=\text{threshold}} \right) $$

(4)

Threshold parameters $\{\phi^+, \phi^-\}$ are included in $\beta_H$, the set of all parameters necessary to compute the summaries.

### 4.3 Learning Process

Our study uses summary features $H$, along with static variables $S$ and timeseries variables $\{X, M\}$ at prediction time $T = 24$ as input to a Logistic Regression model $g$ with coefficients $\beta_g$. Logistic Regression model $g$ outputs predicted probabilities $\hat{y} = p(y = 1|X, S, M)$. Our objective is to learn optimal summary and model parameters $\beta = \{\beta_H, \beta_g\}$. We jointly learn parameters $\beta$ by minimizing the loss function

$$ L(\beta; X, M, S, y) = -\frac{1}{N} \sum_{n=1}^{N} \omega_n \left( y_n \cdot \log[g(X_n, M_n, S_n, \beta)] + (1 - y_n) \cdot \log[1 - g(X_n, M_n, S_n, \beta)] \right) + \Omega(\beta_g) $$

(5)

Our loss function is the sum of the weighted binary cross-entropy loss using predictive model $g$ and the regularization penalty $\Omega(\beta_g)$. To account for class imbalance, we reweight each training example $n$’s loss contribution by $\omega_n$, the inverse of its class frequency in the training dataset.

**Horseshoe Regularization on Coefficients.** We explicitly optimize for sparsity in model parameters $\beta_g$ via our regularization penalty in our training objective. We use a Horseshoe regularization penalty $\Omega(\beta_g)$ with shrinkage parameter $1$ to encourage sparsity in the learned regression coefficients $[25]$.

### 5 Experiments

We compare models learned using our summaries to other interpretable models as well as deep learning baselines. We show that our models outperform other traditional human-interpretable model classes and achieve performance comparable to deep models on the in-hospital mortality task.

**Model configurations.** Our baseline models are: Ridge Logistic Regression models that take as input only the patient timeseries measured at the time of prediction $T$, and Ridge Logistic Regression and LSTM models that take as input all of the patient timeseries. We used an LSTM as our deep baseline architecture as prior works document their superior performance at mortality prediction from clinical timeseries data $[26]$.

Our LSTM models were trained on the sequential timeseries data $\{X, M\}$ with a step size of 1 hour. The LSTM hidden states at each timestep were then used to predict both the next timestep of the patient timeseries $X$, and to predict outcome labels $y$. All $T$ of the output hidden states $X_t$ were input to a fully-connected layer, which output predictions of the next timestep $X_{t+1}$. The last output hidden state at time $T$ was also input with static features $S$ to a fully-connected layer to predict outcome labels $y$. The LSTM models were trained to minimize both the mean-squared error of the next state prediction, and the binary cross entropy loss of the classification prediction. ReLU activation functions were applied to both fully-connected layers.

**Training Details.** For training and testing, we split the cohort of $N$ patients into train and test sets, where all data associated with each patient is either in train or test. All performance metrics are averaged across five train-test splits. Ridge baseline models were implemented using RidgeCV from scikit-learn $[27]$, LSTMs as well as our summary-based Logistic Regression models were implemented with PyTorch, and trained with the Adam optimizer $[28]$ at a batch size of $256$. We trained all of our Logistic Regression models for $30,000$ epochs and LSTM models for $10,000$ epochs using early stopping. All hyperparameters (including the LSTM hidden state and layer dimensions, optimizer learning rate, and regularization parameters) were selected via random hyperparameter search $[29]$. All temperature parameters $\tau$ were set to $0.1$.

Our final learned LSTM models have hidden state dimension $32$, $1024$ nodes in the layer to predict the next timestep, and $64$ nodes in the layer to predict labels $y$. They are trained using a learning rate of $1e^{-05}$. Our final learned models with summaries use $\alpha = 1e^{-05}$, Horseshoe shrinkage parameter $1.0$, and learning rate $1e^{-05}$. 

586
6 Results

Our learned models achieve performance comparable to state-of-the-art baselines. Table 3 compares the performance of our learned models with linear and deep baselines for the in-hospital mortality prediction task. Applying a linear model to the learned summary features $H$ consistently improves AUCs in comparison to using a linear model on clinical timeseries and static data alone. Our models achieve an AUC performance comparable to state-of-the-art LSTM models with test AUCs of $0.9000 \pm 0.0223$. Notably, our models that allow differentiable optimization to learn duration times outperform models that compute all summary features using the entire duration of the patient timeseries. This implies that there is predictive value in explicitly modelling how much of each variable’s clinical timeseries should be considered for a specific prediction task.

Table 3: Performance of learned models on the in-hospital mortality prediction task. AUCs are averaged over five train-test splits with their standard error. Abbreviations: LR, Logistic Regression; LSTM, long short-term memory. $C$ refers to the duration parameters defined in Section 4.2.

Our learned models use fewer features to achieve higher accuracy in comparison to other interpretable baselines. To evaluate the sparsity of each model, we performed a set of ablation experiments where we zeroed all but the $N$ coefficients with the largest magnitudes for each of the learned Logistic Regression models. In Figure 3, we show the average test set AUC for Logistic Regression baseline versus our models using only $N$ coefficients. Our models consistently outperform baseline models when all but $N$ coefficients are zeroed, suggesting that our models learn a smaller and more predictive set of important features.

Our learned models are interpretable. Table 4 shows 15 key summary features that consistently have the largest learned Logistic Regression coefficients across train-test splits. The corresponding coefficients for each feature can be interpreted as a measure of the feature’s contribution to the final classification label. For example, because the mean of the patient’s GCS has a large negative coefficient, this means that patients with higher mean GCS scores will be assigned lower predicted probabilities for in-hospital mortality. Therefore our models are decomposable [30], as each
of the model’s features and coefficients has an intuitive clinical explanation.

**Our learned summary features are clinically sensible.** The vast majority of the key summary features learned by our models shown in Table 4 are supported by studies in medical literature. For instance, it is widely accepted that patients who are older tend to have lower chances of survival in ICU settings [31, 32]. Similarly, patients with lower GCS scores of below 6 tend to have severe injuries and higher chances of mortality [33]. Notably a lower GCS score in the later hours of a patient’s hospitalisation significantly reduces a patient’s chances of survival [34, 35]. Finally, the normal range of features such as the blood oxygen saturation (SPO$_2$) is between 95% and 100%. An SPO$_2$ consistently below 90% indicates hypoxaemia or potential respiratory distress. These patients have to be mechanically ventilated in ICU and frequently have lower chances of survival [36, 37].

Table 4: Key summary features, sorted from largest to smallest coefficient magnitudes, from learned models.

**Initialization sensitivity.** In general, we observed that our optimization procedure is stable, learning the same 15 key summary features across different stochastic parameter initializations and train-test splits. However, there are cases where we observed that the learned duration parameters $C$ varied depending on their initialization. As such, we recommend that practitioners incorporate prior knowledge about the clinical prediction task when initializing the duration time parameters. For example, if examining the entire duration of the patient’s timeseries is necessary for a prediction task, then the duration parameters should be initialized to include the entire timeseries by default.

7 Discussion & Conclusion

In this work, we defined functions to compute interpretable, parameterizable summaries of clinical timeseries, and developed relaxations so that our summary parameters could be jointly learned with a downstream predictive model. In our experiments, we used Logistic Regression to make predictions because its coefficients are easily decomposable [30]. However, because our learned summaries are inherently interpretable, any other interpretable architecture could be used instead. Our methodology is generalizable and enables the efficient learning of intuitive and predictive timeseries summaries without placing any assumptions on the downstream model architecture.

**Future work.** Our study poses many interesting directions for future work. One avenue would be to conduct a user study to validate the human-interpretability and decomposability of our proposed summary features. Another would be to evaluate whether the summary features learned for particular critical care prediction tasks remain predictive for a wider set of critical care prediction tasks. Finally, we could also develop additional summary statistic functions, or expand our framework to consider sharing duration parameters across features or across summaries to better model dependencies between clinical labs and vitals—as many physiological events are characterized by several simultaneous
changes to multiple labs and vitals.  

**Conclusion.** In this paper, we propose a new method to learn interpretable and predictive summary features from clinical timeseries data. In addition to introducing novel summary statistics including slope and threshold features, our work differs from prior work by learning the duration of timeseries data that should be used to compute each summary. We demonstrate that our learned timeseries summaries achieve performance quality comparable to state-of-the-art deep models when trained to predict early patient mortality risk on real patient data. We also qualitatively validate our models to confirm their interpretability and sensibility. Our work is an important step towards optimizing for representations of clinical timeseries data that are both highly predictive and interpretable.

Abstract

Learning health systems have the ability to systematically evaluate treatments and treatment pathways. Characterization of treatment pathways can enhance a health system’s ability to perform systematic evaluation to improve care quality. In this study we use a Long-Short Term Memory (LSTM) autoencoder model to systematically characterize treatment pathways in a prevalent phenotype—Major Depressive Disorder (MDD). LSTM autoencoder models generate representations of medication treatment pathways that account for temporality and complex interactions. Patients with similar pathways are grouped with K-means clustering. Clusters are characterized by analysis of medication utilization sequences and trends, as well as clinical features, such as demographics, outcomes and comorbidities. Cluster characterization identifies endotypes of MDD including acute MDD, moderate-chronic MDD and severe-chronic, but managed MDD.

Introduction

Learning health systems are those that work in a continuous cycle converting data to knowledge to process. These systems have the capability to systematically evaluate treatments from observational data and augment processes to improve system performance¹–³. An important step towards systematic evaluation is characterization of in place treatment pathways⁴. In this study, we perform a systematic characterization of treatment pathways of Major Depressive Disorder (MDD) from observational electronic health record (EHR) data at Vanderbilt University Medical Center (VUMC). Clinical trials have shown the effectiveness of antidepressants in treatment of MDD relative to placebo⁴, but there is a need for better understanding and representation of long term treatment practices⁵–⁷. Efforts to standardize treatment pathways have resulted in decreased variance in treatment of MDD over time, but heterogeneity of treatment pathways remains between institutions⁵. Due to the prevalence of MDD and impact on daily life, characterization of treatment pathways in MDD may be beneficial to healthcare organizations in improving outcomes and quality of care⁶–⁹.

Past studies have modeled treatment paths by visualizing medication sequences²,⁸. We built upon these studies by modeling medication treatment pathways in the VUMC Synthetic Derivative¹⁰ accounting for temporality as well as treatment resistant depression (TRD). TRD is defined as failure to respond to two or more antidepressant trials¹¹. TRD is of particular interest in this study for the potential use of treatment pathways in prediction of TRD in future studies. In this study, electroconvulsive therapy (ECT) was used as a surrogate for TRD¹².

Long-Short Term Memory (LSTM) neural networks are deep learning algorithms that have the ability to model temporal data with complex relationships like those characteristic of medication data. An LSTM is a form of Recurrent Neural Network that stores information over extended time intervals and employs a gating method to address the exploding gradient problem found in some Recurrent Neural Network applications¹³. Autoencoders have the ability to generate simplified encodings of complex data structures. Autoencoders are composed of two sub-models: an encoder and decoder. The encoder receives an input data set and reduces the dimensionality to a hidden layer. The decoder takes as input the hidden layer from the encoder model and reconstructs the input data¹⁴,¹⁵. The hidden layer generated by the encoder model is a denoised continuous vector representation of the model input. LSTM autoencoders have been used to learn representations for video sequences¹⁶ and for biomedical endotyping¹⁷. In this study, we hypothesize that LSTM autoencoders can effectively represent medication treatment pathways and that characterization of encoding clusters will allow for differentiation of clusters by medication treatment pathways and clinically relevant variables.
Methods

Data Description

The patient cohort for this study included patients aged 18 to 90, diagnosed with major depressive disorder (MDD) seen at least two times, six months apart, at Vanderbilt University Medical Center (VUMC) located in the United States Mid-South in Nashville, TN. Patients with MDD were identified that had at least one of the following ICD-9 codes: 311.x, 296.2x, 296.3x, 300.4x or ICD-10 codes: F32.xx, F33.xx, F34.1 and their index diagnosis took place prior to 12/31/2016 to ensure a minimum of three years of medication data. We excluded any patients with a diagnosis of Bipolar Disorder or Schizophrenia and those that were not prescribed an antidepressant (see Table 5) within three years of diagnosis.

Medications were extracted for three years following first MDD diagnosis and subset to include only prescriptions. Because the population with TRD was of particular interest for downstream prediction of TRD status before it occurred, the cohort with MDD who received ECT, a surrogate for TRD in some studies, had medication data censored one day prior to ECT treatment date. Medications were grouped using the World Health Organization Anatomical Therapeutic Chemical (ATC) classification level 5. Medications included in the study are listed in the Appendix Table 5.

Unsupervised Feature Learning

Medication data were converted to a categorical quarterly time series with indicators for each medication class if observed during a quarter. The resulting dataset had dimension N x M x T, with N the number of patients, M the number of medication classes, and T the number of quarters in our observation window.

An LSTM autoencoder was fit on the medication data to generate a continuous-multidimensional representation of each patient’s medication pathway. The model was built using the Keras Python library. We tested multiple model structures in order to tune the number of encoder layers as well as the dimension of the encoder layers. We performed a grid search on 15 candidate models with one to three encoder layers and final encoder layer dimensions of 8, 16, 24, 32 and 64. Models were evaluated based on reconstruction mean squared error (MSE) on a 25% validation test set. Model selection was based on visual inspection of plots with encoding dimension on the x axis and MSE on the y. The model with an MSE such that increasing encoding dimension does not meaningfully reduce MSE was selected for clustering.

The encodings of the selected model were clustered using the K-means algorithm. The Elbow Method was utilized for selection of K—the number of clusters. In this method the sum squared distance from the cluster centroid is plotted against K and the “elbow” is selected by visual inspection as the point at which increasing K does not meaningfully reduce sum squared distance from the centroid.

Cluster Characterization

We characterized clusters by performing an analysis of demographics, clinical outcomes, comorbidities, and utilization trends. Demographics include gender, age and race. The clinical outcomes measured in the study are all cause mortality, admission, ER Visit and a TRD surrogate (electroconvulsive therapy [ECT]) within the three-year period of analysis. Comorbidities are identified using Agency for Healthcare Research and Quality (AHRQ) Clinical Classification Software (CCS) to map ICD 9 and 10 codes to clinically meaningful comorbidities. We perform a Chi-square test of association between clusters and categorical demographics—gender and race—and perform ANOVA for continuous variables—age and comorbidity count—with post-hoc Bonferroni corrected confidence intervals to measure differences between clusters. Mental health comorbidity association with clusters were also analyzed by Chi-square with post-hoc Bonferroni corrected significance tests to identify clusters with enriched comorbidity prevalence.

Medication and visit utilization analysis included: calculating the mean number of prescriptions per patient, mean unique number of prescription classes per patient and single medication treatment rates—the proportion of patients prescribed a single medication class for the entire period of analysis. Trend graphs visualized three-quarter rolling averages of medication utilization. By cluster medication sequences were visualized by sunburst plots. For
visualization purposes medications were combined into clinically meaningful groupings as defined by physicians from the VUMC department of psychiatry. These groupings are available in Table 5 included in the appendix of this paper. Additionally, we account for instances in which patients are prescribed multiple medications in a short time period. We will refer to these cases as Multi-medications-therapy and define it as any instance in which a patient is prescribed two different medications (ATC 5 level) within a five-day period.

**Results**

**Model Selection**

Autoencoder models were fit and validation MSE was plotted by encoding dimension for each of the model structures in Figure 1. The three-layer encoder model outperforms the one and two encoder layer models at each candidate encoding dimension. Validation MSE in the three-layer encoder model is 0.0034 with encoding dimension equal to 24. At dimension 32 and 64 the validation MSE is 0.0032 and 0.0020 respectively. As can be seen in Figure 1, the rate at which the three-layer encoder model MSE (green) is decreasing is reduced at dimension 24. The model with three encoding layers and encoding layer dimension of 24 is selected for our final model. Encodings from the selected model were cluster using the K-means algorithm. The elbow method was utilized for selection of K—the number of clusters. Visual inspection of the Figure 1 (right) indicates that the “elbow” occurs at K=5.

![Figure 1. Autoencoder and K-means clustering model selection plots.](image)

The reconstructed MSE for each candidate model is plotted with lines colored by the number of encoding layers (left). The within cluster sum squares are plotted for the K-means algorithm with K=1 through K=14 (right).

**Cluster Characterization**

Summary statistics by cluster were calculated for demographics, outcomes and comorbidities. 46,454 patients met the inclusion criteria for this study. Five clusters were identified, cluster 2 being the largest (n=13,908, 29.1%). ANOVA and Chi-square tests were conducted for association between clusters and variables of interest. For each of the variables tested differences between clusters were found to be statistically significant. Post-hoc Bonferroni corrected confidence interval margin of errors are included in Table 1. The majority of patients in the study are female (66.4%) and Cluster 4 is higher proportion female (70.4%, 95% CI = 69.4%-71.4%). Cluster 5 has elevated mortality (3.6%, 95% CI = 3.3%-3.9%) and Cluster 2 has elevated admissions (66.6%, 95% CI = 66.0%-67.2%) and ECT (0.56%, 95% CI = 0.46%-0.66%). Cluster 3 has the highest CCS comorbidity count on average (17.6, 95% CI = 17.3-17.6).
Table 1. Clinical characteristics by cluster. For each metric in the table the margin of error for a Bonferroni corrected 95% confidence interval is included in parentheses.

Medication utilization statistics by cluster are included in Table 3 and trend plots of medication and visit utilization in Figure 2. Clusters 2 and 4 have the lowest mean count of prescriptions (3.0, 3.6) during the period of analysis and the lowest number of unique prescriptions by medication class (1.5, 1.4) as well as the highest rates of single medication treatment (66.4%, 68.9%). Clusters 3 and 5 have the highest prescription counts (12.4, 9.8) and the lowest rates of single medication treatment (31.7%, 37.2%).

Figure 2. Medication and visit utilization trends. Three quarter moving average plots of the percentage of patients with a prescription (left) and visit (right) during each quarter of the period of analysis by cluster.

The most common initial medication type prescribed was selective serotonin reuptake inhibitors (SSRI) in the patients studied (50.1%). This ranged from 47.7% in cluster 4 up to 51.4% in cluster 3. For patients receiving an SSRI initially, the majority of these patients did not receive another prescription within the period of analysis (66.2%) and 9.1% were prescribed a SSRI as their second antidepressant. In our study population 18.4% of patients received multi-medicating-therapy. Rates of multi-medicating-therapy range between 11.5% in cluster 1 and 22.6% in cluster 2.
Figure 3. Sunburst plot of medication sequences by cluster. The first (inner) level of the plot represents the distribution of initial antidepressant types with the second level representing the second antidepressant type prescribed and so on.

The Chi-square analysis of association between mental health comorbidities and clusters was conducted to identify comorbidity-cluster pairs that deviated from expected frequency given the overall comorbidity frequency within the population and the cumulative comorbidity burden within the cluster. Results of the analysis are included in Table 4.

Table 3. Chi-square analysis of mental health comorbidities by cluster. Chi-square analysis to test association between cluster and mental health comorbidities. Post-hoc Bonferroni corrected significance tests of the Chi-square statistic are performed for each comorbidity-cluster pair at the 90%, 95%, and 99% significance levels (indicated by color).
Discussion

Overall, we find that the unsupervised learning methods are able to separate the study population into clusters using medication data alone. We find differences in medication utilization, medication heterogeneity, temporal trends, as well as statistically significant differences between clusters in clinical features. This work builds on the characterization of treatment pathways research\cite{2,3,8} by leveraging machine learning methods that account for temporality and extending characterization to analyze relevant clinical features associated with treatment pathways.

Cluster characterization analysis examined three dimensions to describe the autoencoder and clustering outputs: utilization, medication heterogeneity, and temporal trends. Table 2 displays both utilization (mean prescription count) and medication heterogeneity (mean unique prescriptions, single medication treatment rates). The medication sequences in the sunburst plots (Figure 3) visualize medication heterogeneity between clusters and the quarterly moving average plots of percent patients with prescription and visit provide insight into temporal trends (Figure 2). In differentiating between clusters, medication utilization trends are a key factor. The profiles of clusters 3 and 5 are similar in aggregate medication utilization statistics, as well as medication sequences. However, medication utilization trends downward initially after diagnosis, but utilization sustains a consistent level in quarters 6 through 12 from MDD diagnosis. Conversely, cluster 5 medication utilization trends downward throughout the period of analysis.

In addition, we describe the clusters by clinical features such as demographics, comorbidities and outcomes. Differences between each of the demographics measured are found to be statistically significant between clusters. Outcomes measured include mortality, admission, ER visits, and ECT. Themes emerge from characterization analysis. For example, cluster 2 is characterized by higher rates of substance use disorders and self-harm as well as higher provision of ECT. These factors suggest this cluster captures high acuity psychiatric patients with depression at our medical center. This finding is also supported by medication treatment patterns, cluster 2 has high initial medication utilization and the highest rate of multi-medications treatment among the clusters. Clusters 1 and 4 are characterized by low utilization, outcomes and comorbidity profile. We suggest patients in these clusters have a moderate severity chronic MDD. Clusters 3 and 5 convey high utilization, and high comorbid burden with relatively low rates of substance abuse and self-harm. We assert clusters 3 and 5 are patients with severe, chronic, but managed MDD.

Our study is limited to analysis of data from a single institution. Our institution is an open system with finite specialty mental health access: patients included in our study might receive care at an institution other than VUMC or the patients in this study might be incident users of antidepressants\cite{21}. We seek to limit this risk by requiring two visits to VUMC at least six months apart. Additionally, there are limitations in representation of the medication data. Our methods seek to address some of those limitations by representing medications as a time-series and leveraging an LSTM auto-encoder. In this work, we do not explicitly seek to capture concurrent medications. However, concurrent medications may be implicitly captured to some degree by the quarterly time series representation. In this study we limit to including only medications from VUMC at the time they are prescribed. Information about duration of prescription, adherence, or dose changes are not included in our model but remain germane to effective treatment of MDD.

Future work should seek to expand treatment pathway characterization to additional health systems and to analyze additional phenotypes. In addition, health information exchanges can provide a more complete picture of the patient health record\cite{22}.

Conclusion

We clustered the output of an LSTM autoencoder on time-series of antidepressant prescriptions in patients diagnosed with MDD. We identified common, clinically relevant patterns in prescribing practices. Cluster characterization established that prescribing practices differ on multiple dimensions: utilization, medication heterogeneity, temporal trends. Clusters are found to be associated with a clinically meaningful features including demographics, outcomes, and comorbidities. This method provides insight into endotypes of MDD.

Gene-Based Analysis Reveals Sex-Specific Genetic Risk Factors of COPD

Jaehyun Joo, Ph.D.1, Blanca Himes, Ph.D.1
1Department of Biostatistics, Epidemiology and Informatics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Abstract

Sex-specific differences have been noted among people with chronic obstructive pulmonary disease (COPD), but whether these differences are attributable to genetic variation is poorly understood. The availability of large biobanks with deeply phenotyped subjects such as the UK Biobank enables the investigation of sex-specific genetic associations that may provide new insights into COPD risk factors. We performed sex-stratified genome-wide association studies (GWAS) of COPD (male: 12,958 cases and 95,631 controls; female: 11,311 cases and 123,714 controls) and found that while most associations were shared between sexes, several regions had sex-specific contributions, including respiratory viral infection-related loci in/near C5orf56 and PEL11. Using the newly developed R package ‘snpsettest’, we performed gene-based association tests and identified gene-level sex-specific associations, including C5orf56 on 5q31.1, CFDP1/TMEM170A/CHST6 on 16q23.1 and ASTN2/TRIM32 on 9q33.1. Our results identified promising genes to pursue in functional studies to better understand sexual dimorphism in COPD.

Introduction

Chronic obstructive pulmonary disease (COPD) is a public health challenge worldwide1. Smoking is the most important COPD risk factor, accounting for 8 out of 10 COPD-related deaths in the U.S., but the relationship is complex and many smokers do not develop COPD1,2. In the past, COPD was perceived as a disease affecting mostly older men, but recent evidence shows that its prevalence has increased faster in women than men due in part to the increased rate of smoking among women3,4. Women may be more susceptible to the harmful effects of cigarette smoke, as some studies have found that women have worse disease outcomes for the equivalent quantity of cigarettes consumed compared to men, although research on this topic is not conclusive5–7. An observational study found that as women who smoked aged, they had an accelerated decline in percent predicted forced expiratory volume in one second (FEV1) and a faster recovery in lung function after smoking cessation than men8. In smoking- or FEV1-matched men and women, women with COPD reported more symptoms, including dyspnea and cough5,6,7,9. Among people with severe COPD, women had less extensive emphysema and thicker small airway walls relative to luminal perimeters than men6. The mechanisms underlying these sex-specific differences in COPD are largely unknown, but they may be influenced by genetic factors. Genome-wide association studies (GWAS) have linked many genetic loci with COPD and have contributed to the growing recognition that multiple biological mechanisms result in the observed lung function changes that receive the diagnostic label of COPD. Uncovering these so-called endotypes of COPD is a major goal of precision medicine that seeks to provide tailored medical care. However, research into sex-specific genetic risk factors that may inform sex-related COPD endotypes is lacking10.

The UK Biobank is a population-based cohort study with over 500,000 participants, which aims to investigate genetic and nongenetic factors that influence a variety of diseases affecting middle and older aged people11. Because the UK Biobank is the largest spirometric study ever conducted in the UK, it is an especially valuable resource to study COPD genetics compared to other biobanks. We previously showed that defining COPD according to Global Initiative for Obstructive Lung Disease (GOLD) criteria, which relies on lung function measures, yielded UK Biobank GWAS results consistent with those of genetic epidemiology cohorts but quite different from those based on ICD codes or self-reported disease12. Given its large sample size and the availability of many health-related measures and spirometry data for most genotyped participants regardless of health status, the UK Biobank provides an unprecedented opportunity to study sexually dimorphic features of COPD11,13.

Gene-based association methods are a complementary strategy for GWAS that evaluate biologically meaningful units of the genome14–16. They detect joint effects of multiple variants for which individual genetic effects may not reach genome-wide significance by reducing the burden of multiple tests that arise when simultaneously assessing millions of markers that are common to GWAS. In addition, gene-based statistics are often required as input for network- and pathway-based approaches. The versatile gene-based association study (VEGAS) method, which is commonly used to investigate putative genes for a trait of interest15,17, takes as input variant-level p-values and reference linkage
disequilibrium (LD) data and computes gene-based p-values using a simulation-based approach. Although VEGAS is offered as a webserver or local program that can be readily used by anyone with GWAS summary statistics regardless of the underlying study design, its use is hampered in practice when gene-based p-values are very small because the number of simulations required to obtain such p-values is very large. GWAS performed with biobanks that contain a large amount of clinical information linked to biological samples often yield sample sizes large enough to produce hundreds to thousands of nominal associations, which renders the VEGAS approach impractical due to the long run times necessary to obtain gene-based association results.

In this study, we identified sex-specific genetic associations of COPD using UK Biobank data, developed an R package that efficiently estimates gene-based p-values from GWAS summary statistics, and we compared SNP-level GWAS results with gene-based results obtained using the newly developed package.

**Methods**

**Study population and COPD definition**

Phenotypes of UK Biobank participants were obtained from responses to computer-assisted interviews, self-completed questionnaires, and physical measures obtained during in-person visits as reported in data-fields 31 (sex), 50 (height), 20003 (age), 20160 (ever smoked), 22001 (genetic sex) and 22006 (genetic ethnic grouping). To determine lung function, the ‘best’ measures per individual of FEV 1 and forced vital capacity (FVC) were obtained from pre-bronchodilator spirometry blow-volume time-series data following the spirometry quality control steps described in Shrine et al. COPD affection status was assigned based on spirometric evidence of moderate-to-severe airflow limitation by the modified GOLD criteria: cases had FEV 1/FVC < 0.7 and FEV 1 < 80% predicted while controls had FEV 1/FVC > 0.7 and FEV 1 > 80% predicted.

**Sex-stratified GWAS**

For each sex, a GWAS was performed using individuals who self-identified as white British and had very similar genetic ancestry based on genetic principal components, while excluding those who had a mismatch between self-reported and genetic sex as determined by chromosomal make-up, sex chromosome configurations that were not XX or XY, or had non-normal heterozygosity and missing rates according to genetic information provided by the UK Biobank team. These procedures resulted in 12,958 cases and 95,631 controls for males and 11,311 cases and 123,741 controls for females. At the genotype level, variants with imputation INFO score measure < 0.7 or minor allele frequency (MAF) < 0.01 were excluded. Genome-wide association testing was conducted using a generalized mixed model framework implemented in SAIGE (v0.43.3) to account for subject relatedness and fine-scale population structure, while including as covariates age, age-squared (age 2), height, ever-smoking status (ever vs never), and the first 4 principal components obtained from genotypes. Pack-years of smoking was not included due to a large amount of missing values as described in Shrine et al. FUMA, a web-based post-GWAS annotation tool, was used to identify independent risk loci meeting the genome-wide significance threshold of p-value = 5 × 10^-8 using the UK Biobank white British reference panel. Genetic correlation between the sex-specific GWAS results was estimated via LD score regression, while using pre-calculated LD scores based on the 1000 Genomes Project data for European populations. Regional association plots were created with LocusZoom (v1.4). SNP-by-sex interaction tests were performed for the sex-specific genome-wide significant loci using logistic regression models that included data for all participants and the same covariates used in the sex-specific analyses.

**Gene-based association tests**

For gene-based association tests, we employed the statistical model described in VEGAS. Briefly, the test statistic was defined as $Q = Z'Z = \sum_{i=1}^{p} z_i^2$, that is, the sum of squared variant-level z-statistics, where $Z = \{z_1, ..., z_p\}$ is a vector that follows a multivariate normal distribution with a mean vector $0$ and a covariance matrix $K$; i.e., $Z \sim N(0, K)$. VEGAS uses Monte Carlo simulations to approximate the distribution of $Q$, and thus, compute gene-based p-values. Instead of that approach, we rewrote $Q = XAX = \sum_{i=1}^{p} \lambda_i x_i^2$, where $K = \lambda \Sigma \chi^2$, (with a spectral theorem) and $X = P^\chi \Sigma^{-1/2} Z \sim N(0, I_p)$. This represents a quadratic form in independent central normal variables and its distribution can be evaluated with various methods such as numerical inversion of the characteristic function. We developed the R package `snpsettest` (https://CRAN.R-project.org/package=snpsettest) based on this latter version of the test statistic while utilizing the algorithm of Davies, or saddlepoint approximation, to obtain gene-based p-values. We performed gene-based association analyses with `snpsettest` using gene annotations from GENCODE release 19 for the sex-stratified COPD GWAS results. We considered genes in the following biotypes: protein-coding, immunoglobulin variable chain and T-cell receptor genes which included 18,774 entries. For each gene, any
variants within 20 kb of 5′ and 3′ UTRs were selected for association tests and the 1000 Genomes phase 3 European reference panel27 (genotypes of 240 males and 263 females) was used to infer relationships between markers. A significant association was defined as having a Bonferroni-corrected p-value < 0.05. Gene-based results were also obtained with a local instance of VEGAS217 using default parameters (up to one million simulations for p-value calculation) except for gene boundaries for SNP selection that were set to 20 kb of 5′ and 3′ UTRs of a gene.

Results

Sample characteristics

Characteristics of GWAS subjects stratified by sex are provided in Table 1. Male and female COPD cases were older and more likely to have ever smoked. The proportion of COPD cases was higher in males (11.9%) than females (8.4%), which is consistent with a higher portion of male subjects having a positive smoking history. Female subjects were more likely to have a diagnosis of asthma (ICD-based prevalence of 5.7% in male versus 7.2% in female subjects; self-reported doctor’s diagnosis prevalence of 10.9% in male versus 12.5% in female subjects), and a substantially greater proportion of COPD cases had asthma compared to controls. Consistent with the definition of COPD, lung function was lower in cases than controls as measured by percent predicted FEV1 and FEV1/FVC ratio.

ICD: International Classification of Diseases; IQR: Interquartile range.
* Affection status was assigned based on having any sub-categories of ICD-9 493 and/or ICD-10 J45.
† Affection status was assigned based on the UK Biobank data-fields 22127 (Doctor diagnosed asthma) and 20002 (Non-cancer illness code, self-reported).

Most COPD-associated loci were consistent by sex

We identified 17 and 14 genome-wide significant loci in male and female GWAS, respectively (Figure 1), each of which was previously identified in GWAS of COPD and/or lung function-related traits (e.g., FEV1, FEV1/FVC ratio, and smoking behavior). Nine of these loci were present in male and female GWAS results (Table 2), including the most well-replicated COPD locus near HHIP (Figure 2A). The estimated genetic correlation between male and female results was 0.961 (SE 0.04), demonstrating shared genetic effects overall. Male-specific associations were observed at loci in/near C1orf87, PEL11, ARHGEF3, C5orf56, PPP1R3B, BNC1, and CFDP1, and female-specific associations were observed at loci in/near MECOM, ADAM19, C10orf11, KANSL1, and SOGA2. Regional association plots for these genes suggested that some of the sex-specific associations were not due to differences in statistical power attributable to a decreased sample size, most notably that of the C5orf56 locus (Figure 2B). Results of the SNP-by-sex interaction analyses for lead variants are in Table 3. Consistent with the sex-stratified GWAS, rs2158101 at the male-specific locus in C5orf56 had the lowest interaction p-value (P = 1.16×10^-4). The other lead variants in the male-specific loci had interaction p-values < 0.05 except for rs330934 at the PPP1R3B locus. Among the lead variants in female-specific loci, only rs2637261 at the C10orf11 locus had an interaction p-value < 0.05.

The snpsettest package results were comparable to those of VEGAS

Comparison of gene-based association tests obtained with snpsettest versus those of VEGAS found a strong agreement between the two: estimated correlations of -log10(p-value) were 0.981 for the male-specific GWAS and 0.991 for the female-specific GWAS (Figure 3). We observed a lack of consistency with VEGAS for genes whose actual p-values
were < 10^{-6}. When only the gene-based p-values ≥ 10^{-6} were considered, the correlations were 0.999 for both sets of results. A major advantage of the \textit{snpsettest} package over VEGAS was speed. On the same laptop (i9-9980HK, 32GB memory, Windows subsystem for Ubuntu 18.04 LTS), VEGAS took 29 and 32 hours to complete the gene-based association tests for 18,774 genes using ~8.8 million GWAS summary statistics of males and females, respectively, while the \textit{snpsettest} package completed the tests in approximately 9 minutes.

**Figure 1.** Manhattan plots of sex-stratified COPD GWAS results for (A) male and (B) female subjects. Each locus was annotated with its nearest coding gene. The green horizontal dashed line indicates the genome-wide significance threshold of 5 \times 10^{-8}. Overlapping loci in the GWAS are shown in blue. Sex-specific loci are shown in orange when genome-wide significant, with corresponding non-significant region shown in red in the alternate sex-specific plot.

**Sex-specific gene-based association tests identified two additional loci of interest**

Sex-specific gene-based associations were determined as those meeting a Bonferroni-adjusted threshold, while excluding loci in the HLA region (Figure 4). Consistent with the GWAS results, \textit{C5orf56} on 5q31.1 had the strongest sex-specific association. Other male-specific associations included \textit{OTUD4}, \textit{ABCE1}, \textit{ANAPC10} on 4q31.21; \textit{FBXO38} on 5q32; and \textit{TMEM170A}, \textit{CFDP1}, and \textit{CHST6} on 16q23.1. Female-specific associations were \textit{ASTN2} and \textit{TRIM32} on 9q33.1; \textit{LCAT}, \textit{CTRL}, and \textit{PSMB10} on 16q22.1; and \textit{NSF}, \textit{CRHR1}, and \textit{SPPL2C} on 17q21.31. Most of the significant genes were in/near the genome-wide significant GWAS loci, but novel sex-specific gene associations on 16q22.1 and 9q33.1 were observed only via gene-level statistics.

**Discussion**

COPD is a complex disease with sex-specific differences in susceptibility and presentation\textsuperscript{10}. Previous studies by COPDGene (Genetic epidemiology of COPD) found that sex-related genetic components conferred a higher risk of severe, early-onset COPD in women\textsuperscript{33,34}, but the genetic contributions that lead to sex divergence in COPD remain poorly understood. In sex-stratified COPD GWAS, we identified 17 genome-wide significant loci for males and 14 for females. Although the number of significant loci identified was smaller than that in our previous study\textsuperscript{12} that used all subjects—likely due to decreased statistical power—all loci have been previously associated with COPD and/or lung function-related traits\textsuperscript{21,35}. Our results demonstrated that a large proportion of genetic liability are shared between males and females: i) there were 9 overlapping genome-wide significant loci corresponding to genes \textit{FAM13}, \textit{NPNT}, \textit{HHIP}, \textit{HTR4}, \textit{HLA-DQB1} (\textit{HLA-DQA1}), \textit{GRP126}, \textit{CDC123}, \textit{THSD4}, and \textit{CHRNA5} (\textit{HYKK}), and ii) there was substantial genetic correlation when considering the effects of all variants not reaching genome-wide significance.

Sex-specific genome-wide significant associations were observed in 8 male-specific and 5 female-specific loci. SNP-by-sex interaction tests for these loci using data for all subjects supported most of the stratified findings except for the male-specific locus in \textit{PPP1R3B} and female-specific loci in/near \textit{MECOM}, \textit{ADAM19}, \textit{KANSL1}, and \textit{SOGA2}.
